ACTA MINERALOGICA-PETROGRAPHICA
established in 1922

ABSTRACT SERIES

HU ISSN 0324-6523
HU ISSN 1589-4835

Abbreviated title:
Acta Mineral. Petrogr. Abstr. Ser., Szeged

This volume was published for the 375th anniversary of the Eötvös Loránd University, Budapest.

The publication was co-sponsored by the National Office for Research and Technology, Budapest.

IMA2010 (www.ima2010.hu) is organised in the frame of the ELTE375 scientific celebration activities.

Editorial Office Manager

Mineralogical co-evolution of the geosphere and biosphere

Hazen, R.M.
Geophysical Laboratory, Carnegie Institution, Washington DC, USA (rhazen@ciw.edu)

The mineralogy of terrestrial planets evolves as a consequence of varied physical, chemical and biological processes [1]. Initial evolutionary stages include the transition from ~12 nano-scale mineral phases in pre-stellar dense molecular clouds, to ~60 primary chondrite minerals, to ~250 different minerals in altered chondrites, achondrites and differentiated asteroids. Earth's subsequent prebiotic mineral evolution depended on a sequence of geochemical and petrologic processes, including volcanism and degassing, fractional crystallization, crystal settling, assimilation reactions, regional and contact metamorphism, plate tectonics and associated large-scale fluid-rock interactions. These processes resulted in perhaps 1500 different mineral species.

Biological processes began to affect Earth's surface mineralogy by the Eoarchean, when large-scale surface mineral deposits, including carbonates and banded iron formations, were precipitated under the influences of changing atmospheric and ocean chemistry. The Paleoproterozoic "Great Oxidation Event" and Neoproterozoic increases in atmospheric O_2 transformed Earth's surface mineralogy and are responsible, directly or indirectly, for most of Earth's 4300 known mineral species.

Mineral evolution arises from three primary mechanisms: (1) progressive separation and concentration of elements from their original relatively uniform distribution; (2) an increase in range of intensive variables such as pressure, temperature, and the activities of H_2O, CO_2 and O_2; and (3) generation of far-from-equilibrium conditions by living systems. The sequential evolution of Earth's mineralogy from chondritic simplicity to Phanerozoic complexity introduces the dimension of geologic time to mineralogy and thus provides a dynamic alternate approach to framing the mineral sciences.

40 years of nanomineralogy

Buseck, P.R.
School of Earth & Space Exploration and Dept. of Chemistry/Biochemistry, Arizona State University, Tempe, AZ, USA (pbuseck@asu.edu)

The warm feelings conveyed by Figure 1 reflect the substantial progress that has occurred in the study of crystalline materials, including minerals, during the last four decades. That figure, lacking the Valentine Day embellishments, appeared 30 years ago. It followed developments that transformed transmission electron microscopy from a technique used primarily by biologists to one routinely utilized by solid-state scientists, including mineralogists. The changes became possible through the availability of new, highly stable microscopes for producing high-resolution images and new theory for interpreting the results. This combination facilitated the study of defects and other irregularities in crystalline and, eventually, non-crystalline solids. Additional developments continue to this day.

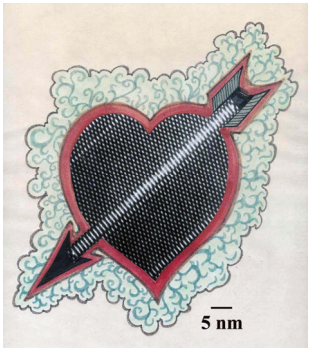

Fig. 1: Slightly edited HRTEM image of defects in biopyriboles; modified (by Sue Selkirk) from Fig. 1c in Veblen and Buseck [1].

High-resolution images of solids allowed the first direct visualization of structural irregularities in crystals. One no longer had to infer the crystal defects that permitted solid-state reactions to occur. Instead, it became possible to actually observe the reaction pathways through transitions and reactions "frozen" before completion. Such new information helped reconstruct processes that previously could only be inferred.

Transmission electron microscopes (TEMs) can be used to measure the crystalline structures and compositions of minerals at the micrometer to sub-nanometer scale. For particles, such as occur in the atmosphere and comprise an area of increasing interest for mineralogists, they can also be used to determine their sizes, 2D and 3D shapes, intergrowths, and coatings, all of which are of interest for atmospheric and climate studies.

The various nanoscale modes of modern TEMs include high-resolution imaging (HRTEM); energy-dispersive X-ray spectrometry (EDS) to determine compositions of inorganic species; electron energy-loss spectrometry (EELS) to measure the abundances of elements heavier than Li, their oxidation states, and chemical speciation; energy-filtered TEM (EFTEM) to show the distributions of elements within substances; selected-area electron diffraction (SAED) to determine crystallographic structures; environmental-TEM (ETEM) to measure hygroscopic properties, volatilities, and reactions at high temperature; electron holography (EH) for magnetic studies; and electron tomography (ET) to determine 3D shapes.

Mineral studies at elevated temperatures are almost routine, and we are currently trying to develop the use of TEMs to study minerals at high pressure. Examples will be provided of a range of problems addressed by studying minerals on a level ranging down to the nanoscale.

Composition and evolution of the SCLM, and the origin of its diamonds

Griffin, W.L.* & O'Reilly, S.Y.
GEMOC, Earth and Planetary Sciences, Macquarie University, Sydney, NSW, Australia (*bill.griffin@mq.edu.au)

Recent developments in seismic tomography and the integrated modeling of geophysical and petrological data have stimulated a major re-evaluation of the original composition and present extent of Archean subcontinental lithospheric mantle (A-SCLM). Analyses of seismic and gravity data, and consideration of relationships in exposed Archean peridotite massifs, suggest that the primitive A-SCLM probably was a highly depleted, moderately oxidised dunite-harzburgite, formed by high-degree melting at high T and P. Seismic tomography of cratons at regional and local scales shows "knobs" of high-Vs material that can be modeled as primitive A-SCLM, surrounded by zones of lower Vs. Kimberlites preferentially intrude these low-Vs belts, bringing up xenolith suites dominated by garnet lherzolites. By analogy with Archean peridotite massifs, these less-depleted rocks are interpreted as the result of metasomatic refertilisation, with progressive addition of cpx and garnet, and lowering of Mg#, in the peridotites. Within individual kimberlite fields, there is a direct correlation between this refertilisation process and the presence of diamonds of the peridotitic paragenesis [1]. A strong correlation between subcalcic garnets and diamonds suggests a model in which diamonds are deposited as CH_4-rich fluids are oxidized by the SCLM, producing carbonate-rich, hydrous fluids.

EMP and FTIR analyses of µm-sized fluid inclusions in "fibrous" diamonds have identified a more complex suite of high-density fluids (HDF), ranging from carbonatitic melts to "hydrosilicic" fluids and super-saline brines. LAM-ICPMS analysis of such diamonds [2] yields trace-element patterns similar to kimberlites and carbonatites, with high LREE/HREE, and high contents of alkali elements (Na, K, Rb, Cs, Ba) and HFSE (Ti, Zr, Nb…). Within single localities, carbonatitic, hydro-silicic and saline fluids have broadly similar trace-element patterns. The different types of HDF may reflect complex interactions between low-volume (mostly carbonatitic) melts, saline brines and different wall rocks (peridotitic vs eclogitic, refractory vs metasomatised).

In contrast to the fibrous diamonds, most monocrystalline diamonds have REE patterns that are either are essentially flat, or are depleted in LREE relative to HREE. They also are depleted in the alkali elements relative to the LREE, and many show strong negative anomalies in Y and Sr. These fluids and those that form fibrous diamonds may be related through carbonate/silicate melt immiscibility; the transition between them has been observed in single stones. In the Diavik mines, some monocrystalline diamonds and their fibrous/granular coats appear to have grown from the same type(s) of fluid.

If most peridotitic diamonds are related to the metasomatic modification of the dunitic Archean SCLM, then progressive metasomatism of the SCLM through time should decrease its overall prospectivity for diamonds. However, in tectonothermally younger terrains, diamonds are commonly hosted primarily in eclogites. In the absence of oxidized dunites, these mafic rocks may provide the redox environment required to deposit diamonds. Metasomatism is an ongoing process, and it is not obvious that diamonds necessarily are ancient; some may be quite „modern."

Mineralogical and glass compositional variations during the 2010 eruption of Eyjafjallajökull, Iceland

Sigmarsson, O.
Inst. of Earth Sciences, University of Iceland, Reykjavik, Iceland (olgeir@raunvis.hi.is) and
Laboratoire Magmas et Volcans, CNRS - Université Blaise Pascal, Clermont-Ferrand, France

After three months of magma injection beneath Eyjafjallajökull volcano, and corresponding inflation of the volcano, a lateral eruption started March 20 at the Fimmvörðuháls pass. Relatively primitive olivine and plagioclase bearing basalt was produced from ca. 500 m long fissure. After the first two days, the activity was concentrated in a single strombolian crater until March 31 when a new eruption fissure opened orthogonal to the first one. Last lava-forming activity was observed March 12. The basalt composition has a restricted whole-rock compositional range (8-9% MgO) from 3% Hy-normative at the beginning to 3% Ne-normative composition at the end. The euhedral phenocrysts assemblage is composed of Cr-rich spinel (picotite), olivine in the range Fo79-71 (with four crystals of Fo86), and a bytownite plagioclase (An81-76). Abundant vesicules and microlites characterize the groundmass, suggesting degassing-related crystallization. The interstitial glass composition is similar to the evolved FeTi-basalts of the neighbouring Katla volcano (MgO: 4.5-5.0%). During the historical period Katla has erupted twice per century; it last erupted in 1918.

On April 14 an explosive summit eruption started beneath an ice-cap with an eruption column occasionally rising as high as 8-10 km. Very fine-grained tephra of trachy-andesitic composition was produced and dispersed to the east and later to the south covering the neighbouring area with a few cm thick tephra layer. Finest part of this tephra was ejected to significant heights in the atmosphere where it sojourned for several days, and was brought over continental Europe by prevailing northeast wind directions. The fine grain-size of the tephra is not only due to rapid quenching caused by ice-magma interaction but also by fragmentation caused by rapid strain of a relatively viscous melt. The trachy-andesite produced during the first five days result from a binary mixing between fractionated basalt (similar in composition to those of Katla volcano) and a dacitic melt, possibly left-over from the penultimate eruption at Eyjafjallajökull (the 1821 dacite), and a consequent rapid magma ascent. The magma mixing is reflected by linear correlations on element-element plots between major- and trace-element concentrations obtained on whole-rock samples and in-situ by EMPA and LA-ICP-MS methods applied to primitive melt-inclusions, groundmass glasses and tephra fragments from the 1821 eruption. Three glass types are observed in the early tephra with SiO_2 concentrations of 49-51%, 60-61% and 69-70% that illustrates a mechanical magma mingling without enough time for homogenization before eruption. This results in complex mineralogical zonation with Fo64-50, An69-9 and Mg-number of clinopyroxene in the range 72-26. On May 4 a deep seismic swarm (over 20 km deep) occurred with consequent higher magma output as measured from the height of the May 5 eruption column. The tephra produced that day is comprised of well-mixed glass with SiO_2 of 62-63% but has 50µm zoned-olivines with 10 µm tick rim of Fo_{48-50}. The core has Fo_{80}, a composition similar to the olivines of the Fimmvörðuháls basalts. These results indicate a direct link between the arrival of primitive basalts, deep seismicity, increased magma pressure in the plumbing system, and higher magma output rate. Taken together, the explosive phase of the 2010 Eyjafjallajökull eruption was caused by dynamic magma mixing of mantle-derived basalt with older silicic intrusion remobilized by the crystallizing primitive basalt.

The mineral-microbe interface and its defining role in controlling contaminant mobility in the subsurface

Lloyd, J.R.
School of Earth, Atmospheric and Environmental Sciences, The University of Manchester, UK (jon.lloyd@manchester.ac.uk)

Recent advances in mineralogy and microbiology have led to a molecular-scale understanding of the critical role of the mineral-microbe interface in controlling contaminant mobility in the subsurface. Of particular note are respiratory processes, mediated by specialist bacteria and archaea, and coupled directly to the redox transformations of minerals. These effectively control the mobility of both inorganic and organic species in a wide range of environments and, if harnessed, may offer the basis of a wide range of innovative biotechnological processes. These applications include the bioremediation of metal contaminated land and water, the oxidation of xenobiotics under anaerobic conditions, metal recovery in combination with the formation of novel functional bionanominerals, and even the generation of electricity from anoxic sediments. Under certain conditions, however, microbial redox transformations of minerals can also mobilise toxic metals and metalloids with potentially calamitous effects on human health.

Focusing on "dissimilatory" mineral reduction processes, I will discuss recent advances in the understanding of the mechanisms of anoxic Fe redox cycling in the subsurface, and the impact of Fe mineral biotransformations on sediment biogeochemistry and the mobility of trace metals, metalloids and radionuclides. The biotechnological application of mineral-transforming metal-reducing bacteria for the generation of commercially useful bionanominerals will also be discussed, alongside their use in a range of innovative *ex situ* applications. The dramatic impact of advanced imaging, synchrotron spectroscopy and genomics-enabled techniques in dissecting the mineral-microbe interface will be highlighted alongside current challenges in this rapidly developing area of multidisciplinary science.

Toward theoretical mineralogy: the bond-topological basis of structure stability and mineral energetics

Hawthorne, F.C.
Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada (frank_hawthorne@umanitoba.ca)

The electronic properties of the constituent atoms of a structure may be represented as the diagonal elements of a square matrix, and the interactions between these atoms may be represented by the off-diagonal terms of this matrix. The form of this matrix is identical to that of the adjacency matrix of the weighted chromatic digraph of the bond network. The electronic energy density-of-states can be derived using the method of moments [1], where the trace of the diagonalized Hamiltonian matrix (of the usual secular determinant equation) has a topological interpretation in terms of closed paths in the graph of the constituent orbitals. The energy difference between two structures depends primarily on the first few disparate moments of their respective energy density-of-states [2]. Consider what this means: (1) zero-order moments are >walks in place= and define chemical composition; (2) second-order moments define coordination number; (3) fourth- and sixth-order moments define local connectivity of coordination polyhedra; energy differences between structures are dependent on these features. Open-system behaviour changes zero-order moments, closed system behaviour does not change zero-order moments. Within this framework, we may divide mineral reactions into two types: (1) those where bond topology is conserved; (2) those where bond topology is not conserved. *Conservation of Bond Topology:* The edge set of the digraph is conserved but the weights may vary depending on local changes in the vertex set. Thus the energetically most important changes involve variation in patterns of Short-Range Order (SRO). In order to conserve bond topology with varying T and P, thermal expansion and elastic compression must be accompanied by element substitutions that accord with the short-range version [3] of the valence-sum rule of bond-valence theory [4]. Thus variation in SRO is an integral part of continuous mineral reactions and drives compositional change. *Non-conservation of Bond Topology*: In a closed system, zero moments are fixed and the lowest-order changes involve second-order moments, *i.e.*, changes in coordination number. Many reactions of geological interest involve conservation of cation-coordination number, and such reactions are driven primarily by changes in anion-coordination number. The correspondence principle of Lewis acidity – Lewis basicity [5] may be used to explain the structural and chemical complexity of many surficial minerals. Where data are available, species in aqueous solution follow the valence-sum rule, and their Lewis basicities scale with the pH values of the solution at maximum abundance of the species in solution. The complex species in aqueous solution actually form the building blocks of the crystallizing minerals, and in principle, the structures thus retain a record of the pH of the nascent solutions from which they crystallized. This general approach has an atomistic basis and yet is sufficiently simple that complex problems can be addressed in a transparent yet quantitative manner.

X-ray spectroscopy on geomaterials using synchrotron radiation

Wilke, M.
Helmholtzzentrum Potsdam Deutsches GeoForschungsZentrum, GFZ, Potsdam, Germany (max@gfz-potsdam.de)

In the last two decades, synchrotron radiation (SR) has become an indispensable tool for studying geomaterials using X-ray spectroscopic techniques. The continuous spectrum and the high brilliance produced by a SR source not only enable the acquisition of high quality data in short time, but also provide the possibility to focus the SR beam into small spots with very high photon flux. Particularly the latter feature is a prerequisite for many applications in Earth sciences. In this lecture, a sequence of examples using X-ray spectroscopic techniques is discussed, which highlight the versatile applicability to many materials of geological interest at the relevant geological conditions.

One very important application using the fine structure observed at the X-ray absorption edge (XANES) represents the investigation of redox processes. For Fe, the pre-edge region provides an almost direct way of quantifying the oxidation state in many crystalline and non-crystalline compounds [1], even with microscopic spatial resolution, e.g. [2]. XANES at the S K-edge may be used to study S-redox equilibria in melts, e.g. [3]. E.g., new XANES derived data show a much narrower transition from sulfide to sulfate with oxygen fugacity than previously determined with the electron microprobe. This may have considerable implications for the sulfur behaviour in subduction-related magmas [4]. Time-resolved XANES may even be used to determine the progress and mechanism of redox reactions. E.g., this was nicely shown for the case of oxidation of Mn(II) by bacteria [5].

Due to the rather low absorption of hard X-rays by matter, SR opens up the possibility to perform measurements in high-pressure or reaction cells. SR micro-XRF is used for obtaining trace element concentrations in aqueous fluids in-situ at high P and T using an XRF-optimized diamond anvil cell, with detection limits in the lower ppm range [6,7], even for low Z elements such as Ti [8]. A particular advantage over any quench technique is the possibility to study directly the kinetics of equilibration [9]. Furthermore, the high-pressure setup is used to investigate the element complexation in aqueous fluids by acquiring X-ray absorption spectra at conditions of the Earth's crust, e.g. REE in model fluid compositions [10]. XANES on Fe in hydrous melt at P & T provides evidence for non-quenchable structural re-organizations in the Fe environment during the cooling to a hydrous glass [11]. These valuable insights cannot be achieved on quenched samples at all and show the importance of these studies particularly for the understanding of processes at high P and T.

The soon dedication of new and upgraded SR sources for hard X-rays, will make sure that the conditions for such studies will improve and will certainly open up possibilities for new experiments to provide access to parameters not accessible so far.

Phosphate mineral reactivity: from nano to global scales

Valsami-Jones, E.[1*], Oelkers, E.H.[2], Skartsila, K.[1] & Klasa, J.[1]
[1]Dept. of Mineralogy, Natural History Museum, London, UK ([*]evj@nhm.ac.uk)
[2]Biogéochimie et Géochimie Expérimentale, LMTG-Université de Toulouse-CNRS-IRD-OMP, Toulouse, France

Life as we know it on Earth needs phosphate for its many biological roles, for example as the backbone of DNA. As a result, phosphorus availability often regulates biological productivity in many terrestrial and marine environments, but when in excess, leads to uncontrollable biological growth linked to water quality problems (eutrophication).

Phosphate minerals have a central role in this process, as they are the "gatekeepers", sources and sinks, of phosphorus in environmental and biological systems. Phosphate mineral solubility is particularly relevant, but exceptionally complex, notably in the case of apatite, the most common and perhaps most important of all phosphate minerals.

An important aspect of the phosphorus global cycle is that its only primary source is phosphate ore, which is a finite resource, with some predictions suggesting there remain as little as 125 years worth of global reserves. If phosphorus is no longer available or becomes too expensive, major consequences on global food production can be expected. It is therefore essential that the use of phosphorus be reviewed and potentially regulated.

Apatite in its various forms as a biological or chemical precipitate will form the focus of this paper. Its dissolution and precipitation kinetics and the influence of organic species in these processes will be reviewed and our efforts to understand its reactivity within environmental and biological matrices will be discussed. These processes, happening at the nano scale, could potentially have global consequences.

The nuclear fuel cycle: role of mineralogy and geochemistry in the safe management of nuclear waste

Ewing, R.C.
Dept. of Geological Sciences, University of Michigan, Ann Arbor, MI, USA (rodewing@umich.edu)

During the past five years, there has been a renewed interest in nuclear power as a source of energy that does not emit green house gases. An important consideration remains the environmental impacts of mining uranium and the final disposition of nuclear wastes. In addition, advanced nuclear fuel cycles, which involve new reactor types and reprocessing of used fuel, will require the development of new materials and create new waste streams.

In parallel with this renewed interest in nuclear power, the Office of Science of the U.S. Department of Energy has conducted a series of *Research Needs* workshops that have outlined cutting-edge research areas that will be required in order to support the nuclear "renaissance". Two of the reports, *Basic Research Needs for Advanced Nuclear Energy Systems* and *Basic Research Needs for Geosciences: Facilitating 21st Century Energy Systems* outline a research agenda for mineralogists and geochemists involved in both the "front-end" and "back-end" of the nuclear fuel cycle. A third report, *Basic Research Needs for Materials Under Extreme Environments* outlines a research agenda that has important overlaps with the research of the mineral physics community. The research agenda are organized according to:

- immediate research needs,
- "use-inspired" basic research,
- cross-cutting fundamental research,
- grand challenges

Typical of the scientific Grand Challenges are: *i.*) physics and chemistry of actinide-bearing materials; *ii.*) first principles, multi-scale modeling of complex materials under extreme conditions; *iii.*) the design of molecular systems for chemical selectivity during processing.

I will identify the relevant areas of research for mineralogists and geochemists with examples from:

- the design and properties of nuclear waste forms;
- corrosion of spent nuclear fuel;
- radiation effects under extreme conditions.

Zircon – more than just a chronometer

Kelly, N.M.
Dept. of Geology & Geological Engineering, Colorado School of Mines, Golden, CO, USA (nkelly@mines.edu)

Zircon ($ZrSiO_4$) is a mineral of singular importance in Earth Science. Based on its robust retention of formation ages and its ability to substitute a wide variety of trace elements that record the conditions of its formation or alteration, zircon has become the foremost among our geochronometers. No other mineral has the capability to help us unravel so much about how our Earth has evolved chemically and structurally through time. In addition, zircon is continually revealing how broad its capacity is to record the timing of events that have occurred across a vast range of geologic environments from the upper mantle through to the near surface environment. The rock types and environments in which we find zircon seems only limited by our curiosity to look.

The use of zircon for U-Pb dating by isotope dilution or microbeam methods has become almost routine, supported by continued advances in our ability to analyse smaller and smaller sample volumes at higher and higher analytical precision. However, it is the ability to directly link geochemical signatures with absolute time constraints that makes zircon such a powerful tool to be brought to bear on any number of geologic problems. For example it is now commonplace to integrate U-Pb zircon ages with Hf isotopes to fingerprint the sources of magmatic rocks; O isotopes to evaluate the contribution of mantle melts to crustal magmas as well as the role of high- vs low-temperature processes in the environment of zircon growth or alteration. The rare earth and other trace elements are commonly used to trace the environments of zircon growth be they high-temperature and in the presence of melts or during hydrothermal fluid events. The addition of Ti to this arsenal of geochemical tracers has now given us the ability to place direct temperature estimates on zircon growth. Moreover, U-Pb dating is now being integrated with U-Th/He methods thereby providing us with valuable information about exhumation in mountain belts and the coupled depositional histories of the detritus eroded from these mountains.

In the coming years research will address our incomplete understanding of the true complexity recorded at the micro-scale in zircon and what part of a geologic history fragments of a single zircon may represent. This work will hopefully enhance our ability to interpret the mechanisms that lead to zircon growth and modification, not only improving the meaning of zircon ages but also giving us robust means with which to use such fine-scale features to describe the intricacies in geologic processes that individual zircon grains bore witness. Such advances will continue to emphasise the importance of this tiny, but timely, mineral.

Biomineral attractions: magnets in organisms

Pósfai, M.[1*], Kasama, T.[2], Simpson, E.T.[3], Faivre, D.[4], Schüler, D.[5] & Dunin-Borkowski, R.E.[2]
[1]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary ([*]mihaly.posfai@gmail.com)
[2]Center for Electron Nanoscopy, Technical University of Denmark, Kongens Lyngby, Denmark
[3]Dept. of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom
[4]Dept. of Biomaterials, Max Planck Institute of Colloids and Interfaces, Potsdam, Germany
[5]Dept. of Microbiology, Ludwig Maximilians-Universität, München, Germany

Many organisms contain ferrimagnetic nanocrystals. Bacteria, pigeons and fish are known to use magnets for navigating in the Earth's magnetic field, whereas some animals use the iron minerals for hardening or protection. However, in most cases the biological functions of magnetic crystals remain unknown.

Magnetotactic bacteria are the best known examples of organisms that contain nanoscale magnets. Specific strains of bacteria form magnetite (Fe_3O_4) or greigite (Fe_3S_4) crystals, or both, in their cells. The membrane-bound, ferrimagnetic nanocrystals (magnetosomes) have species-specific sizes and morphologies and various arrangements, most often in linear chains. Cells of magnetotactic bacteria provide a natural laboratory, in which the magnetic properties of nanometer-sized particles can be studied.

We have used a combination of advanced transmission electron microscopy techniques, including off-axis electron holography, to study the structural, magnetic and chemical properties of magnetic nanocrystals inside magnetotactic bacteria. The samples studied included uncultured magnetotactic cells collected from both marine and freshwater environments, and cultures of the strain *Magnetospirillum gryphiswaldense* and its genetically-modified mutants.

We studied the fine details of magnetic induction maps determined from electron holograms obtained from magnetosomes with a range of sizes and spacings. Based on these results, an experimental "magnetic-state phase diagram" was constructed that highlights the delicate balance between the magnetic state of a crystal, its size, shape and orientation, and the chain configuration, and illustrates graphically whether cells are able to respond effectively to the geomagnetic field. In general, the shape anisotropy of each crystal is the most important factor in controlling the magnetic microstructures of ferrimagnetic crystals in bacteria, followed by interparticle interactions and, least important, magnetocrystalline anisotropy. Despite significant variations in the magnetic properties of magnetosome chains, all of the wild-type cells had permanent magnetic dipole moments that were sufficient for magnetotaxis.

Biogenic magnets exhibit fascinating combinations of magnetic properties and biological functions. However, except for ferrimagnetic particles in magnetotactic bacteria, relatively little is known about them. Further work is needed to understand magnetic sensing in animals and the functions of magnetite particles in humans. A key challenge is the localization and preparation of tissues that contain ferrimagnetic particles. Once such samples are available, advanced analytical techniques, including off-axis electron holography, can be used to provide detailed characterization of the structures, compositions, arrangements and magnetic properties of biogenic nanomagnets.

Mechanisms of cellular and biomacromolecular interactions with minerals in humans

Sahai, N.[1,2*], Zhang, N.[2], Murphy, W.L.[3], Molenda, J.[3], Yang Y.[1] & Cui Q.[4]
[1]Dept. of Geoscience, University of Wisconsin-Madison, USA
[2]Materials Science Program, University of Wisconsin-Madison, USA ([*]sahai@geology.wisc.edu)
[3]Dept. of Biomedical Engineering, University of Wisconsin-Madison, USA
[4]Dept. of Chemistry, University of Wisconsin-Madison, USA

Medical Mineralogy involves the mechanistic study of interactions between of cells and biomacromolecules with minerals and aqueous solutions that are of relevance to biomedical applications and human health. The unique contribution of mineralogists to the health-related fields can be to emphasize the critical contributions of structure, composition, particle size, bulk and surface chemistry of the mineral or amorphous solid phase to the thermodynamics or kinetics of the relevant reactions of interest.

I will illustrate these ideas with two example studies. The first study deals with the potential for using bioactive silicate glasses and ceramics (wollastonite, pseudowollastonite) in orthopaedic implants for bone-tissue engineering. Porous silicate implants can be seeded with human mesenchymal stem cell (hMSCs). As the implant dissolves in the body, the silicon released from silicate hydrolysis may promote the differentiation of hMSCs down the osteoblastic lineage, promoting rapid bone growth and, eventually, complete replacement of the implant by newly-formed bone. However, Si released may also be potentially cytotoxic to and reduce adhesion of the hMSCs. Additional soluble factors such as Ca and P in the ambient fluid environment may also work cooperatively or as antagonists to Si, and physical factors such as surface rougness, porosity, etc., also affect hMSC adhesion, viability, and differentiation. Thus, numerous factors must be optimized simultaneously.

In the second example, I will discuss the potential role of acidic, non-collagenous proteins (ANCPs) in controlling the nucleation and growth of hydroxyapatite in bone biomineralization. Bone is a nano-composite material of collagen matrix fibrils in strict hierarchical arrangement with nancrystals of highly non-stoichiometric, highly substituted hydroxyapatite and associated ANCPs. I report the potential role of a NCP called Bone Sialoprotein (BSP) in nucleating a calcium phosphate phase. Using Molecular Dynamics simulations, we have studied the effects of both structure (alpha-helix versus random coil) and primary amino-acid sequence (wild-type versus *in silico* mutations) of a highly-conserved acidic peptide from BSP interacting with dissolved Ca^{2+} and HPO_4^{2-} ions to form an initial calcium phosphate nucleus, and to interact with (100) and (001) faces of hydroxyapatite in modulating crystal growth.

Mineralogy and geochemistry at lower dimensionality: mineral-water interfaces and nanoparticles

Waychunas, G.A.
The Berkeley Nanogeoscience Center, Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley CA, USA
(gawaychunas@lbl.gov)

Over the last ten years experimental methods using synchrotron radiation have been developed to determine and refine the *in situ* molecular structure at mineral surfaces in analogy to that historically accomplished for bulk solids many years ago. We can thus begin to apply the rules of crystal chemistry, appropriately upgraded to include modern simulation tools, to surfaces, interfaces and grain boundaries. As surfaces are rarely precisely like the terminated bulk structure in terms of reactivity, chemistry and stoichiometry, we are thus gathering new insights into interface reactions like sorption, precipitation and acid-base equilibria [1]. These developments are timely inasmuch as nanomineralogical studies benefit markedly from an improved ability to understand the chemical characteristics of surfaces, edges and other "low coordination" surface topologies. Additionally, studies on both surfaces and nanoparticles yield information on local water structuring and hydrogen-bonding, with both being needed to completely define a nanoparticle surface and its properties [2].

Current studies include various surface-sensitive scattering and spectroscopic techniques, supported by both classical and ab initio calculations, but with almost all efforts aimed at characterizing near equilibrium or steady state interface structure. In the future, dynamic studies will be possible, with processes such as crystal growth, dissolution and even electron transfer reactions accessible on a true molecular level for the first time.

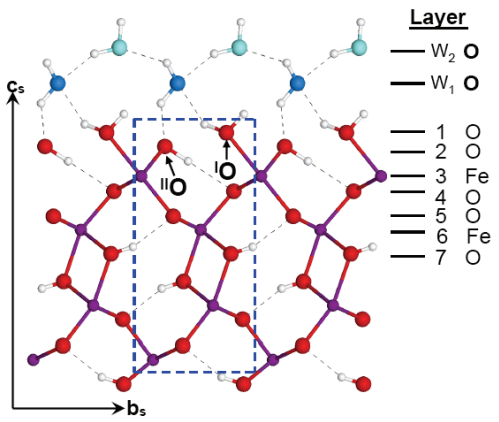

Fig. 1: Structure of the (100) cleavage face of goethite obtained from surface x-ray scattering showing surface bound functional groups ($FeOH$, $FeOH_2$) and two layers of ordered water [3]. The surface oxygens in Layer 1 and 2 are relaxed from their positions in the bulk structure. Dashed lines indicate likely hydrogen bonds.

A new model of kink site reaction kinetics unifies crystal dissolution and growth theory

Luttge, A.[1,2*] & Arvidson, R.S.[1]
[1]Dept. of Earth Science, Rice University, Houston, TX, USA
[2]Dept. of Chemistry, Rice University, Houston, TX, USA
([*]aluttge@rice.edu)

It has been long recognized that kink site reaction kinetics govern crystal growth and dissolution at the molecular scale. It has also been uncritically assumed that equilibrium at kink sites is achieved if arrival and departure rates of lattice-building molecules are equal. Lastly, we have accepted that inhibition and catalysis of crystal growth and dissolution are controlled at kink sites.

New considerations, however, raise significant doubt that this simple model is correct. A detailed analysis of the elementary processes that imperatively occur at kink sites during the overall dissolution reaction leads to initially surprising results: the probability is always in favor of lattice destruction – this result is in agreement with the thermodynamic rule of increasing entropy. The destructive processes are eventually countered by the arrival of molecules at the kink sites. This modified model of kink site kinetics can explain several experimental observations that were unexplained or at odds with the existing theory. Importantly, the new model predicts that the reaction rate as a function of the distance from equilibrium (ΔG) must be continuous at equilibrium. Ultimately, our model allows us to unify crystal dissolution and growth theories.

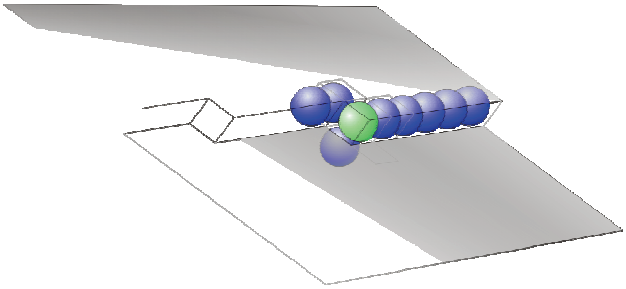

Fig. 1: Schematic view of kink site and nearest neighbours.

Dissolution of dolomite in HCl

Järvinen, L.J.[1-4*], Leiro, J.A.[1], Bjondahl, F.[5], Jäsberg, J.[2], Kara, J.[2], Carletti, C.[5,6], Sierra, S.[5,7] & Eklund, O.[2]

([*]ljjarv@utu.fi)
[2]Dept. of Geology, University of Turku, Finland
[3]Finnish Graduate School in Geology, Finland
[4]Graduate School of Materials Research, Turku, Finland
[5]Dept. of Chemical Engineering, Åbo Akademi University, Turku, Finland
[6]Universidad Simón Bolívar, Caracas, Venezuela
[7]Universidad Complutense, Madrid, Spain

Limestones are widely used as absorbents in various processes for removal of SO_2 from power plant flue gases. The most common method is called Wet Flue Gas Desulphurisation (WFGD) process, where the dissolution rate of limestone is essential for sizing and operation of the process. The presence of magnesium in limestones has been reported to reduce the dissolution rate [1], thus deteriorating the potentiality of the use of the rock in WFGD. The main limestone constituting mineral is calcite ($CaCO_3$), which can easily contain Mg^{2+} cations in its lattice. Another common mineral in limestones is dolomite ($(Ca, Mg)CO_3$), which has a bulk structure similar to calcite with the exception of every other cation layer in the c direction being composed of Mg atoms instead of Ca atoms. Obviously magnesium content in a limestone can vary greatly, and more profound knowledge of the influence of magnesium on the dissolution rate is needed.

The reactivity, calculated from the rate of dissolution and particle size distribution, of several dolomitic rocks has been tested using stepwise titration with hydrochloric acid (HCl) [2]. The specimens were crushed and ground into three size fractions of 63-106, 106-150 and 150-250 μm. The experimental setup consists of a stirred beaker containing sample particles in water, a pH electrode and a laser diffractometer for measurement of the particle size distribution. HCl has been used in the experiment, because the use of sulphur dioxide or sulphuric acid would result in the precipitation of calcium sulphate particles, which would influence the measurement of the particle size distribution.

The samples were characterised with X-ray Photoelectron Spectroscopy (XPS), Scanning Electron Microscopy (SEM), X-Ray Diffraction (XRD) and X-Ray Fluorescence (XRF). The rate determining steps of a dissolution reaction are generally considered to be surface kinetics and/or diffusion of reaction stimulating components through a barrier layer (that is surrounding the particle) to the immediate vicinity of the surface. Therefore the focus was kept on the surfaces of the dolomitic rocks with surface sensitive XPS and SEM.

The results show clear differences (an order of magnitude) in the reactivities of the dolomitic samples. Atomic concentrations were obtained with XPS and XRF, the former concentrating on surface composition and the latter on bulk composition. Mineral phases present in the rocks were identified from XRD spectra and polarizing microscope studies of polished thin sections. SEM micrographs obtained before and after the reactivity experiments gave information about the dissolution process on the surfaces of the samples. Relations between the reactivity and characterisation results are discussed.

Transformation of illite to K-feldspar on brick clay firing

Kristály, F.[1*] & Papp, I.[2]
[1]Inst. of Mineralogy and Petrology, University of Miskolc, Hungary ([*]askkf@uni-miskolc.hu)
[2]Inst. of Earth Sciences, University of Debrecen, Hungary

Two varieties of brick clay with chlorite – illite – muscovite dominated phyllosilicate fraction were applied in laboratory experiments. Before test body preparation, the raw clay was investigated for mineralogical and chemical composition. X-ray Powder Diffraction (XPD) was applied on whole-rock, random powder specimens, >106µm, >45µm and >2µm fraction random powder specimens. Oriented specimens were applied for clay mineral species investigation. Oriented specimens were analyzed in air-dried, ethylene-glycol saturated, 350°C and 560°C heated state. Thermal Analysis (TA) was performed to determine the temperature values at which transformation reactions occur. Simultaneous Differential Thermal Analysis (DTA), Thermogravimetry (TG) and Derivative Thermogravimetry (DTG) were run on a MOM-C Derivatograph. A second set of TA was performed with coupled Evolved Gas Analysis (EGA) by Quadrupole Mass Spectrometry (QMS). Both series of TA were run under similar conditions. Chemical composition of clay samples was analyzed by Atomic Absorption Spectrometry (AAS).

Prior to test body firing, powdered clay samples were undertaken for sequential firing experiment. The same specimen of clay was heated and subsequently analyzed by XPD. The experiment was repeated at temperatures of 560°C, 740°C, 780°C and 950°C, temperatures at which reactions were detected in TA. Fired test body samples were subjected to XPD and Scanning Electron Microscopy (SEM) with Energy Dispersive Spectrometry (EDS) and Wavelength Dispersive X-ray Mapping (WXRM).

The chemical investigations (both AAS and EDS) confirmed the existence of K-dominant mica in the clay samples. As shown by XPD analysis, the mica is present as a continuous series from muscovite to illite. Results are supported by the broadening of the 10Å and 5Å peaks by the lowering of grain size domain and oriented specimen investigations. Chlorite is Fe dominant, negligible amount of interstratified illite-smectite was detected. Plagioclase, Ca-dominant, was detected in the raw samples. Calcite contents are >3% in weight fractions.

TA and EGA indicated dehydration by H_2O and ^-OH loss up to ~240°C. From ~350°C a continuously increasing H_2O and ^-OH loss is registered up to ~960°C. CO_2 liberation is low, spiking at 733°C, corresponding to the low organic matter content and the low crystallinity calcite. After continuous base-line rising, an endothermic reaction was registered at ~780°C on DTA, with weight loss on DTG. This corresponds to the H_2O and ^-OH loss maxima.

On the XPD patterns registered during sequential firing experiment, besides the continuous decrease in illite – muscovite content the inversion of feldspar composition is observed. After ~900°C the K-feldspar (microcline – orthoclase mixtures) becomes dominant. A spinel-like phase is formed starting from ~850°C.

The chemical investigations, together with XPD and TA-EGA analysis confirmed the transformation of illite to K-feldspar by firing.

To our knowledge, this is the first experiment with this set of instrumentation demonstrating the transformation of illite to K-feldspar in dominantly illitic brick clay materials. Besides industrial applications, this type of reaction also has an important role in investigations on archaeological ceramics.

Evidence for the inability of periclase-calcite based monolithic refractories to absorb alumina inclusions in Al-killed steel liquids

Lee Yu-Chen[1,2*] & Jiang Wei-Teh[1]
[1]Dept. of Earth Sciences, National Cheng Kung University, Tainan, Taiwan ([*]t621@mail.csc.com.tw)
[2]New Materials R&D Dept., China Steel Corporation, Kaohsiung, Taiwan

Removal of alumina inclusions and retention of Al content in Al-killed steel liquids are of great importance to the control of the final properties of steel products. Periclase-calcite monolithic gunning refractories have been widely used for tundish materials in many steel plants and suggested to possess a subtle function to absorb alumina inclusions by some factories. Test samples obtained from laboratory experiments using periclase-based gunning refractories containing calcite up to 30 wt.% in Al-killed molten steel at 1600°C for 20 minutes were examined by cathodoluminescence microscope, XRD, and SEM-EDS in this study. All calcite grains in the refractories in a 1200°C preheating process transformed into porous lime grains of micrometer sizes. The refractories subsequently tested at 1600°C exhibited three distinct zones including (1) the outermost lime-free zone which was porous and contained Mg-bearing wüstite, (2) the transition zone consisting principally of lime and relatively Mg-rich wüstite, and (3) the inner unreacted zone composed of primitive periclase and lime clusters. Dissolution of lime grains, formation of magnesian wüstite phases, and slight surface splitting were recorded with no evidence of reactions between alumina inclusions and lime or periclase. Removal of alumina from Al-killed steel liquids by reactions with periclase-calcite gunning refractories was previously proposed on the basis of the reduced Al content in bulk steels. The aforementioned result suggests that such an absorption process is unlikely and the true mechanism for reduction of the bulk Al concentration in Al-killed steel melts needs further investigations.

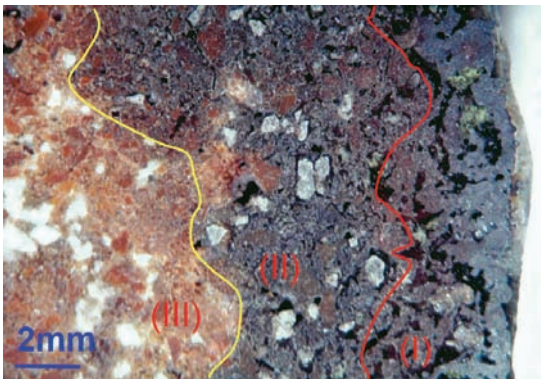

Fig. 1: Optical micrograph showing occurrence of the outermost lime-free zone (I), the transition zone (II), and the unreacted zone (III) on a periclase-based refractory with 18 wt.% CaO after being heated at 1600°C in a Al-killed steel melt for 20 minutes. White = lime particles; brown = periclase (detailed description given in the text).

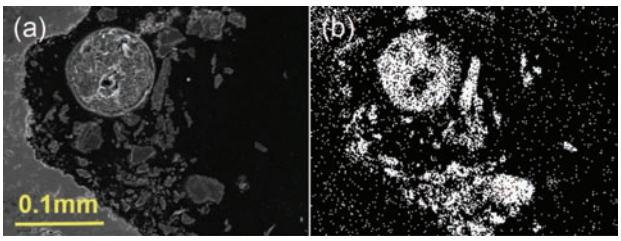

Fig. 2: SEM image of a spherical alumina inclusion in a steel melt at the edge of a periclase-lime refractory (a) and its Al X-ray elemental map (b).

Deciphering elemental substitutions in clinker minerals: a way to greener cements

Sulovský, P.[1,2*] & Staněk, T.[2]
[1]Dept. of Geology, Palacky University, Olomouc, Czech Republic ([*]petr@sulovsky.com)
[2]Research Inst. of Building Materials, Brno, Czech Republic

Among inorganic man-synthesized materials, clinker is the one that is produced in the greatest quantities. Clinker production consumes a lot of natural resources – fossil fuels as well as natural raw materials, what contributes to a great extent to the world CO_2 emissions. Substitution of both the fossil fuels and natural raw materials by waste materials represents a possibility to not only decrease the costs, but also to spare the natural reserves as well as to decrease CO_2 emissions. In the clinker burning process, any deviation from the customary fuel and raw meal chemistry can cause problems with the phase composition of clinker as well as with the reactivity of individual clinker minerals and devaluate thus the final product. Study of clinkers by mineralogical methods and application of mineralogical knowledge can help to solve such problems. Using electron microprobe to analyze individual clinker minerals can indicate the modes of occurrence of elements commonly absent in usual fuels or raw materials, but present in substantial quantities in the waste materials substituting them. Thus revealed substitution mechanisms can be utilized both to change the phase composition by accommodating higher amounts of foreign ions in the main clinker minerals, and/or to stabilize the more hydraulically active polymorphs of clinker minerals. An example of both benefits provided our study of clinkers burned with meal-and bone-meal (MBM) as alternative fuel [1]. Phosphorus from MBM normally hinders the formation of tricalcium silicate (alite) and causes excess formation of free lime and dicalcium silicate (belite). Earlier, phosphorus was assumed to enter the structure of both belite and alite via the $Ca_3(PO_4)_2 \leftrightarrow Ca_2SiO_4$ substitution. EMPA analysis of clinkers burned from raw meals enriched with P has revealed that phosphorus is also incorporated into the di- and tri-calcium silicate lattices by two other coupled substitutions: $Al^{3+} + P^{5+} \leftrightarrow 2Si^{4+}$ (berlinite substitution) and $Fe^{3+} + P^{5+} \leftrightarrow 2Si^{4+}$ (rodolicoite substitution). If the raw meal contains equivalent amounts of Al and Fe, the prevalent substitution mechanism of P incorporation into alite and belite structure is the berlinite one. Of these two, berlinite substitution proved to be more effective in incorporating P atoms in both Ca silicates and at the same time stabilizing the α´polymorph of belite as well as M1 form of alite – in both cases the most reactive forms of these clinker minerals. Design of raw meal compositions utilizing these findings enabled to produce white (Fe-free) clinker with P_2O_5 content exceeding 3.5 wt.% and „normal" Portland clinker with more than 2 wt.% P_2O_5 with standard phase composition. Another benefit of production of P-enriched clinkers is the possibility of using them as toxic elements immobilizing binder, as phosphate released from Ca silicates upon their hydration forms Ca phosphate fixing both cationic heavy metals as well as oxyanions-forming elements like As, Cr, V.

Combustion synthesis of ZnO powders and nitrogen analysis with Prompt Gamma Activation Analysis

Söllradl, S.[1], Canella, L.[2], Kudejova, P.[3*], Türler, A.[1] & Niewa, R.[4]
[1]Paul Scherrer Inst., Villigen, Switzerland
[2]RCM, Technische Universität München, Garching, Germany
[3]FRM II, Technische Universität München, Garching, Germany
([*]petra.kudejova@frm2.tum.de)
[4]IAC, Universität Stuttgart, Germany

Zinc oxide experienced a research boom within the last few years as cheap and less toxic alternative to GaN derivates in optoelectronics. ZnO is a direct, wide band gap semiconductor with a band gap of 3.37 eV [1] at ambient temperature.

Prompt gamma activation analysis (PGAA) is a radioanalytical, non destructive and bulk sensitive method, where samples are irradiated with a cold neutron beam. The $^{A}Z(n,\gamma)^{A+1}Z$ reaction is then utilised to measure the emitted prompt gamma spectra and analyse the chemical composition of the sample. Especially for light elements as H, Li, Be, B, C, N, P, S it is more effective than neutron activation analysis.

In this study a recently reported solution combustion method was utilised to synthesise nitrogen doped zinc oxide (ZnO:N) as described in [1] to estimate the detection limits for nitrogen within a ZnO matrix for PGAA measurements. The solution combustion method was chosen as it offers a simple sample preparation and promising results are reported.

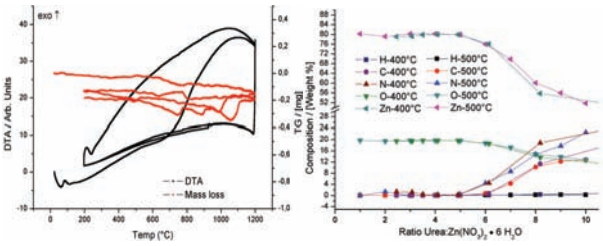

Fig. 1: DTA/TG diagram of sample prepared from a molar ratio of urea:zinc nitrate of 1:1 (left); Results of PGAA measurements for different treated samples (right).

In order to obtain similar data with the results from [1] differential thermal analysis with coupled thermo gravimetric measurements (DTA/TG), scanning electron microscopy with electron dispersive x-ray spectroscopy, Raman spectroscopy and powder x-ray diffraction are applied to the samples. Further PGAA measurements are applied and verified by elementary analysis (CHN).

After synthesis deep orange powders are obtained. After one DTA/TG cycle with a heating rate of 5 K/min up to 1200°C the product of the measurement is white ZnO powder. A measurement of two heating cycles (Fig. 1 left) shows a clear difference in the DTA curves and no significant change in weight (Fig. 1 left).

When evaluating the PGAA measurements (Fig. 1 right) it is clearly shown, that no nitrogen is found in deep orange samples (indicated with ratios 1-4, Fig. 1 right) at all. Only accompanied with an increasing presence of carbon, nitrogen is detected in PGAA and CHN measurements. These results show clearly, that the measurement of nitrogen in presence of a ZnO material is possible. On the other hand, nitrogen incorporated in ZnO can not be the source for the orange colour. A possible conclusion may be the introduction of defects under the harsh combustion conditions. The increasing carbon and nitrogen content are probably due to organic polymers, resulting from the decomposition of excess urea.

The mineralogy and crystallography of pyrrhotite from selected nickel and PGE ore deposits

Becker, M.[1*], de Villiers, J.P.R.[2] & Bradshaw, D.J.[3]
[1]Centre for Minerals Research, University of Cape Town, South Africa ([*]megan.becker@uct.ac.z)
[2]Dept. of Materials Science and Metallurgical Engineering, University of Pretoria, South Africa
[3]Julius Krutschnitt Mineral Research Centre, University of Queensland, Australia

The non-stoichiometric sulfide pyrrhotite ($Fe_{(1-x)}S$), common to many ore deposits, occurs in a variety of crystallographic forms and compositions and occasionally is also inter grown with stoichiometric troilite (FeS). In this study, the mineralogy of pyrrhotite derived from several different nickel and PGE ore deposits in South Africa, Botswana and Canada, were examined in detail in terms of pyrrhotite association, crystallography and mineral chemistry. Pyrrhotite samples were subdivided into two phase 6C $Fe_{11}S_{12}$ pyrrhotite intergrown with 2C FeS troilite, two phase 4C Fe_7S_8 pyrrhotite intergrown with 5C Fe_9S_{10} pyrrhotite, single phase 5C Fe_9S_{10} pyrrhotite and single phase 4C Fe_7S_8 pyrrhotite. None of the pyrrhotite samples analysed was classified as two phase 4C pyrrhotite intergrown with pyrite due to the scarcity of pyrite in these samples. Average solid solution Ni contents of NC pyrrhotite (0.75 ± 0.10 wt% Ni) in this study were found to be greater than in 4C pyrrhotite (0.43 ± 0.10 wt% Ni), but only when the pyrrhotite occurred as two phase 4C pyrrhotite intergrown with NC pyrrhotite. For single phase pyrrhotite occurrences in this study, 4C pyrrhotite was more Ni-rich (up to 2 wt% Ni) than NC pyrrhotite (0.75 ± 0.19 wt% Ni). The average atomic metal/S ratios obtained for 4C Fe_7S_8 pyrrhotite was 0.869 ± 0.013 (n=699), for 5C Fe_9S_{10} pyrrhotite was 0.895 ± 0.013 (n=316) and for 6C $Fe_{11}S_{12}$ pyrrhotite was 0.918 ± 0.017 (n=101). The histogram comparing metal/S ratios of all the pyrrhotite samples analysed showed a continuum of metal/S ratios, although with frequency maxima corresponding to the ideal compositions of 4C, 5C and 6C pyrrhotite. The presence of the continuum however, was interpreted to be representative of non-stoichiometry in the pyrrhotite structure.

Grain size determination in the micrometer range from 2D X-ray diffraction patterns of polycrystalline samples

Rodriguez-Navarro, A.B.[*] & Alvarez-Lloret, P.
Dpto. de Mineralogía y Petrología, Universidad de Granada, Spain ([*]anava@ugr.es)

Crystal sizes can be calculated from peak intensities of spotty diffraction rings produced by a polycrystalline sample. Such patterns are collected using a small X-ray beam and an area detector. Peak intensities can be automatically measured using specially designed software. This technique is independent of the aggregation state of the material and can be applied to power and fully compact ceramics. Also, crystal sizes of different mineral phases present in a sample can be analyzed independently. This methodology has been applied to the characterization of different polycrystalline materials (i.e., quartz, SiC and α-Al2O3). The crystal sizes determined ranges from 3 to 100 micron, a much larger range than that obtained by conventional X-ray line-broadening analyses.

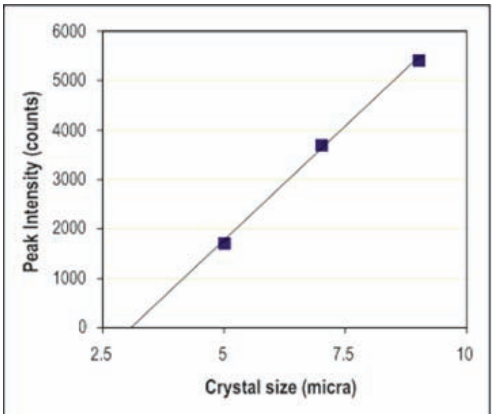

Fig. 1: Average intensity of peaks along the corundum 116 ring as a function of grain size of abrasive.

$Mg_xCu_{1-x}Cr_2O_4$ spinel solid solution: Jahn-Teller distortion and phase transitions

Tarantino, S.C.[1,2], Zema, M.[1,2*] & Giannini, M.[1,3]
[1]Dipt. di Scienze della Terra, Università di Pavia, Italy
([*]michele.zema@unipv.it)
[2]CNR-IGG, Pavia, Italy
[3]Bayerisches Geoinstitut, Bayreuth, Germany

Spinels are one of the most extensive series of related chemical compounds known and have a remarkable record of applicability, being used in numerous areas, including magnetic devices, electronics, catalysis, and batteries [1]. Chromium-rich spinels MCr_2O_4 are part of a group of exciting and challenging materials that have attracted much research interest in recent years due to complex magnetic ground states resulting from high geometrical frustration [2]. $MgCr_2O_4$ crystallises with the archetype cubic spinel structure (*Fd*-3*m*), while $CuCr_2O_4$ is a tetragonally distorted spinel with $c/a < 1$. The distortion is due to a cooperative Jahn-Teller (cJT) effect which is also associated, as recently proposed, with orbital ordering [3]. $CuCr_2O_4$ undergoes a first-order structural transition from $I4_1/amd$ to *Fd*-3*m* at 853 K [4].

The temperature- and composition-dependence of the $I4_1/amd$ – *Fd*-3*m* phase transition in $Mg_xCu_{1-x}Cr_2O_4$ solid solution, due to the melting of the cJT distortion, has been studied by means of single-crystal X-ray diffraction. Black octahedral crystals of $Mg_xCu_{1-x}Cr_2O_4$ (with x = 0, 0.10, 0.12, 0.18, 0.44, 0.50, 1), typically twinned and with a maximum size of 1×1×1 mm^3, have been prepared by flux decomposition method. All synthesised crystals but the Mg end-member have the $I4_1/amd$ symmetry. In situ high-temperature single-crystal diffraction data have been collected up to 900°C. The progressive substitution of the Jahn-Teller and d^9 Cu(II) cation with the spherical and closed-shell Mg(II) cation has a dramatic effect on the crystal structure. The tetragonal distortion, as measured by the c/a unit-cell parameters ratio and by the flattening of the tetrahedra, decreases with increasing Mg content. The substitution of Cu for Mg causes a shift of the transition temperature towards lower temperatures and a reduction of the discontinuity at the transition. Structure refinements of diffraction data collected at different temperatures reveal that heating induces a gradual reduction in the CuO_4 tetrahedron compression, which however remains significant until near the transition temperature. The variation with temperature of the tetrahedral O-Cu–O angles mimics the change in the lattice parameters.

The Mg ions, distributed over the tetrahedral sites, dilute the nearest neighbour interactions of the Cu ions, thus reducing the efficiency of the cooperative distortion. Indeed, the strength of the Cu-Cu interaction can be modulated by varying the Cu/Mg ratio.

Utilization of perlite and waste slag from the South African steel and copper industry as cement extenders

Mogoru, T.J.[1], Verryn, S.M.C.[1*] & Kruger, R.A.[2]
[1]Dept. of Geology, University of Pretoria, South Africa
([*]sabine.verryn@xrd.co.za)
[2]Richonne Consulting, Pretoria, South Africa

The manufacturing of Portland cement is an energy-intensive process consuming substantial amounts of natural resources (limestone, shale and iron bearing mineral) and generating copious volumes of CO_2. The Portland cement can however be extended by the addition of alternative suitable material, which reduces the requirement from natural resources. This study discusses results from an investigation into the use of waste slag from copper- and steel industries and natural glass (perlite) as supplementary materials to Portland cement. The slags and perlite are blended in various ratios with ordinary Portland cement. The two South African cements used for this study are both of class Cem I (42.5). These are commercially available, ordinary Portland cement from PPC (Pretoria Portland Cement) and from AfriSam (South Africa) (Pty) Ltd.

The properties of the mixtures depend on the phase composition, chemistry, grain size and the sources of the materials. Compressive strength test results (Table 1), as well as heat flow curves showing the hydration behaviour, indicate that addition of the slag and perlite to ordinary Portland cement is viable. There is a large potential to use these materials in blended cements. The results of this study can be used to develop binder formulations that will reduce CO_2 emission, energy required in the production of cementitious binders and help to reduce large slag stockpiles.

Study of interaction of colorants with natural and modified clays for an environmental application

del Hoyo Martínez, C.[1*], Sánchez Escribano, V.[1], Queiruga Dios, A.[2] & Valero Juan, M.[3]
[1]Dept. of Inorganic Chemistry, University of Salamanca, Spain ([*]hoyo@usal.es)
[2]Dept. of Applied Mathematics, University of Salamanca, Spain
[3]Dept. of Physical Chemistry, University of Salamanca, Spain

Different materials are used in the adsorption and immobilization of chemical contaminants, most of whom remain under patent, therefore the procedures and products used are not known for the public. But in all cases, the safety and/or biodegradability of materials used are important issues in selecting them for environmental applications. Some biodegradable materials used for environmental purposes are lignins [1], alginate gel [2] and some derivatives cellulose [3].

In regard to materials, safe and low costs, clays and clay minerals must be mentioned, whose colloidal properties, ease of generating structural changes, abundance in nature, and low cost make them very suitable for chemical contaminants adsorption. The clay materials have led to numerous applications in the field of public health [6,7] having been demonstrated its effectiveness as adsorbents of all contaminants. The most used are organo-montmorillonites and hydrotalcite [4,5].

We have studied the adsorption of several colorants by natural or thermally modified clays, searching their interaction mechanisms and the possible recycling of these materials for environmental purposes and prevention of the public health.

Mineralogy meets pharmacy - polymorphism of drug compounds

Kahlenberg, V.[1*] & Griesser, U.J.[2]
[1]Inst. of Mineralogy and Petrography, University of Innsbruck, Austria ([*]volker.kahlenberg@uibk.ac.at)
[2]Inst. of Pharmacy, University of Innsbruck, Austria

Polymorphism, i.e. the ability of a compound to form different crystal structures is frequently encountered among minerals. Since almost every important rock forming mineral undergoes at least one structural phase transition as a function of temperature and/or pressure, mineralogists are quite aware of this phenomenon and have gathered a considerable knowledge to deal with this solid state problem.

However, polymorphism is not a feature that exclusively concerns natural or synthetic inorganic materials, but occurs in organic compounds as well. Apart from being an intellectual challenge related to basic research, the importance of identifying and characterizing different crystal forms of a drug has been well documented in the literature. Differences in solubility, dissolution rate, morphology, mechanical properties and physicochemical stability of different modifications demand a detailed study of polymorphism of any new drug molecule. This has been recognized by the public authorities in the mid 90th why such studies are nowadays an integral part in drug development. Moreover, patenting of new solid state forms became an important part of modern life-cycle management of innovative pharmaceutical compounds.

The solid state characterization of the different polymorphs of a drug substance requires many analytical tools that are well established in mineralogy, including polarized light and hot stage microscopy, thermal analysis (DTA-DSC-TG), spectroscopic techniques (IR, Raman, solid state NMR) or X-ray diffraction (single crystal, powder).

In this contribution we will present some results from an industrial funded project where two groups from pharmacy and mineralogy work jointly in a research program and share their expertise for the benefit of a comprehensive understanding of the materials under investigation.

Optical microscopic observation of natural zeolite gravel after water purification treatment

Minato, H.[1*], Morimoto, T.[2] & Ogushi, N.[2]
[1]The University of Tokyo, Tokyo, Japan
([*]ogushi@mx3.alpha-web.ne.jp)
[2]ASTEC Corporation, Japan

The book entitled "Natural Zeolite, Quantification Guides and Data for Application, JSPS. Tokyo, Sept. 2006" [1] has been published to establish a common standard to evaluate the quality of natural zeolite commodities available in the market for the use of industries and/or agriculture fields. This book covers comprehensive technical procedures to evaluate natural zeolite commodities using physical, chemical, and mineralogical characteristics, together with various practical examples.

We present here an additional example of application of "natural zeolite" for pond water purification at famous Japanese garden named "Koko-En" that locates at Himeji Castle, Hyogo Prefecture, west of central Japan [2] (Fig. 1). The pond in the garden cultivates various kinds of decorative carp. The water quality to prevent an arising of algae is required to be kept pH between 6.8-8.6, SS below 5.0 mg/l, BOD below 3.0 mg/l, DO over 7.5mg/l, total N below 0.5mg/l, and total P below 0.02mg/l.

To maintain this condition, the water of the pond is provided from the pump station, and then flows out to the shallow stream that imitates a natural rivulet as a part of the scenery, before returning to the original pump station. The floor of the rivulet is covered by gravel of "natural zeolite" that comes from Futatsui, Akita Prefecture, north of central Japan, is an altered dacitic tuff of Miocene, and consists mainly of clinoptilolite. The returned water is filtered by matt with an aid of coagulant of natural inorganic materials to remove out solid suspensions at the pump station before providing the pond again.

After running the system for a year, recovered "natural zeolite" gravel shows dark coloured surface of manganese and iron oxides and significant adsorption of heavy metals such as Pb, As, Mn, and Fe, and loss of alkali and alkali earth metals, by X-ray fluorescence analysis, both on the surface and the core.

High magnification optical microscopic observation confirms the adsorption of manganese and iron oxides/oxy-hydroxides and the arising of some new phases of silicate minerals along the surface of the block and the surface of internal fissures and cavities of the altered tuff. Details of the arising new mineral species are under the investigation.

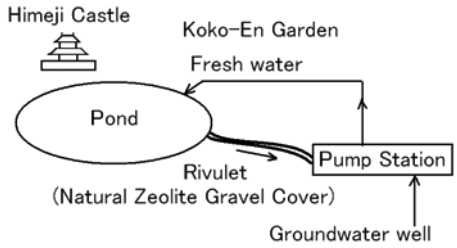

Fig. 1: Sketch of pond water purification system.

Carbonation of iron metallurgy slags as a method of CO_2 sequestration

Kasina, M.[*] & Michalik, M.
Inst. of Geological Sciences, Jagiellonian University, Krakow, Poland ([*]monika.kasina@uj.edu.pl)

Mineral carbonation is one of the CO_2 capture and storage (CCS) methods. It is based on the crystallization of stable carbonates (calcite, magnesite, siderite) by the reaction of minerals rich in divalent cations (Ca^{2+}, Mg^{2+}, Fe^{2+}) with CO_2.

The aim of this research was to determine the potential application of industrial wastes in CO_2 capture from ambient air. Blast furnace and steel slag samples after different ageing periods were used in experiments. Powdered samples and crushed fragments (ca. 1 cm) were subjected to 21 wetting and drying cycles (50 g of a sample + 400 ml of deionised water in every cycle; dried under IR radiator).

Studied samples of blast furnace slag are composed mostly of calcium silicates: akermanite, gehlenite, rankinite, and wollastonite. Steel slags are composed of larnite and oxides (srebrodolskite and wüstite).

Blast furnace slag composition was not changed during experiments. Calcite crystallization and partial dissolution of larnite and srebrodolskite (relative decrease of XRD peaks intensity) were noted in steel slag samples.

Chemical analysis indicates the increase of LOI and C_{Tot} content in slag samples after experiments.

SEM-EDS analysis of slag fragments shows that both kinds of slag were subjected to mineral carbonation process. In case of blast furnace slag this process was not very advanced. Calcite crystalize as rims (~25 μm) of small crystals around some of slag fragments. In steel slag this process seems to be more advanced. Calcite appears not only as rims of small crystals around slag fragments but also as infillings in pore spaces. Rims around steel slag fragments composed mostly of SiO_2 (~50 wt%), CaO (~30 wt%), P_2O_5 (up to 20 wt%) and C (carbonate anion?) were also noted. Some of larnite crystals (especially those close to the border of slag fragments) are partly or fully replaced by material of composition similar to rims described above.

Results suggest that silicate minerals in blast furnace slag are less reactive, what is connected with lower dissolution rate of components. In case of steel slags divalent cations (mostly Ca^{2+}) required for calcite crystallisation come from the dissolution of silicate minerals (larnite), and oxide phases as well. Results indicate that slags, especially from steel production is an useful material in CCS procedures.

The influence of Fe content in Fe-Mg tourmalines on their intrinsic dipole moments and pyroelectric properties

Zhao Changchun & Liao Libing*
School of Materials Science and Technology, China University of Geosciences, Beijing, China (*lbliao@cugb.edu.cn)

Single-crystal X-ray diffraction data of four Fe-Mg tourmalines with different iron contents from Xinjiang, Sichuan and Yunnan (China) have been collected at room temperature and liquid nitrogen temperature. Polyhedras' intrinsic dipole moments and the total intrinsic dipole moment of the crystal unit cell have been calculated. The pyroelectric coefficients of the four Fe-Mg tourmalines have been determined and the influence of the intrinsic dipole moments in Fe-Mg tourmalines on their pyroelectric properties has been investigated. The results show that for tourmalines with different iron content, the intrinsic dipole moments decrease with the increasing of Fe content at room temperature and increase with the increasing of Fe content at liquid nitrogen temperature. It is inferred that in the temperature interval between room temperature and 80°C, the electric dipole moment of Fe-Mg tourmaline decreases with the increase of Fe content.

By calculating and comparing the intrinsic electric dipole moments of X, Y, Z, T and B polyhedron, we find that T polyhedron makes the most contribution to the total intrinsic dipole moment. X polyhedron takes the second place. However, the electric dipole moments generated by the two polyhedrons of the same crystal are in the opposite directions. The electric dipole moment of T polyhedron decreases with the increase of iron content, while the electric dipole moment of X polyhedron increases with the increase of iron content. From fluid nitrogen temperature to room temperature, the reversal of the electric dipole moment of Y polyhedron occurs. Iron affects T, X and other polyhedra's electric dipole moment through the distortion of its occupied Y and Z polyhedron and the electric dipole moment reversal of Y polyhedron, thus the total intrinsic electric dipole moment of Fe-Mg tourmaline.

The pyroelectric coefficient of tourmaline decreases with the increasing of Fe content in the temperature range of room temperature to 80°C. It is inferred that the pyroelectric coefficient of tourmaline also decreases with the increasing of Fe content in the temperature range of liquid nitrogen temperature to room temperature.

Characterization of reaction products from reductive decomposition of a natural garnet

Aparicio, C.[1*], Filip, J.[1], Mashlan, M.[1] & Všianský, D.[2]
[1]Centre for Nanomaterial Research and Dept. of Experimental Physics, Palacký University, Olomouc, Czech Republic
([*]claudia.aparicio01@upol.cz)
[2]Research Inst. of Building Materials, JSC, Brno, Czech Republic

The thermal decomposition of garnets from pyrope-almandine series occurs between 750°C and 1200°C, the decomposition products depends on the experimental conditions, i.e. temperature and duration of heating, heating and cooling rate, pressure and type of atmosphere. The present work is devoted to study the characteristics of the reaction products from decomposition of pyrope-almandine garnet in reducing atmosphere.

Natural garnets of near end-member composition pyrope – $(Mg_{2.22}Fe_{0.47}Ca_{0.33})(Cr_{0.11}Fe_{0.06}Al_{1.81})Si_{2.98}O_{12}$ – and almandine – $(Fe_{2.85}Mg_{0.15})(Al_{1.99})Si_{2.99}O_{12}$ – were dynamically heated from 35°C to 1200°C in a simultaneous thermal analyzer, including thermogravimetric analysis and differential scanning calorimetry, with a heating rate of 10°C/min. The decomposition products were identified by X-ray powder diffraction (XRD) and Mössbauer spectroscopy. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), and energy-dispersive X-ray spectroscopy (EDX) were used to observe the morphology of the reaction products. Subsequently, in-situ monitoring of reductive decomposition was done by high-temperature XRD.

Pyrope decomposition started at 1105°C; the identified decomposition products are metallic iron (alpha and gamma), enstatite (ortho- and clino- polymorphs), spinel phase, and anorthite. Enstatite and spinel phase have been reported in previous works as decomposition products of pyrope in air [1,2], the difference here is the presence of metallic iron instead of iron oxides formed in oxidizing atmosphere. On the other hand, almandine decomposes at 1055°C, with the following decomposition products: hercynite, fayalite, cristobalite, Fe-cordierite and metallic α-iron. Metallic iron forms rounded-shape particles with sizes between 60 nm and 600 nm, they are randomly distributed over the surface of above mentioned reaction products (Fig. 1). The observed decomposition mechanism and structure could have an analogy in historical pottery [3].

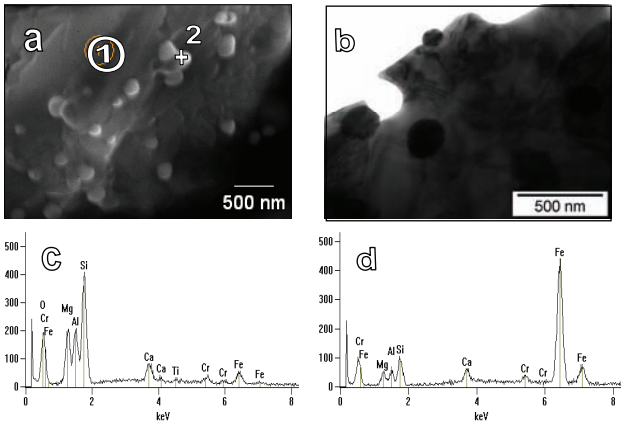

Fig. 1: SEM (a) and TEM (b) image of the decomposition products of pyrope showing the metallic iron particles. EDX analysis (c) and (d) from regions labelled 1 and 2 on figure 1a, respectively.

High-temperature borate crystal chemistry and self-assembly of boron-oxygen fundamental building blocks (FBB)

Bubnova, R.S.[1*] & Filatov, S.K.[1,2]
[1]Inst. of Silicate Chemistry RAS, St. Petersburg, Russia
([*]rimma_bubnova@mail.ru)
[2]Dept. of Crystallography, St. Petersburg State University, St. Petersburg, Russia

Nowadays borates are well known as advanced materials due to their non-linear and linear optical, luminescent, piezoelectric, refractive and other useful properties. The functional, thermal, mechanical and chemical properties of material are caused by its crystal structure. One of distinguishing characteristics of unique borate crystal chemistry is occurrence of rigid groups consisting of the BO_3 and the BO_4 polyhedra. These groups constitute fundamental building blocks (FBB).

Coefficients of thermal expansion tensor have been investigated for more than 50 borates by powder X-ray diffraction. About 3/4 of them demonstrate highly anisotropic expansion; moreover, about half of them show negative linear expansion.

The structural temperature-dependent behavior has been investigated by single-crystal high-temperature X-ray diffraction for several borates as well. As a main result, thermal stability of size and configuration of BO_3 and BO_4 polyhedra and the rigid B–O groups have emerged from the studies [e.g. 1,2]. Here we present fundamental rules of high-temperature borate crystal chemistry [1,3,4 and refs therein] in contrast to those of high-temperature silicate crystal chemistry [5,6 and refs therein]. Finally from these principles it emerges self-assembly in borates at level of rigid boron-oxygen groups as a result of thermal vibrations of boron and oxygen atoms and the groups. Self-assembly of rigid groups in borates is explained in terms of exampling thermal vibrations anisotropy of isolated groups consisting of 3 and 5 B–O polyhedra.

A study on shapes of hollow glass microspheres by glass composition

Choo KoYeon, Jeong HeonDo & Kim TaeHwan*
Reaction and Separation Materials Research Center, Korea Inst. of Energy Research, Daejeon, Republic of Korea
(*thkim@kier.re.kr)

Research on hydrogen to prepare for hydrogen economy is an urgent task which should be promoted constantly as a means of resolving skyrocketing energy issues. But regarding its application, hydrogen storage technology is a precedent study in energy storage. Many researchers are in the midst of development on hydrogen storage technology. In our country, hydrogen storage researches have been conducted according to the national R&D plan since hydrogen frontier R&D center was launched.

Our center is carrying out research on hydrogen storage using hollow glass microspheres among solid hydrogen storage materials. They were studied by J.E. Shelby's research group in Alfred University, New York, USA, according to the US DOE hydrogen project and can now store hydrogen up to 2.2 wt.% [1].

Hollow glass microspheres are non-toxic and lightweight as a solid hydrogen storage material and can be prepared from low-cost starting materials. They have a reversible hydrogen storage property, as well. Although they are sufficiently competitive with conventional organic and inorganic materials, their hydrogen storage capacity per unit weight is not even close to the target value of the US DOE (by 2010, on-board hydrogen storage systems achieving 2 kWh/kg or 6 wt.%) [2].

We investigated shape change of glass microspheres after heat treatment by controlling composition of sodium borosilicate gel as a starting material. The products were characterized by XRD and SEM, and the BET surface area was measured.

Although various processing methods can be applied to produce hollow spheres, for examples, the sol-gel/emulsion method, the sacrificial-core method, layer-by-layer deposition on colloidal templates, spray drying and the coaxial-nozzle method [3], we applied flame forming method containing a blowing agent as a feed.

[2]Vinča Institute, Belgrade, Serbia
[3]Faculty Mining and Geology, University of Belgrade, Serbia
(*milogar@eunet.rs)

The manufacturing processes of non-ferrous metals and their alloys, particularly the flotation enrichment and metallurgical processing of waste materials, cause major environmental pollution problems. Flotation waste dumps and slag from smelters represent large areas of degraded land and the permanent pollution of soil, water and air. This study is dedicated to examining the possibility of using flotation waste from RTB Bor (Serbia) in the production of silicon-ceramic materials.

Mineral composition of flotation waste consists of fayalite and magnetite with minimal amounts of copper and iron sulfide. By changing the conditions of heat treatment and cooling modes microstructure and properties of products can be controlled and desirable glass-ceramic materials can be produced [1].

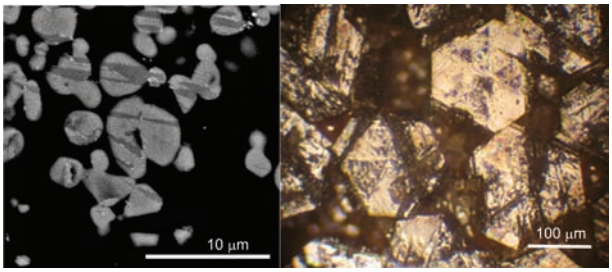

Fig. 1: Glass ceramics 1150°C/4h (left); 1480°C/6h (OM) (right)

Fig. 1 presents the two glass-ceramics microstructures build of glass and hematite crystals made at different temperature. At t = 1150°C the content of hematite is 32%. The crystals are anhedral, rarely subhedral, with diameter generally below 10 microns. At 1480°C viscosity decreases and the glass starts to flow. Therefore the glass surface is exposed to oxidation in the highest degree and growing rate of hematite becomes faster which leads to the formation of larger euhedral crystals, whose content reaches 44%. Between these two obtained microstructures, a series of glass-ceramic materials were synthesized under different time and temperature level by adding of basalt and tuff. The purpose is to find the optimal composition and crystallization conditions to obtain the applicable glass-ceramic materials.

[5]Inst. of Geological Sciences, Free University Berlin, Germany

The task for renewable energy resources is stimulating the research for new materials allowing setting up low cost and high conversion efficiency solar cells. Lowering the costs of raw materials, as well as increasing attention paid to the environmental consequences of the industrial production, both drive the development and the choice of materials on the basis of their chemical composition. The kesterite-like quaternary chalcogenides (Cu_2ZnSnS_4, or CZTS) attracted a relevant interest from worldwide researchers, due to their good performances with a simple chemistry and to the absence of relevant economic or environmental concerns associated to their use in the solar cells production.

The crystal chemical features of both natural and synthetic phases belonging to the pseudoternary system Cu_2FeSnS_4-Cu_2ZnSnS_4-Cu_3SnS_4, to which the CTZS materials belong, still await a definitive assessment. Major points of debate include the isostructurality between stannite and kesterite, the assessment of the structural model for kuramite, the possible occurrence of Cu and Fe in oxidised valence states, the mixed occupancy of structural metal sites. The last points in particular are related to two relevant topics of chalcogenide studies, i.e. the extent of cation disorder and the occurrence of partial intervalence charge transfer in Cu-, Fe-bearing chalcogenides. Moreover, both aspects can dramatically affect the physical properties of the host phase, and ultimately its eventual exploitation in photovoltaic materials. We approached the growth of these materials by solid-state reactions, hydrothermal syntheses and electrochemical deposition under morphological and compositional control to obtain ternary chalcogenide compounds (at the Cu end-member) with different physical properties. Moreover, this study reviews the state of the art of the literature on the knowledge about the pseudoternary system, and it sets up perspectives for photovoltaic applications.

Mullite-type Al_5BO_9 and $Al_{18}B_4O_{33}$, a crystal-chemical puzzle?

Fisch, M.[1*], Armbruster, T.[1] & Rentsch, D.[2]

[1]Mineralogie-Kristallographie, Institut für Geologie der Universität Bern, Switzerland ([*]fisch@krist.unibe.ch)

[2]EMPA Swiss Federal Laboratories for Materials Testing and Research, Dübendorf, Switzerland

Ceramic materials in the system Al_2O_3-B_2O_3-SiO_2 are of particular interest for industrial applications. Among these, whiskers of the most common aluminum borate, often cited as $Al_{18}B_4O_{33}$, are used to reinforce aluminum alloys and refractory linings [1]. This mullite-type compound is reported with two slightly different stoichiometries, Al_5BO_9 ($5Al_2O_3$:$1B_2O_3$) [2] and $Al_{18}B_4O_{33}$ ($9Al_2O_3$:$2B_2O_3$) [3-7]. Available crystal structure refinements are essentially identical, comprising $Al^{(IV)}$, $Al^{(V)}$, $Al^{(VI)}$ and $B^{(III)}$ [2-7]. However, to comply with the boron-richer formula of $Al_{18}B_4O_{33}=Al_{4.91}B_{1.09}O_9$, 9% of $Al^{(IV)}$ must be replaced by $B^{(IV)}$. In this study, samples from different starting mixtures representing both stoichiometries (Table 1) were investigated by single-crystal and powder XRD, as well as by ^{11}B and ^{27}Al solid state MAS-NMR.

Table 1: Sample description

Sample	Starting materials	Al_2O_3:B_2O_3
1[a]	Al_2O_3, B_2O_3	9:2
2[b]	Al_2O_3, B_2O_3	9:2
3[b]	Al_2O_3, B_2O_3	5:1
4[c]	$Al(NO_3)_3 \cdot 9H_2O$, H_3BO_3	1:2
5[b]	Al_2O_3, H_3BO_3	1.1:1

[a]flux grown single-crystals, [b]heat-treated for 10h at 1200°C [c]according to [7] but heat-treated for 10h at 1100°C.

Our single-crystal structure refinement is consistent with previous results [2,5,6]. Cell parameters are a=5.6686(2)Å, b=15.0060(9)Å, c=7.6892(4)Å and V=654.07(6)Å^3 in $Cmc2_1$; Z=4. Single-crystal X-ray data indicated a fully occupied $B^{(III)}$ site ($<d_{B-O}>$=1.3769(17)Å) and a "pure" $Al^{(IV)}$ tetrahedron ($<d_{Al4-O}>$=1.7464(12)Å). Refinements including a constrained 9% B $\rightarrow$ Al substitution at $Al^{(IV)}$ converged to significantly higher agreement factors.

Powder XRD was used to determine precise lattice parameters of all samples and to identify corundum as excess phase in samples 1-3 and boric acid in sample 5. Refined cell dimensions are identical for all samples within a few standard deviations.

^{11}B MAS-NMR spectroscopy indicated a single $B^{(III)}$ site and no sign for any $B^{(IV)}$, which is agreement with previous findings [8]. Judging from simulations, $B^{(IV)}$ amounts lower than 2% can be detected. ^{27}Al MAS-NMR spectra were consistent with Al-coordinations derived from our single-crystal structure refinement and previous NMR investigations [9].

Excess corundum in samples 1-3 could suggest B_2O_3 as limiting factor for $Al_{18}B_4O_{33}$ formation. However, results were the same for sample 5 having excess boron: Crystallographic and NMR data of all samples are consistent and no indication of $B^{(IV)}$ was found as expected for $Al_{18}B_4O_{33}$. We assume that all aluminum borate samples investigated in this study represent Al_5BO_9, casting doubt on the existence of $Al_{18}B_4O_{33}$.

Impact of zeolitic material in improving sandy soil fertility features (Albania)

Goga Beqiraj, E.[1*] & Gjoka, F.[2]
[1]Faculty of Geology and Mines, Polytechnic University of Tirana, Albania ([*]ea_beqiraj@yahoo.com)
[2]Agricultural University of Tirana, Albania

This work presents an attempt for studying the effects of zeolitic material from Munella region (Albania) in improving the fertility features of a sandy soil from Divjaka region (Albania) [1].

On the basis of their petrographic and geochemical characteristics (Table 1) the following zeolitic rocks can be distinguished: basalts and basaltic andesites, dacites and rhyolites [2]. The zeolitic phase composes up to 60-80 % of these rocks.

Table 1: Geochemical data of zeolitic rocks

	SiO_2	Al_2O_3	Fe_2O_3	MnO	MgO	CaO	Na_2O	K_2O	TiO_2	P_2O_5	LOI	TOT
Mu1	60.95	11.97	5.84	0.056	2.07	5.18	0.27	0.09	0.378	0.1	13.01	99.92
Mu2/3	72.7	10.08	4.13	0.053	0.82	2.9	1.82	1.01	0.308	0.08	6.48	100.4
Mu3/5	60.2	12.44	5.69	0/072	1.16	6.15	0.39	0.14	0.411	0.16	13.27	100.1
Mu4/1	65.26	11.63	4.27	0.083	0.97	4.72	0.98	0.54	0.362	0.09	11	99.89
Mu5	64.77	11.4	5.48	0.092	0.9	4.71	0.58	0.8	0.364	0.09	11.11	100.3
Mu6	69.97	10.1	3.21	0.08	0.37	4.72	0.28	0.27	0.305	0.07	10.84	100.2

The sandy soils of Divjaka are characterized by small thickness of the active layer, low content of humus and other essential nutriments of plants. These soils have homogeneous mechanical and mineralogical composition because of their uniform parental material, mainly composed of quartz from sea-sediment formations (Tables 2 & 3).

Table 2: Chemical properties of the soil

pH		Humus %	N-total (%)	$CaCO_3$ %	P	K	KKK	Microelement-total				
H_2O	KCl				Available mg/kg			Cu	Zn	Mn	Fe	Ca
								mg/kg		%		
8.5	7.8	0.8	0.066	7.14	13.2	75	11.5	44	78.4	0.07	4.57	8.8

Table 3: Physical properties of the soil

Hygroscopic Moisture (%)	Water Capacity (%)	Clay (%)	Silt (%)	Sand (%)
3.08	30.21	2.6	8.0	89.4

Zeolites of Munella were tested as fertilizers for the sandy soils of Divjaka region (Central-western Albania). The experiment was realized in a greenhouse, in a randomized block with four repetitions of 7 fertilizer types obtained from zeolitic material alone or mixed in various proportions with NPK (nitrogen, phosphorous, potassium). Lolium multiflorium (ryegrass) was used as experimental plant.

Application of both zeolites and mixtures with NPK resulted in a significant increase in the shoot and roots yield of ryegrass compared to the control sample in the experiment (no NPK and zeolitic material added).

The buffer role of zeolites in improving the water capacity of soils was observed especially during the driest period of the year (July-August).

Chemical and mineral composition of steel slag – reasons of slag instability

Kasina, M.[*] & Michalik, M.
Inst. of Geological Sciences, Jagiellonian University, Krakow, Poland ([*]monika.kasina@uj.edu.pl)

Slags from iron metallurgy (steel slags) are considered as important co-products used in many fields of industry and civil-engineering. Slag is usually composed of high-temperature phases which are very reactive for a long period of time. The most unwanted result of slag reactivity is its swelling, which is caused by chemical reactions of slag components.

The aim of this study was to characterise chemical and mineral composition of two steel slag samples after different ageing periods (sample A – less than 1 year; sample B - after 4 years) to indicate which of slag component is responsible for its instability. Chemical and mineral composition of slag samples were studied using XRD, SEM-EDS, ICP-ES, and ICP-MS.

Chemical composition of studied slag is typical for this material. The main components are: CaO – 47.41 wt% and, 39.62 wt%; SiO_2 – 16.51 wt%, and 11.33 wt%; Fe_2O_3 – 28.29 wt%, and 42.79 wt%; MgO – 5.16 wt% and 3.35 wt% for sample A and B respectively. BI (basicity index) is 3.5 (sample A) and 3.0 (sample B). Chemical composition and BI values indicate that the risk of hydratation and slag dissolution is high.

The main slag components determined using XRD are: dicalcium silicate – larnite (Ca_2SiO_4), dicalcium ferrite – srebrodolskite ($Ca_2Fe_2O_5$), and iron oxide – wüstite (FeO). Using SEM-EDS minor components were determined: metallic iron and lime (CaO).

Previous studies (e.g. [1]) indicate that slag stabilization is related to: 1) larnite $\beta \rightarrow \gamma$ transition; 2) magnesia and lime hydratation and carbonation.

In studied samples MgO phase was not detected. Most of magnesia is combined with iron oxides (up to 15 %wt MgO in oxide phase). The presence of P_2O_5 in larnite (up to 5 wt%) may suggest that it is fully stabilized form [2] because phosphorus can be present in larnite in low temperature. However, taking into consideration lamellar texture of larnite, a complete stabilization is not so obvious, and it may suggest that stabilization processes has not been completed. Lime hydratation was not noted in studied samples, whereas carbonation of slags is a common reaction.

Lack of larnite-γ peaks in XRD patterns suggests that larnite $\beta \rightarrow \gamma$ transition is in initial stage or absent. Lime is the only oxide phase subjected to carbonation. Results indicate that slag is not stabilized.

The role of liquid inclusions in the interface-mediated polymorph transition

Kulkov, A.[1,2*], Glikin, A.E.[1] & Putnis, A.[3]
[1]St-Petersburg State University, St. Petersburg, Russia ([*]aguacrystals@narod.ru)
[2]NITIOM "Vavilov State Optical Institute", St. Petersburg, Russia
[3]Institut für Mineralogie, University of Münster, Germany

The natural and synthetics crystals contain bubbles of liquid inclusions. Studying the composition and form of these inclusions allows drawing a conclusion about PT – conditions of crystal foundation and composition of mother solution. In this work we carried out the in-situ observation of behavior of bubbles of liquid inclusions during the interface-mediated (metasomatics) polymorphic transition of nickelhexahydrite to retgersite (β-$NiSO_4$*6 H_2O –> α-$NiSO_4$*6 H_2O). Crystals of nickelhexahydrite were grown by slow evaporation at 60°C. The study of bubbles was carried out with the help of optical microscope with digital camera at 20-25°C.

The bubbles had partly faced form. The bubble faces were paralleled to the parent crystal faces. Isolated inclusions were not the centers of beginning of phase transition but the transition began from the surface of parent. When the front of transition runs up to the liquid inclusion, rapid increasing of transition velocity takes place (from first μm / hour up to tens μm / min) (Fig. 1). The form of transition boundary changes from feather-like to flat. It is known that bubbles of liquid inclusions can faced through both the dissolution and the precipitation. In our case, the form of bubbles demonstrates the precipitation of salt from the inclusion solution. Thus, bubbles of inclusions facing during the temperature decreasing until temperature stabilize.

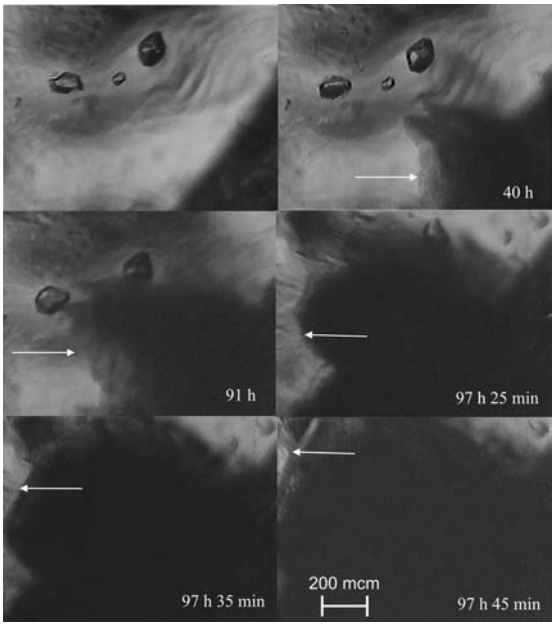

Fig. 1: Type changing of Nh-Rt transition boundary (boundary marked by arrow) and increasing of transition velocity after the capture the liquid inclusions by transition front.

Consequently, behavior investigation of bubbles of liquid inclusions during the interface-mediated polymorphic transition from nickelhexahydrite to retgersite demonstrated that isolated liquid inclusions: a) partly facing after the extraction the parent crystal from solution; b) cannot be the centers of transition beginning; c) have the influence on the velocity and boundary type of polymorph transition as the source of solution.

Efficient conversion and high stability: performance of Ni/NFS catalyst in CH_4-CO_2 reforming

Li Xuejun[1*], Wang Lijuan[1,2], Lang Bao[3], Ma Junhong[1,2] & Chen Jiawei[4]
[1]National Laboratory of Mineral Materials, China University of Geosciences, Beijing, China ([*]lixuejunwang@163.com)
[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China
[3]State Key Laboratory of Chemical Resource Engineering, Beijing University of Chemical Technology, Beijing, China
[4]School of Earth Sciences and Resources, China University of Geosciences, Beijing, China

Nano-fibriform silica (NFS) (SiO_2 content is 90.5%) extracted from chrysotile by acid-leaching is a kind of mesoporous material with a high specific surface area, high adsorptive capacity and a large pore volume. A series of Ni/NFS catalysts was prepared by soaking NFS into 5, 7.5, 10, 12.5, 15, 20 wt% $Ni(NO_3)_2$ solutions for 24 hours and baking the filtered and washed residues at 550°C for 5 hours under air atmosphere. The catalytic performances of the Ni/NFS catalysts in CH_4-CO_2 reforming (CH_4/CO_2=2, O_2 as a gas feedstock) were investigated in a fixed-bed quartz micro-reactor. The results indicate that when $Ni(NO_3)_2$ concentration is ≥ 10 wt%, the CH_4 and CO_2 conversion by the corresponding Ni/NFS catalyst can respectively rise to 97.7% and 93.8% at 850°C. Stability evaluation of the Ni/NFS catalyst from 10 wt% $Ni(NO_3)_2$ solution shows that during 100 hours no catalyst deactivation occurs under the test condition of 850°C, 1atm, and GHSV=28200 $mL \cdot g^{-1} \cdot h^{-1}$, and the CH_4 and CO_2 conversion keeps 95% and 90% respectively with a H_2/CO ratio of ca. 1.25. The Ni/NFS catalysts were characterized using X-ray diffraction, transmission electron microscopy, physical N_2 adsorption techniques, and H_2 temperature-programmed reduction (H_2-TPR). It was found that the Ni/NFS catalyst is also a mesoporous material and the size of NiO particles is 5.3-6.3 nm. The NiO particles accrete on the surface of NFS fibers and fill in a single NFS tube or in other pores in NFS to exhibit a well distribution and a higher anti-aggregation ability. The H_2-TPR result shows that the Ni/NFS catalysts from ≥ 10 wt% $Ni(NO_3)_2$ solutions can be completely deoxidized at rather low temperature and effectively decrease the energy consumption in reaction. These properties ensure Ni/NFS catalysts, especially the Ni/NFS catalyst from ≥ 10 wt% $Ni(NO_3)_2$ solution, to have high activity and excellent performance in CH_4-CO_2 reforming.

Diatomite as both the template and the catalyst to produce hierarchically porous carbon

Liu Dong[1,2], Yuan Peng[1*], Tan Daoyong[1,2], Liu Hongmei[1,2], Zhu Jianxi[1] & He Hongping[1]
[1]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China ([*]yuanpeng@gig.ac.cn)
[2]Graduate School of Chinese Academy of Sciences, Beijing, China

Porous carbon-based materials with high specific surface area are currently attracting significant interest because of their increasing applications in various industrial fields, such as adsorption and purification. Templating method has been widely reported as a well-established route for the preparation of porous carbon in which various synthetic porous materials are used as templates. Some natural mineral materials are also chosen as templates due to their special porous structures and economical viability, such as zeolite and diatomite. Diatomite, the mineralised exo-skeletons of diatoms, has highly developed porous structure which is mainly macroporous with small amount of mesopores. In the few reports about the preparation of diatomite-based porous carbon, sulfuric acid was often used as the catalyst to catalyze the carbon precursor. However, the addition of liquid acid is potentially harmful to the environment, as well as increases the cost of the preparation. In our previous study, we have found that the diatomite itself contains solid acid sites. In this sense, it should be very interesting to utilize these inherent acid sites of diatomite instead of the additive acid to catalyze the carbon precursor, and to investigate the key effects of the solid acidity on the final structure of porous carbon.

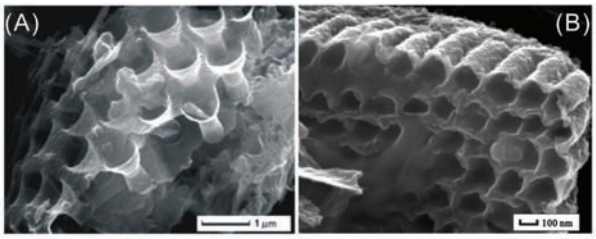

Fig. 1: SEM images of the differently macroporous structures: (A) disordered and (B) ordered macroporous structures.

In this study, we have successfully prepared hierarchically porous carbons by using intentionally selected diatomite and their thermally and acid activated derivatives as both the templates and the catalysts. The combined study by SEM, TEM, and N_2 adsorption indicates that there exists a highly morphological dependency between all of templates and their carbon counterparts which contain macropores, mesopores and micropores. The macroporous structures derive from two different types of pores of templates, one is replicated from the disordered central pores of the diatom shell, and the other from the smaller ordered edge-pores (Fig. 1). The micropores are generated mainly by the breaking of the carbon film, occurred universally in the process of the removal of the templates. The surface areas and pore volumes of the carbon products are higher than those of previously reported diatomite-based carbon prepared by using additional liquid acid as the catalyst, and there is a dramatically positive correlation between the concentratation of acid sites in the diatomite templates and the resulting values of surface area and pore volume of the crabon products. The obtained diatomite-based porous carbon products also exhibit desirable petrol absorption and H_2 storage performance, enabling potential applications in the fields of environment and energy.

Use of perlite in combination with clays for the production of low environmental impact filter for heavy metals polluted aqueous solution

Marchetto, P., Brigatti, M.F., Laurora, A. & Malferrari, D.[*]
Dipto. di Scienze della Terra, Università di Modena e Reggio Emilia, Modena, Italy ([*]dmalf@unimore.it)

The aim of this work is to prepare a relatively cheap mixture of perlite (a volcanic rock with intermediate composition between rhyolite and dacite) and clays, effective in the retention of heavy metals even after treatments at relatively high temperatures. The obtained product could be possibly reused and therefore not disposed of as toxic waste. The perlite used in this study comes from Greek quarries and is provided by the company "Perlite Italiana". Three different types of clay materials were used: 1) a clay material coming from the Argille Varicolori formation; 2) a commercial bentonite (supplied by Laviosa, Italy; 3) a standard montmorillonite (STx-1, from the County of Gonzales, Texas, USA), to be used as reference materials.

Column and batch tests were carried out on several different mixtures of the previously described materials in order to evaluate the effective adsorption of Cd, Pb, and Zn from aqueous solution. Pb, Zn, and Cd contents of the "polluted" mixtures were thus measured via inductively coupled plasma optical emission spectroscopy (ICP-OES) after acid digestion.

The obtained results indicate that the mixture consisting of Varicolori clay and perlite can be profitably used as adsorbent of metals in solution. Adsorption data are consistent with those expected from theoretical calculations.

The method chosen for the permanent inertization of polluted samples is thermal treatment, which, as evidenced by numerous literature data, can lead to a chemically inert product, eventually suitable for reuse in construction. Before being fired, each mixture was added from opportune amount of kaolinite and feldspar. Release tests were, thus, carried out on fired products using weakly acid solution (pH values between 5.5. and 6) as leaching media. Results, which are very encouraging, are reported in the Table 1.

Table 1: Heavy metals (Pb, Cd and Zn) contents in prepared mixtures, after applied tests

	Perlite + Bentonite Laviosa	Perlite + Argilla Varicolori	Perlite + STx-1
Pb, Cd, Zn concentration in the different adsorbants			
Pb (mg/100g)	719,53	157,20	286,30
Zn (mg/100g)	360,33	43,938	175,82
Cd (mg/100g)	2,1461	0,3675	1,6596
Pb, Cd, Zn release in weakly acid leaching solution			
Pb (μg/g)	n.d.	n.d.	n.d.
Zn (μg/g)	n.d.	n.d.	n.d.
Cd (μg/g)	n.d.	n.d.	5.45×10^{-6}

Sintering behavior of calcium silicate ceramics

Meiszterics, A.[1], Rosta, L.[2], Vainio, U.[3] & Sinkó, K.[1*]
[1]Inst. of Chemistry, L. Eötvös University, Budapest, Hungary (*sinko@chem.elte.hu)
[2]Neutron Spectroscopy Dept., RISP of the Hungarian Academy of Science, Budapest, Hungary
[3]Hamburger Synchrotronstrahlungslabor at DESY, Hamburg, Germany

A new preparation method based on solution technique was developed for synthesis of bioactive ceramic samples. The first step is the synthesis of calcium silicate gel samples by sol-gel technique. The hydrogel samples must be dried and heat treated to obtain the final ceramic product. One of the most important advantages of the sol-gel technique is the low energy requirement, much lower than that of conventional powder or melting technologies: 600-700°C in contrast to 1200-1300°C. In addition, the sol–gel processing allows one to produce gel glasses with compositions lying within the liquid–liquid immiscibility dome of several silicate systems. According to some published results, the bioactivity of the sol-gel derived glass-ceramics is unambiguously better than that of ceramics prepared by quenching of melts. The increase in bioactivity can be explained by the great differences in the textural properties of the materials synthesized by different techniques. The structure of a higher porosity obtained by sol-gel method can more fit the porous bone tissues than the compact one.

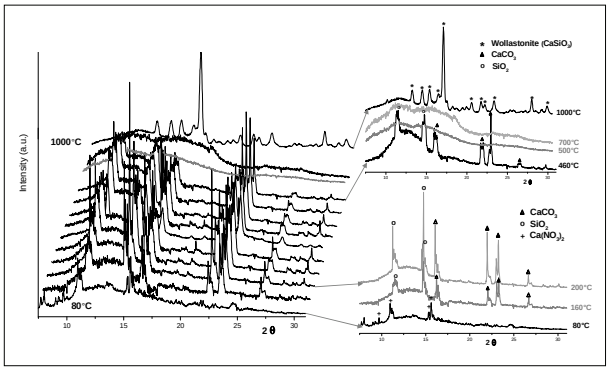

Fig. 1: WAXS curves for calcium silicate samples heat treated at various temperatures.

The present research work focused on the investigation of correlations in the *particle size – sintering temperature – Vickers-hardness* triangle. The synthesis route is: 1. preparation of hydrogel; 2. drying the wet gels (powders); 3. sintering (bulk). Ammonia catalyzed samples can be described with compact structure and good mechanical strength, however they keep some porosity. The structures of sol-gel derived calcium silicate ceramic products differ from that of fused product, which has crystalline wollastonite structure. The new structure can be characterized mainly with amorphous feature; it contains only a small volume of crystalline ordering (Fig. 1). The crystalline phase may be mono- or dicalcium silicate depending on the temperature of heat treatment. The Vickers-hardness, the water solubility, and the particle size of dried gels change together. The larger the particle, the better the strength is.

X-ray difraction study of opal-CT in siliceous rocks

Naumkina, N.I., Ilicheva, O.M.*, Vasserman, D.V. & Lygina, T.Z.
Central Research Institute for Geology of Industrial Minerals, Kazan, Russia (*atsic@geolnerud.net)

Siliceous sedimentary rocks are composed by silica (quartz and opal-CT), aluminium silicates (clay minerals, feldspars, zeolites), and, sometimes, carbonates. The originality and specificity of the opal-CT (the amount and structure) are determining the usage of siliceous raw materials: for the manufacture of liquid glass, ceramics, abrasives, rubber, refractories, concrete products, etc. We present the results of the opal-CT study with a phase-structural (mineralogical) term of a large number of samples of siliceous sedimentary rocks of Russia: flasks, tripoli, and diatomite, but not precious opals.

XRD patterns of natural opal-CT are showing complex profiles in a narrow range of 18-25° 2Θ CuK(α)(4.40-3.80 Å) and the reflex of 2.50 Å. The correct choice of standards is very important for the quantitative calculation of opal-CT by XRD method. Therefore as the majority of constituent phases is dispersed state, it's almost impossible to prepare the pure-phase substance. This difficulty is to be resolved by Rietveld method. Opal-CT profile is described by the reflection superposition of opal (low broad diffuse halo with a peak at 4.10 Å), cristobalite (clearly defined peak with a value of interplanar distance d = 4.05 Å) and tridymite (triplet reflections with values d =4.31-4.07-3.81 Å). At studying and quantifying the opal-CT in natural objects should be considered as a possible overlap the reflexes of zeolite, clay minerals, calcite, etc. The contribution of such "interfering phases" is clearly visible on the diffraction pattern of samples before and after hydrothermal leaching. Comparison of quantifying the content of opal-CT by XRD and of SiO_2 by hydrothermal leaching (5% KOH) gives a high value of the pair correlation R = 97%. XRD analysis of different Russian's deposit samples showed that the intensities ratio of the opal-CT diagnostic reflections with d = 4.3; 4.1; 2.5 Å to their sum is constant: 31.50% for d ~ 4.30 Å, 53.48% - 4.10 Å and 15.02% - 2.50 Å. [1]. In the presence of calcite in the sample use reflection d = 2.50 Å is not correct because of the superposition of calcite and opal-CT reflexes. Therefore, it was considered the ratio of two reflections 4.30 and 4.10 Å, given the contribution of the amplitude of their sum close to 37% and 63% respectively. It is seen that all points on the diagram lie close to the line with a high degree of correlation (R^2=0.92), such as for pare of quartz reflection with d=3.34 and 1.82 Å. The similar dependence of the reflex opal 4.1 Å – quartz 3.34 Å is shown in the figure for comparison.

XRD study of burned sample of opal-CT showed that the diffraction pattern does not change to 900-1000°C. At higher temperatures, it has been detected a sharp increasing of the intensity of the reflex of 4.10 Å, and reduction of 4.30 Å. The crystallite size has increased to 400 Å at 1300°C, whereas up to 1000°C it was 160 Å. TA-studies showed only the effects associated with the loss of water up to 220°C, decomposition of carbonates and destruction of zeolites at 500-800°C. No other effects in the temperature range up to 1000°C were detected.

Thus, the results of XRD and TA studies on opal-CT leads to the following conclusions: 1) Opal-CT is a stable mineral formation, solid-phase reaction of β-cristobalite formation begin after 1000 ºC. 2) Diagnostic reflexes of this phase are 4.30 Å (60 % from a maximum), 4.10 Å (maximum intensity), and 2.50 Å (30 % from a maximum). 3) The structure of opal-CT should be considered as alternating layers of α - cristobalite and tridymite with a deterministic quantitative ratio between them.

Selective exchange process limit for dioctahedral smectite: case of solution saturated by Cu^{2+} and Co^{2+} cation

Oueslati, W.*, Meftah, M., Ben Rhaiem, H. & Ben Haj Amara, A.
Laboratoire de Physique des Matériaux Lamellaires et Nanomatériaux Hybrides, Faculté des Sciences de Bizerte, Tunisia (*walidoueslati@ymail.com)

Wyoming Montmorillonite (i.e SWy) is a clay mineral with ''T-O-T" layer consisting of an octahedral sheet sandwiched by two tetrahedral sheets. Isomorphic substitutions in octahedral and/ or tetrahedral sheets commonly make the clay platelets negatively charged, which are compensated by exchangeable cation. Water and other polar solvents can enter interlayer regions and cause clay-swelling. In addition, clays are able to retain inorganic and organic pollutants, and to stop the circulation of contaminated fluids in both aquatic and soil environments. Several works studied exchange process realized when clays mineral is in contact with solutions containing only one metallic cation [1-4] and shows a different hydration behavior related to the nature of exchangeable cation. The selective exchange problem was imposed when several metallic cation are present in solution, which is the most realistic case if we wants to apply clay properties in the context of industrial waste storage [5]. This paper aims at characterizing the structural bond between selectivity and exchangeable cations abundance in the case of Na-dioctahedral smectite. This goal was determined by equilibration of the clay with a mixed equinormal solution containing two competing heavy metal cations (i.e Cu^{2+}, Co^{2+}) with various concentrations. The quantitative XRD analysis is achieved using an indirect method based on the comparison of experimental XRD patterns to calculated ones.

XRD investigation showed that exchange process are stopped for a limit concentration values (i.e.10^{-3}N) characterized by a weak ions population and which does not saturate the intrinsic cation exchange capacity (i.e. CEC) of the host materiel. For high ions solutions abundance (i.e 1N), the clay CEC was saturated by Co^{2+} species characterized by d_{001}=15.17Å basal spacing value related to two water layer hydration state (2W). All structural parameter are reported in (Table 1).

Table 2: Optimum structural parameters used for the simulation of XRD profile in the case of mixture containing ($0.5Cu^{2+}$, $0.5Co^{2+}$) with variable concentration

conce	d_{001} (Å)	exch/cati	Z_n (Å)	W_A W_B	M

Physico-chemical constraints of apatite and crandallite formation in phosphorites from Ervenik, Croatia

Posilović, H.[1], Kniewald, G.[2*], Žigovečki-Gobac, Ž.[1] & Bermanec, V.[1]
[1]Dept. of Geology, Faculty of Science, University of Zagreb, Croatia
[2]Dept of Marine and Environmental Research, Rudjer Bošković Institute, Zagreb, Croatia (*kniewald@irb.hr)

Apatite group minerals and their secondary alteration phases were studied of Upper Cretaceous phosphorite-bearing deposits. Outcrops of these deposits are situated at the foot of the SE part of Mt. Velebit near Ervenik, Croatia. Phosphorite deposits can be found in fossil caves, caverns and other karstic phenomena in limestone, generally of Cretaceous age. The exact age of the deposits is not known but is assumed to be Pleistocene. The source of phosphorus could be the phosphate-rich guano material originating from bats and birds [1].

Collected sediment samples were disintegrated, or cut–and polished and analyzed by optical microscopy, SEM, EDS, and XRD. Phase stability diagrams were constructed on the basis of mineral phases identified in the samples. The aluminium, calcium and phosphate concentrations chosen for stability field calculations are considered normal for pore fluids in contact with soil and sediments [2]. The phosphate minerals occur as white to greyish spherulitic aggregates or single crystals up to 2 mm in size. Cave sediments are usually compact and reddish or greyish in colour, with a high Al_2O_3 and FeO content, but low in carbonate. Optical microscopy and SEM of spherulitic aggregates showed at least two different phosphate phases identified by EDS and XRD as hydroxylapatite and crandallite. In the inner core of the spherulites, apatite is precipitated in the form of sprays up to 1.5 mm in length; outer parts of the spherulites volume contain very fine grained radial to fibrous crandallite. Some spherulites are banded and composed of alternating apatite and crandallite layers.

Apatite and crandallite spherulites were formed during early diagenesis of the cave sediment; each single spherulite was precipitated in partially closed microenvironment of the sediment voids and pores. Apatite occupying the central portions of the spherulits centre formed prior to crandallite in the outer spherulite sector. The calculated stability fields for apatite and crandallite may be used to explain the bi-phase precipitation in the spherulites. Higher phosphate and lower aluminum concentrations with higher pH will favour apatite precipitation; such conditions prevailed during precipitation of the spherulite core. As a consequence of apatite precipitation, phosphate concentration is decreased and aluminum is increased, the stability field of crandallite prevails and crandallite becomes stable phase precipitating in the spherulite outer volume.

Entry of SO_3 into the structure of dicalcium silicate

Staněk, T.[1*], Leichmann, J.[2] & Sulovský, P.[1]
[1]Research Inst. of Building Materials, Brno, Czech Republic
([*]stanek@vustah.cz)
[2]Faculty of Science, Masaryk University, Brno, Czech Republic

Dicalcium silicate containing foreign ions (Ca_2SiO_4 – C_2S) occurs as a component of Portland cement clinker and is called belite. Belite has lower hydraulic activity than alite (contaminated tricalcium silicate), which is the main component of Portland cement clinker. Belite can be prepared with lower expenditures and its hydraulic activation can have important impact on the economy and sustainability of cement industry.

Our research is focused on the activation of C_2S by incorporation of SO_3 into its crystal structure. Experiments with pure chemicals have shown that S substitutes Si, stabilizing thus monoclinic β-belite. Such stabilization was already described [1]. Analyzing a set of samples burned at 1450°C we found that the SiO_2 content decreases with increasing SO_3 content in C_2S with very high correlation coefficient R = -0,91 (see Fig. 1).

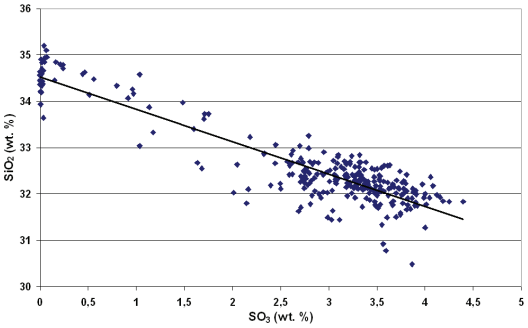

Fig. 1: The correlation of SiO_2 and SO_3 contents in C_2S.

Sulfur enters the structure of C_2S in the form of sulfate anion. The substitution of SiO_4 tetrahedra by sulfate is known e.g. in tobermorite structure, where the charge compensation compensation is by heterovalent substitution of SiO_4^{4-} with SO_4^{2-} and $2OH^-$. This is not possible in case of C_2S.

Results of belite microanalyses from belite clinkers doped with SO_3 in further experiments indicate that incorporation of S into the belite structure is connected with incorporation of increased amounts of Al. The charge compensation is probably similar to that known in the nagelschmidtite group or as berlinite substitution in silicates. The determination of the charge compensation by incorporation of other elements into the C_2S structure will be the subject of further study.

Maximum content of SO_3 in C_2S was observed in our sandwich experiments; it amounts (under normal burning conditions) to 4.4 wt.%. The empirical formula of this C_2S is $Ca_{1,929\pm0,004}Mg_{0,014\pm0,002}\square_{0,055}[(SiO_4)_{0,902\pm0,002}(SO_4)_{0,082\pm0,002}]$ (95%-confidence interval from 30 analyses, □ - vacancy). Taylor 1999 [2] found by analysis of industrial clinkers that at bulk content of SO_3 up to 3 wt.% belite contains more than 2 wt.% SO_3 only exceptionally; bulk SO_3 exceeds 3 wt.% are rare in industrial clinkers.

The incorporation of SO_3 into the C_2S structure leads to the decrease of CaO content (from 65.6 wt.% to about 63.7 wt.%), but the Ca:Si ratio rises from 2.03 ± 0.01 at 0 wt.% SO_3 in belite up to 2.16 ± 0.01 at 4.4 wt.% SO_3 in belite. The correlation between the Ca:Si atomic ratio and the number of S atoms per formula unit is 0.78, what at high number of analyses is statistically very significant value.

Crystallization properties of Nb containing bioactive phosphate glass-ceramics

Stunda, A.[1*], Mironova-Ulmane, N.[2], Borodajenko, N.[1], Vempere, D.[1] & Berzina-Cimdina, L.[1]
[1]RTU Riga Biomaterials Innovation and Development Center, Riga Technical University, Riga, Latvia
([*]agnese.stunda@rtu.lv)
[2]Institute of Solid State Physics, University of Latvia, Riga, Latvia

Glass-ceramics are relatively new material. Glass-ceramics have higher solubility than ceramics and higher mechanical strength than glass. Both properties are important for using material as implant material and depend on crystallinity properties.

In this research glass-ceramics were obtained by crystallization of previously produced glass powder. The aim of research was to compare crystallization data given by differential thermal analysis (DTA), X-ray powder diffraction (XRD), infrared spectroscopy (FT-IR) and RAMAN spectroscopy. Samples contain transition element niobium which can replace either cation, either P in anion. Hence scrupulous investigation of processes is requested.

Materials investigated in this research were niobium and sodium containing calcium phosphates. Glass powders were melted from batch of analogous composition but using different techniques. FT-IR results indicate that glass structures differ a lot.

Crystallization temperatures were detected by DTA. 8 of samples crystallize above ~800°C, only 3 samples around 720°C. Glass transition temperatures for all samples are close to 650 degrees. In literature it is shown that glasses in pure P_2O_5-CaO-Na_2O system or with TiO_2 [1] or with ZnO [2] additives start to crystallize at 650°C. It can be concluded that Nb_2O_5 additives increase crystallization temperature, although crystallizing phases mainly are the same: $Ca_3(PO_4)_2$, $Ca_{10}Na(PO_4)_7$, $Ca_2P_2O_7$ and also $Na_4(Nb_8P_4O_{32})$, $NaNbO_3$.

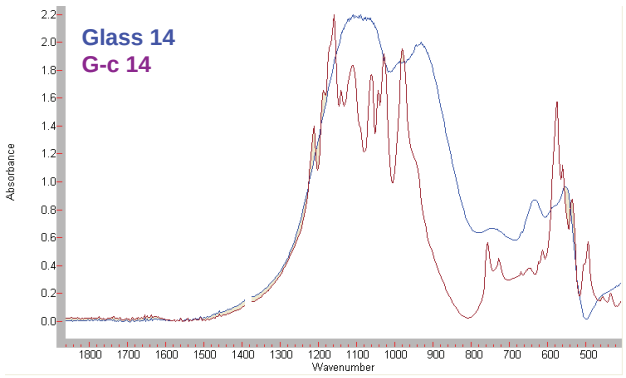

Fig. 1: Comparison of IR spectra of phosphate glass and glass ceramics.

Crystallization starts at lower temperature than temperature when first exothermal peak in DTA occurs. There are different intensities and temperatures of exothermal peaks but structures detected by XRD are almost similar. For more detailed investigation FTIR (Fig. 1) and RAMAN spectroscopy are used.

It was found that crystallization of every single phase does not have a corresponding DTA peak. In XRD pattern and IR spectra it can be seen that crystallization starts at lower temperatures than are exothermal DTA peaks. The DTA peaks can be explained by changing oxidation state of niobia. For all samples and all temperatures multiple crystalline phases are forming.

Recycling BOF-slag: experimental constraints

Su Tung Hsin[1*], Yang Huai Jen[1], Lee Yu Chen[2], Shau Yen Hong[3] & Lin Ming Fong[2]
[1]Dept. of Earth Science, National Cheng-Kung University, Tainan, Taiwan ([*]l4897101@mail.ncku.edu.tw)
[2]China Steel Corporation, Kaohsiung, Taiwan
[3]Dept. of Marine Biotechnology and Resources, National Sun Yat-sen University, Kaohsiung, Taiwan

In the basic-oxygen furnace (BOF) process for steel-making, excess carbon in molten iron is reduced to carbon dioxide by oxygen inflow, meanwhile the phosphorus, silica, and other impurities in molten iron are also partitioned into the added stony material, usually lime (CaO). The resulting stony material is known as "BOF-slag". It mainly consists of dicalcium silicate (Ca_2SiO_4; C_2S), calcium ferrite ($Ca_2Fe_2O_5$), free-lime (CaO), wustite (FeO) and periclase (MgO). Because of a high production rate of 100 kg slag /ton steel, recycling of these "solid wastes" is an important issue for the operation of a steel-making plant. Theoretically, BOF-slag can be recycled as flux in blast furnace (BF) process for steel-making or as aggregate or as cement, after proper treatments. Being used as BF-flux, the BOF-slag must has P content < 0.1%. On the other hand, relatively higher volume stability from free-lime removal is required for utilization as aggregate or cement. In this study, experiments were carried out to develop proper treatments for recycling BOF-slag.

A series of high temperature experiments were designed following the concepts for phosphorus and free-lime removal; specifically, converting free-lime to stable silicates with the addition of SiO_2 and releasing phosphorus as a gas phase under high-T and reducing conditions. Mixtures of BOF-slag (< 0.5 mm) and coke were heated to 1600°C for 5 hours. Si-sand was added to react out free-lime and to suppress crystallization of C_2S, which is a major host of phosphorus in the BOF-slag. Detailed examination on experimental products using XRD and EDS confirmed that the free-lime in starting materials was completely reacted out, forming volumetrically stable Ca-Al-Mg silicates, although bulk phosphorus contents remained unchanged. However, it was found that the experimental products were segregated into two phase domains; metal and stony domains. The former is a Fe-Mn-Si-P alloy composed of three phases, Fe-Mn-Si, Fe-Mn-P and Fe-Mn alloys. The stony domain consists of akermanite (a major constituent phase of blast-furnace slag) and merwinite with low phosphorus content of < 0.1% and absence of C_2S. Magnetic separation effectively split the metal alloy from the stony matrix. The major oxides of the resulting stony domain (46-48% CaO, 36-38% SiO_2, 8–10% MgO, 3–4 % Al_2O_3, < 3% total iron, and < 0.3% P_2O_5) is similar to that of BF-slag, a major raw material of slag-cement. This low phosphorus and free lime stony matrix is not only suitable for recycling to steel-making processes but also of high quality aggregate. Compared to common dark BOF-slag, the stony matrix from our treatment is in light colors of white-grey with marble-like appearance that can be dyed to colorful glass ceramics. After these treatments, BOF-slag can be converted into 80 wt% high quality slag and 20 wt% high phosphorus metal alloy possibly for further refinement. Although scaling our experimental methods up to a practical level remains as a challenge, these experimental results provide a reference for commercializing BOF-slag.

Modification of copper phthalocyanine blue by nano-fibriform silica

Wang Lijuan[*], Li Yuanyuan, Chen Jiawei, Ma Junhong & Li Jinhong
State Key Laboratory of Geological Processes and Mineral Resources; National Laboratory of Mineral Materials, China University of Geosciences, Beijing, China
([*]lijuanwang@cugb.edu.cn)

The modification of copper phthalocyanine blue (CuPc) by nano-fibriform silica (NFS) with an in-situ polymerization method was studied by transmission electron microscopy, infrared spectroscopy, physical N_2 adsorption techniques, color difference analysis, and durability experiment. The results show that the best modified product (NFS-CuPc) is composed of $CuCl_2$, CuPc, gelatin and NFS at a mass ratio of 4:28:3:40, with a specific surface area of 98.4 m^2/g, adsorptive capacity of 485 cm^3/g, pore volume of 0.76 cm^3/g and average pore diameter of 30.9 nm, and is of the lowest value (0.20) of color difference in a lightfastness experiment. Compared to CuPc and PS-CuPc (CuPc modified by precipitated silica), NFS-CuPc is of the best durability, owing to the nano-tube form and anti-aggregation ability of NFS that make CuPc particles hard to be taken off. So NFS-CuPc is a better pigment and NFS is a good additive in pigments.

Shell–core morphology of injection molded polyamide–6 and polyamide–6/montmorillonite nanocomposites

Yebra-Rodríguez, Á.[1*], Álvarez-Lloret, P.[2], Cardell, C.[2], López-Galindo, A.[3] & Rodríguez-Navarro, A.B.[2]
[1]Dept. of Geology, IACT Associated Unit (CSIC-UGR), University of Jaén, Spain ([*]ayebra@ujaen.es)
[2]Dept. of Mineralogy and Petrology, University of Granada, Spain
[3]Andalusian Inst. of Earth Sciences (IACT, CSIC-UGR), Granada, Spain

Polymer/clay nanocomposites display an array of properties thus far not achievable from the neat polymer. The enhancement of mechanical, thermal, barrier and other properties ([1] and references therein) has been related to the close interaction between the polymer matrix and the organically modified clay minerals. Processing conditions during injection molding do affect the crystal structure and the crystallinity of the samples [2]. Moreover, the crystal structure of polyamide–6 (α, β and/or γ) depends strongly on the sample thickness [3].

This paper presents a study of the microstructure of injection molded samples of polyamide–6 (PA6) and polyamide–6/montmorillonite nanocomposites (PA6MMT) cooled to different temperatures (40, 60, 80 and 100 ºC) after the molding to 2 mm thickness tool. The samples were manufactured as described elsewhere [3] and examined by X-ray Diffraction (XRD, (Siemens D5005), Differential Scanning Calorimetry (DSC, DSC 2920; TA Instruments), and Transmission Electron Microscopy (TEM, Zeiss EM 902).

Results show that samples are organized in a shell-core structure across the sample thickness. Polyamide-6 crystals are better oriented in the nanocomposites (PA6 MMT) than in the pure polyamide (PA6 samples), and better in the shell than in the core for both sets of samples. The same trend is observed in the crystallinity values. The lamellae stacks of the shell slices are more highly oriented than in the core. In the PA6MMT samples, the montmorillonite platelets also present higher orientation in the shell than in the core. These observed characteristics may help to establish the most appropriate cooling temperature in the fabrication of thick pieces where these kinds of materials are involved.

Pyrite generations and ankerite in the deepest sediments of the Makó trench (Pannonian basin)

Zajzon, N.[1*], Vető, I.[2], Demény, A.[3], Pintér, F.[4] & Földvári, M.[5]
[1]Inst. of Mineralogy and Geology, University of Miskolc, Hungary ([*]nzajzon@uni-miskolc.hu)
[2]Consultant, Balogh Á. street 18/c, 1026, Budapest, Hungary

[4]Scientific Laboratory, Federal Office for Protection of Monuments, Vienna, Austria
[5]Geological Institute of Hungary, Budapest, Hungary

Chemical, mineralogical and isotopic records of the thermochemical sulphate reduction (TSR) active below 5 km in the Makó trench have been described briefly by [1]. Here its mineralogical aspects will be discussed in more details.

The most interesting core sample is studied by BSE, where four pyrite types are visible (Fig. 1): Type 1 consists of framboids of early diagenetic, obviously microbial origin forming balls and mat layers with the size of up to 100 µm. Types 2–4 are products of TSR. Type 2 infiltrates particular grains with uncertain organic origin, while type 3 consists of 100 µm sized aggregates of smaller crystals of pyrite and pyrite matrix, with somewhat spongeous texture. Type 4 is represented by hexagonal forms of 50–100 µm size. Types 2 and 3 are considered as transitional forms leading to formation of the final variant of the late diagenetic pyrite, represented by hexagonal crystals. TSR is likely a process active even today.

DTA curves show two pyrite peaks at around 405 and 465°C. According to micro XRF (attached to SEM) measurements, types 1–3 contain only Fe and S above the detection limit. Type 4 can be divided to two subtypes: the first is also free of other elements, till the second contains Zn and Mn, probably homogenously distributed in the pyrite, because no inclusion could be observed. The Zn enrichment could explain the higher thermal stability of the pyrite, reflected in the second DTA peak.

Ankerite was also observed in the samples, where TSR pyrite appears. The C and O isotope compositions show subtle variations. Ankerite (+dolomite): $\delta^{13}C$ = –0.6 to 2.8‰, $\delta^{18}O$ = –10.0 to –7.4‰; calcite: $\delta^{13}C$ = 2.1 to 3.4‰, $\delta^{18}O$ = –9.9 to –9.0‰ (V-PDB). A combined evaluation of mineral contents and isotopic compositions lead us to suggest that the TSR process may have happened at deeper positions, and the migrating H_2S+CO_2 fluid underwent significant isotopic exchange with the surrounding carbonate rocks. The pyrite+ankerite(+dolomite) formation was induced by mixing of this TSR-related fluid with a local one containing dissolved Fe and Mg.

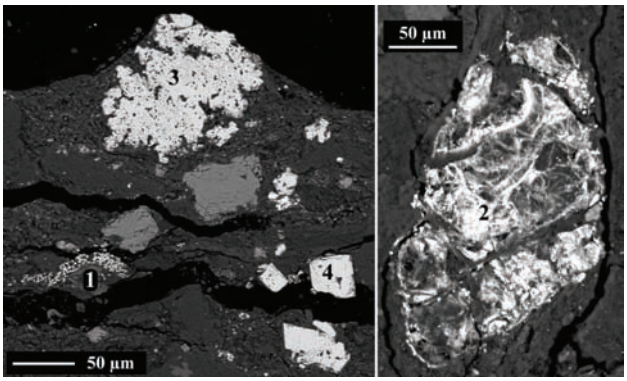

Fig. 1: BSE images of the different pyrite generations of the sample. The numbers are marking the different types (see in text).

Formation of diamond in the lithospheric mantle

Stachel, T.[1*] & Harris, J.W.[2]
[1]Dept. of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada ([*]tstachel@ualberta.ca)
[2]Dept. of Geographical and Earth Sciences, University of Glasgow, UK

With the exception of rare "super-deep" diamonds, gem diamonds derive from peridotitic, eclogitic and minor websteritic sources in the subcratonic lithospheric mantle. Geothermometry, based on silicate inclusions and the aggregation state of nitrogen in diamonds, shows that irrespective of source paragenesis, crystallization and storage of diamonds in the lithospheric mantle commonly occurs in a narrow temperature interval of ~1150 ±100°C. Geobarometry, based on garnet-orthopyroxene inclusion pairs, indicates diamond formation at depths of generally less than 200 km along 38-42 mW/m^2 model geotherms. Lower geothermal gradients observed for some diamonds likely represent re-equilibration of touching inclusion pairs during cooling ambient conditions, suggesting that diamond formation is associated with transient heating events.

Direct conversion from graphite is not considered relevant for the formation of gem diamonds since the high activation energy and associated overstepping will likely cause the graphite-diamond conversion to occur catastrophically resulting in very fine grained polycrystalline aggregates [1]. Precipitation of lithospheric diamonds is interpreted to occur during redox reactions associated with the infiltration of melts (super-solidus conditions) or CHO-fluids (sub-solidus), involving either carbonate reduction or methane oxidation. Both of these diamond growth modes are documented in nature [2,3].

Studies of mantle xenoliths from Phanerozoic kimberlites indicate a decrease of oxygen fugacity with depth that is presumed to reflect crystallochemical effects. Along the resulting depth-fO_2 trend, at pressure exceeding ~3 GPa elemental carbon (graphite/diamond) rather than carbonate is stable in "normal" subcratonic peridotitic mantle [4]. This implies that reduction to diamond can only occur for carbonate dissolved in upward migrating fluids/melts. Such comparatively oxidized melts/fluids cannot derive from the reduced deep upper mantle and, therefore, likely relate to recycling of oceanic lithosphere. Carbonate reduction appears to be the dominant mode of diamond formation during the Proterozoic and Phanerozoic [5].

For generally Paleoarchean harzburgitic diamonds (3.5-3.2 Ga) co-variations of $\delta^{13}C$–N suggest methane reduction as the principal mode of precipitation, relating their formation to upward percolation of reduced asthenospheric fluids. The apparent transition to carbonate reduction as the dominant mode of diamond formation after the Archean coincides with increasing recycling of biogenic carbonates into the mantle since the Paleoproterozoic.

Trace element substitution in gem feldspars using XAFS and XEOL

Taylor, R.P.[1,2*], Finch, A.[1] & Mosselmans, J.F.W.[2]
[1]Division of Earth Sciences, University of St Andrews, UK ([*]rpt5@st-andrews.ac.uk)
[2]Diamond Light Source, Didcot Oxford, UK

X-ray Absorption Spectroscopy (XAS) is used extensively in the study of local atomic coordination in materials. Here we apply this methodology in the investigation of minor and trace elements within feldspar. We compare and contrast the XAS information encoded in X-ray fluorescence (standard fluorescence XRF-XAS) with that expressed in the X-ray Excited Optical Luminescence (XEOL).

We have analysed Fe substitution in a suite of gem-quality material. For many samples, we obtain XAS spectra consistent with tetrahedral Fe^{3+} substituting for Al. Average bond distances around Fe have been determined. However Fe in many feldspars is present dominantly as nanoparticles of Fe oxides such as magnetite. The XRF-XAS data here provide a composite of the oxide and Fe substituted into feldspar.

To deconvolute the responses of the two phases, we have explored the XAS information expressed by the XEOL. Such methods have been applied successfully in other systems [1] although the interpretation is sometimes far from trivial. In principle, XEOL comes solely from the feldspar component of intergrowths and can provide a route to determine Fe coordination in feldspar independently of the nanoinclusions. These experiments require further development of the i18 beamline at Diamond but our preliminary experiments show no XAS information in the XEOL response. We hypothesise that the long (ms) lifetimes of luminescence in Fe-bearing feldspars divorces the XAS information from the XEOL response. Future experiments will isolate the fast (ns) component of the luminescence in the time domain and explore that for XAS information.

We will present data on Cu coordination in gem-quality red plagioclases (Plush feldspars) [2] that have recently been the subject of great controversy. Our results will include a comparison of XEOL and XRF-XAS data.

Emeralds from the Piteiras mine, Minas Gerais State, Brazil: genetic implications from fluid inclusion studies

Costanzo, A.[1*], Blamey, N.J.F.[2], Feely, M.[1], Lynch, E.P.[1], Pironon, T.[3] & Lavin, P.[1]
[1]School of Natural Sciences, Earth and Ocean Science, National University of Ireland, Galway, Ireland
([*]alessandra.costanzo@nuigalway.ie)
[2]Dept. of Earth and Environmental Science, New Mexico Tech, Socorro, USA
[3]UMR G2R, CREGU, Universite´ Nancy I, Vandoeuvre-le`s-Nancy, France

The Piteiras mine in Itabira is located in the Minas Gerais State, Brazil and produces gem quality emeralds. Ultramafic rocks in contact with granites are the preferred mineralised zones with amphibolite-phlogopite schists acting as the host rock for emeralds. The emerald crystals (~0.5-50mm in length) are spatially related to quartz boudins within the schists. Samples of emerald and boudined quartz were subjected to fluid inclusion (FI) studies, i.e., petrography, microthermometry, laser-Raman microprobe and gas analysis using mass spectrometry. The results presented below highlight significant differences between the chemistry of fluids trapped in FIs in emerald and in the boudined quartz. The geological constraints on emerald formation resulting from these differences will be discussed.

In quartz aqueous-rich FIs are trapped as secondary inclusions distributed along planar arrays in healed fractures. FIs consist of two-phase (L_{H2O}+V_{H2O}) aqueous inclusions Type 1 and monophase aqueous (L) Type 2. In Type 1 T_{Htot} to the liquid phase is between 182 and 381°C and to the vapour phase between 339 and 420°C; salinity ranges from 0.88 to 14.77 eq.wt.% NaCl. Primary fluid inclusions in emeralds are very abundant and occur as isolated individuals, in groups of FIs or distributed in trails parallel to the crystal growth zones. FIs consist of four FI types: Type 1 are two-phase (L_{H2O}+V_{H2O}) aqueous inclusions; type 2 are solid-rich aqueous inclusions (L_{H2O}+V_{H2O}+S); type 3 are three-phase (L_{H2O}+L_{CO2}+V_{CO2}) aqueous-carbonic inclusions (CO_2 ranging from 30 to 80 vol.%); type 4 are solid-rich aqueous-carbonic inclusions (L_{H2O}+L_{CO2}+V_{CO2}+S) with CO_2 occupying ca. 40–80 vol% of the inclusions. In emerald hosted aqueous-rich FIs type 1 and 2 T_{Htot} occurs to the liquid phase between 260 and 400 °C and salinity range from 4 to 7 eq.wt.% NaCl. Dissolution of the solids occurs from 220 to 255 °C. In aqueous-carbonic FIs type 3 and 4 CO_2 homogenises to the liquid state between 28.7 and 31 °C, and to the vapour between 27.7 and 31.8 °C indicating CO_2 densities between 0.31 and 0.64 g/cm^{-3}. CO_2 melting temperatures range from -56.6 to -58.8 °C. Clathrate melting takes place between +2.2 and +9.5 °C, indicating salinity for the aqueous phase between ~13 and 1 eq.wt.% NaCl. T_{Htot} to the vapour occurred between 330 and 440 °C.

The Raman microprobe analyses reveal a heterogeneous assemblage of solid phases trapped in Type 4 FIs. Carbonates are the dominant species (solid solutions of Ca-, Mn- and Fe-rich carbonates) but quartz, muscovite and sulphur phases are also present. Quantitative FI gas analysis by mass spectrometry showed that quartz analyses have <1% gas with very high argon and N_2/Ar ratios of ~2. The most probable source of argon is from K-bearing minerals above the closure temperature for argon systematics, thus implying a metamorphic origin. In contrast, the emeralds have about 17 mole% gas, dominated by CO_2 attributed to a metamorphic devolatilisation reaction. The emerald data indicates two potential end-member fluid sources, one that is metamorphic and the other where the N_2/Ar ratio is about 60. Fluid gases are attributed either to deep basinal brines or were sourced directly from basaltic rocks during metamorphism. Genetic models for Brazilian emeralds will be discussed in light of the data presented above.

Crystal chemistry and crystal growth of pezzottaite from Myanmar

Devouard, B.[1*], Labat, F.[1], Fritsch, E.[2] & Devidal, J.-L.[1]
[1]LMV, Univ. Blaise Pascal - CNRS, Clermont-Ferrand, France
([*]devouard@opgc.univ-bpclermont.fr)
[2]IMN, Univ. Nantes - CNRS, Nantes, France

Pezzottaite was described in 2003 as a new mineral species from Ambatovita, Madagascar [1,2]. It is the Cs-Li end-member of the beryl group, and an attractive gem with deep purplish pink color. Pezzottaite has subsequently been recognized from two other localities, in Afghanistan [3] and in Momeik, Myanmar [4]. Studying the crystal chemistry of pezzottaite is challenging, since it contains Li, Be and H_2O. It can be done, however, by combining EPMA, LA-ICP-MS, micro-FTIR, and SC-XRD analyses.

Pezzottaite crystals from Myanmar are slightly tabular hexagonal {10.0}+{00.1} prisms up to ca. 1 cm. We cut two crystals and prepared thick (90-400 µm) sections perpendicular to the **a** and **c** crystallographic directions. Both crystals displayed similar features.

The crystals show a complex hourglass sector zoning with a late-stage overgrowth on the basal faces (Fig. 1). Color is concentrated in the sectors bounded by the {10.0} faces (zone A), and in the overgrowths (zone C). The sectors outside the hourglass (zone B) are near colorless. SEM-BSE imaging further revealed small sectors (zone D) at the limit of zones B and C, corresponding to the development and resorption of {*h0l*} faces, and minute sectors parallel to **c**, in the C zone. Rare inclusions of elbaite, pollucite and calciotantite were identified by EDS.

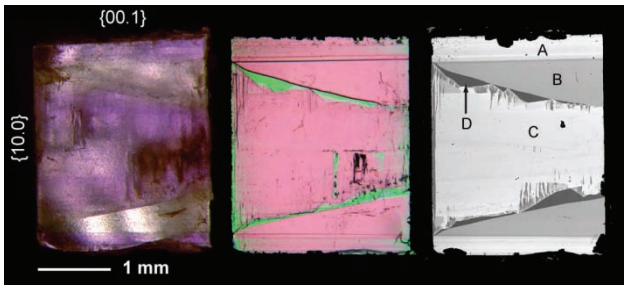

Fig. 1: Pezzottaite crystal cut parallel to the **a** axis (**c** vertical), showing half of the hourglass sector zoning (center of the stone to the right of the images); [left] polarized transmitted light, [middle] under crossed polarizers (section ca. 180 µm thick), and [right] SEM-BSE image.

Zones A and C have the highest Cs contents, averaging 12.8 wt% Cs_2O (0.56 apfu) and 12.1 wt% Cs_20 (0.53 apfu), respectively, and locally up to 14.3 wt% Cs_2O (0.63 apfu). Zone B has lower Cs contents, 8.8 wt% Cs_2O (0.37 apfu), and zone D is Cs-poor, 2.77 wt% Cs_2O (0.11 apfu). These crystals thus appear to be mixed pezzottaite-beryl crystals. Cs and Na show a negative correlation, except in zones D which are Cs-poor but contain Na up to 0.2 apfu. Although Na and Cs occupy distinct sites in the channels, these sites appear to be mutually exclusive because of electrostatic repulsion. Water content was determined using micro-FTIR spectrometry, using extinction coefficients estimated according to [5]. H_2O ranges from 1.1 to 2.0 wt%, and is anti-correlated with the Cs content. IR spectra show only type I water molecules in the Cs-rich zones, but a mixture of type I and type II water in the Cs-poor zone D.

See through pearls using X-rays: micro-radiography vs. micro-computed tomography

Karampelas, S.[1*], Michel, J.[2], Zheng-Cui, M.[1], Schwarz, J.-O.[2] & Enzmann F.[2]
[1]Gübelin Gem Lab Ltd., Lucerne, Switzerland
([*]s.karampelas@gubelingemlab.ch)
[2]Inst. of Geosciences, Johannes Gutenberg University, Mainz, Germany

Understanding the internal textures of pearls can help to the separation natural vs. cultured pearls. The vast majority of the pearls' internal textures studies up-to-date were done using X-ray μ-radiography; e.g. in [1]. Recently, high resolution X-ray computed tomography (μCT), a method originally developed by the medical field and the last decade used in geosciences [2], is applied on some cultured pearls [3,4]. The originality of this study is that μCT and radiography in different directions were applied on the same cultured and natural pearls in order to better reveal and understand the internal structures observed by the latter method.

This study comprises samples which are covering the different major categories of both natural and cultured pearls presented in the market; i.e., saltwater natural (SWNPs), freshwater natural (FWNPs), saltwater with cultured solid nucleus -bead- (SWBCP), saltwater cultured and freshwater cultured without bead (SWNBCPs -a.k.a. "keshi" cultured pearls- and FWNBCPs respectively). Some of the studied samples were drilled and one was mounted in a white metal pendant. As expected, when using μCT, growth textures and cracks (when present) of all pearls, as well as the tissue related textures of cultured pearls are better revealed compared to those observed in X-ray film μ-radiography. This is, because results of μCT analyses give 3-dimensional information of sample related features.

Moreover, some textures are barely visible using X-ray film μ-radiography, thus the identification of their natural or cultured origin could be an issue (see also [1,5]). With μCT some of these textures are better revealed, and easier to interpret. Additionally, complicated internal textures, observed sometimes in X-ray film μ-radiography of FWNBCPs, are better revealed with μCT. Some of them seem to be related to more than one tissue. However, in the case of pearls mounted on metal it is difficult to get more details than with X-ray film μ-radiography. This is because the metal sometimes masks the internal textures of samples.

Despite the disadvantages of the method (e.g., measurement time and data reduction last more than 5 hours) the μCT seems to be a promising method for investigating the internal textures of natural and cultured pearls. Studies of a large number of samples using this method could help the better interpretation of internal textures of pearls as observed with X-ray μ-radiography. This will also lead toward a better understanding of pearl biomineralization.

The blue-green-yellow sapphires from Nam Khun-Nam Yuen, Thailand, and Garba Tula, Kenya

Wathanakul, P.[1,2*], Atichat, W.[2], Satitkune, S.[1], Somboon, C.[2] & Leelawattanasuk, T.[2]
[1]Gem & Mineral Sciences SRU, Dept. of Earth Sciences, Faculty of Science, Kasetsart University, Bangkok, Thailand
([*]fscipww@ku.ac.th)
[2]The Gem and Jewelry Institute of Thailand, Bangkok, Thailand

The blue-green-yellow (BGY) sapphires have been reported related to various basaltic gem fields, e.g., Antsiranana, Northern Madagascar, Tumbarumba, NSW Australia, and Nam Khun-Nam Yuen, NE Thailand (e.g., [1-3]). The BGY sapphires of similar appearances have also occurred in other different geological terrane, i.e., the Pan-African monzonite dyke of the mantle origin, such as the Garba Tula BGY sapphires, Kenya [4].

Two groups of the similar looking BGY sapphire samples from Nam Khun-Nam Yuen and from Garba Tula (Fig. 1) have been analysed for their physical and optical characteristics, and trace element chemistry. BGY sapphires from both localities are commonly clear and contain rare inclusions, possibly only some fingerprints.

Fig. 1: Basaltic BGY sapphire samples from Nam Khun-Nam Yuen gem field, NE Thailand (top) compared to BGY sapphires from Garba Tula, central Kenya (bottom).

The results revealed the overlapping of their physical characteristics as well as chemistry. Nonetheless, the BGY sapphire samples from each locality did show their differences in the UV-Vis-NIR absorption spectra. Though having similar content of iron, and their colour is attributed to Fe^{3+}, Fe^{2+}/Fe^{3+}, and Fe^{2+}/Ti^{4+}, the basaltic BGY sapphire samples from Thailand tend to have Fe^{2+}/Fe^{3+} component more than the Garba Tula ones, and the latter tend to contain more Fe^{2+}/Ti^{4+}. Thus, differences in Fe^{2+}, Fe^{3+} as well as Ti^{4+} species can be used to distinguish the BGY sapphires of different geological gem fields.

The role of spectroscopy for the distinction of natural color and color treated diamonds in the 21st century

Hainschwang, T.
GEMLAB Laboratory, Balzers, Liechtenstein
(thomas.hainschwang@gemlab.net)

While the vast majority of diamond researchers work on the growth and defect characterization of synthetic diamonds for industrial applications there is a second important market which demands for in-depth diamond research: the gem diamond market. The high value of untreated natural diamonds versus the distinctly lower value of treated natural diamonds has driven the demand for the analytical capacities to distinguish untreated natural diamond specimens from treated ones.

Until the end of the 20th century the only important diamond treatments were irradiation with high energy particles, and annealing after irradiation when needed. The behavior of diamonds upon irradiation is rather uniform and consists of the formations of vacancies and interstitials. Annealing after irradiation of nitrogen-containing diamonds results mainly in nitrogen-vacancy type defects. In the gemological field such stones used to be mainly identified by UV luminescence and the use of direct vision spectroscopes; only from about 1977 spectrometers started to replace the spectroscopes in gemological labs ([1]; first published spectra: [2]).

With the appearance of the HPHT treatment in the 1990's the issue of diamond color treatments changed dramatically and became a highly complex matter (see e.g. [3]).

In the HPHT treatment brown type I and type II diamonds with deformation-related color are usually treated at temperatures of 1900 to near 2500°C and 55 to 85 kbar. The type I material generally turns yellow to yellow-green while the type II material turns either colorless or blue depending on the presence or absence of boron.

The HPHT treatment forced all laboratories that wanted to identify this treatment to work extensively with spectroscopic equipment; the technique of photoluminescence spectroscopy spread throughout the labs mainly because of this treatment.

After the introduction of HPHT in the 1990's the first decade of the 21st century brought many modifications of the HPHT process and today any type and color of diamond may be HPHT treated at temperatures up to nearly 3000°C; stones can be irradiated before or after HPHT, or treated by multiple steps involving HPHT, irradiation and annealing. The extreme variability of treatment conditions and diamonds that can potentially be treated makes a proper identification of colored diamonds a real challenge.

Today origin of color determination requires the characterization all types of naturally colored diamonds by a variety of methods including low temperature UV-Vis-NIR spectroscopy, FTIR spectroscopy and low temperature photoluminescence spectroscopy with various excitation wavelengths. Thus a complete picture of the defects occurring naturally in colored diamonds needs to be obtained and exactly the same needs to be done for the different groups of diamonds after the treatments.

This presentation gives an overview of all treatments, and important defects produced or destroyed by them; and it aims at demonstrating the importance of spectroscopy for origin of color determination of diamond in the 21st century. Furthermore a short tour through the properties of the different types of treated diamond is provided, and it is shown how treated diamond samples are commonly distinguished from their naturally colored counterparts.

The role of evaporites in the formation of high value coloured gemstones

Giuliani, G.[1,2*], Ohnenstetter, D.[2], Fallick, A.E.[3], Banks, D.[4] & Feneyrol, J.[2]
[1]IRD, Toulouse, France
[2]CRPG/CNRS, Vandœuvre-lès-Nancy, France
([*]giuliani@crpg.cnrs-nancy.fr)
[3]SUERC, East Kilbride, Glasgow, Scotland, UK
[4]School of Earth & Environment, University of Leeds, UK

The combination of field and geochemical studies on high value coloured gemstone deposits in meta-sedimentary platform carbonates has elucidated the role of evaporites and organic matter in their genesis. Emerald and ruby localities, from several areas worldwide, have in common, moderate to high temperatures of origin, saline fluids, high $\delta^{18}O$, and a lack of associated igneous rocks.

Colombian emeralds are hosted by Cretaceous carbonaceous black shales, and occur in veins, breccia and pockets with carbonates, quartz, albite and pyrite. Intense albitisation by hydrothermal fluids mobilized the Be necessary for emerald formation from the black shales. Stable isotopic studies of emerald and gangue minerals indicate a basinal brine source at ~300°C with high $\delta^{18}O$ and sulphate reduction by organic matter from evaporitic sulphur to form pyrite. δD ratio, cation and anion content indicate that two fluids were involved, a basinal brine (40 wt% eq. NaCl), and a surface-derived fluid.

Afghani emeralds are associated with a strong Na-K metasomatism of the host medium-grade metamorphic schists. The hydrothermal fluids derived their high salinity (40 wt% eq. NaCl) and halogen characteristics from leaching of meta-evaporite sequence.

Rubies in marbles from Central and South-east Asia were formed in a closed fluid system, at P ~3 kbar and $620<T<670$°C. The fluids were rich in CO_2 released, during metamorphic devolatilization of the carbonates, and in F-B-Cl-SO_4 released by melting of salts derived from evaporites. The presence of salts and sulphates in rubies and the unusual composition of the CO_2-H_2S-COS-S_8-AlO(OH)-bearing fluid inclusions confirms the thermal reduction of sulphate by organic matter, during the high temperature-medium pressure metamorphism of the Tertiary India-Asia collision. The carbonates were enriched in Al- and Cr-V-bearing detrital minerals, such as clays that were deposited on the platform, and in organic matter. Molten salts mobilized in situ Al and metallic transition elements contained in marble, leading to crystallization of rubies.

'Tsavorite' (vanadian grossular) in quartz veins deposits from the Lemshuku and Namalulu areas in Tanzania, are hosted by vanadian-graphitic schist i.e. amphibolite facies black shales. The association of anhydrite (and gypsum) with 'tsavorite' in quartz veins in Lemshuku, the presence of gypsum-anhydrite intercalations and lenses of graphite-scapolite-diopside-pyrite in carbonates at the bottom of the Namalulu marbles that overlay the graphitic schists, indicate the deposition of evaporites in a euxinic platform environment. H_2S-rich fluid inclusions, the high $\delta^{18}O$ of 'tsavorite', the presence of pyrite and graphite in the metasomatic zones indicate that sulphate reduction by graphite probably played a key role in gem formation.

The formation of evaporite-related gemstones can therefore be linked with meta-sedimentary platform carbonates. The association of evaporite-organic matter and black-shale-carbonates, plays a key role, as does the formation of highly saline fluids in open hydrothermal systems, and molten salts in high temperature closed metamorphic systems for mobilisation of the chemical elements necessary to produce the gemstones.

Mineral chemistry and structural relationships of inclusions in diamond crystals

Satitkune, S.[1*], Zubko, M.[2], Häger, T.[3], Kusz, J.[2] & Hofmeister, W.[3]
[1]Dept. of Earth Sciences, Faculty of Science, Kasetsart University, Bangkok, Thailand ([*]ton_toey@hotmail.com)
[2]Institute of Physics, University of Silesia, Katowice, Poland
[3]Inst. of Gemstone Research, Johannes Gutenberg University, Mainz, Germany

Co-existing inclusions occurring in individual diamonds are the special keys for determining the equilibrium of mantle mineral assemblages as well as the physical conditions prevailing in the mantle during diamond growth. The partitioning of Fe and Mg between two coexisting mineral phases has been recognized as potentially useful geothermometer [1]. The last equilibrium temperatures between the mineral assemblage diamond – chromium pyrope – enstatite, were calculated at a fixed pressure of 5.0 GPa, within the diamond stability field. The pressure evaluations were also estimated from alumina contents of orthopyroxenes coexisting with pyrope garnet [2]; average temperatures and pressures for diamond samples were calculated as shown in Table 1.

Table 1: Average temperature and pressure

Diamond localities	Temperature (^{o}C)	Pressure (GPa)
Koffiefontein mine	1087 (±15)	5.2 (±0.1)
Finsch mine	1041 (±5)	5.0 (±0.1)

The structural relationships of the host diamond crystals and their inclusions were studied by calculating the angle correlation between the [111] face of the diamond and specifically selected directions of their distinct mineral inclusions. Chromium pyrope or chromite inclusions, which are representing more than one trapped crystal in the individual diamond hosts, showed the angle correlation with small degrees of different orientations. The angle correlations between diamond [111] and chromium pyrope [111] or chromite [111] showed relatively small misalignments up to 2.2° and up to 3.4° between diamond and chromium pyrope, or chromite inclusions. The chromium diopside and olivine inclusions, however, showed a degree of miss-orientation up to 10.2° between diamond [111] and chromium diposide [010], and up to 12.9° between diamond [111] and olivine [100].

All inclusions of cubic phases (i.e., chromium pyrope and chromite) exhibit a relatively similar orientation to their diamond hosts, when the inclusions grew together in individual diamond. The crystal inclusions show the typical small misalignment angle among each other. Furthermore, all inclusions of the same cubic phase captured in diamond crystals from the same mine show nearly the same angle orientation to their host diamond. In contrast, inclusions of non-cubic phases (i.e., monoclinic chromium diopside and orthorhombic olivine) always show more extensive, variable orientations between the inclusions and their respective diamond host.

Structure and provenance of freshwater cultured pearls

Jacob, D.E.[1*], Soldati, A.L.[1,2], Wehrmeister, U.[3] & Brügmann, G.[4]
[1]Dept. of Geosciences and Earth System Science Research Centre, Johannes Gutenberg-Universität, Mainz, Germany ([*]jacobd@uni-mainz.de)
[2]CONICET, Grupo Caracterización de Materiales, Centro Atómico, S.C. de Bariloche, Argentina
[3]Dept. of Gemstone Research, Johannes Gutenberg- Universität, Mainz, Germany
[4]Max-Planck Institut für Chemie, Mainz, Germany

Freshwater pearls, cultured in bivalves of the genus *Hyriopsis* have been increasing constantly in quality and size over the last years. Main producing countries are China and Japan, but other countries, e.g. Thailand, are also known to culture freshwater pearls. We review here the micro- and nanostructure of pearls that lead to their extra-ordinary material properties including the occurrence of vaterite which can cause considerable loss of quality and value [1,2].

Vaterite in freshwater cultured pearls has higher concentrations of organic material and higher manganese contents than aragonite. Most extreme values of ca. 3 wt% Mn are found in so-called lacklustre pearls [3] which consist entirely of vaterite. Freshwater bivalve shells incorporate Mn seasonally connected with algal blooms and it can therefore be suspected that water quality plays a significant role in the formation of vaterite in pearls.

Environments for pearl culturing are very different in China, where pearl farms of different sizes are located along the Yangtse Rivers, and in Japan, where freshwater are cultured traditionally in Lake Biwa and Lake Kasumigaura. These differences are mirrored by the trace element chemical composition of the pearls.

Trace element concentrations in the pearls were measured in situ by LA-ICP-MS. This method allows simultaneous measurement of ca. up to forty minor and trace elements with sub-ppm detection limits [4]. Laser craters of 100 µm or less are created on the surfaces of the samples and are hardly visible by eye. Additionally, Sr isotopic compositions were measured in situ in the pearls by LA-MC-ICP-MS to explore the potential of this geochemical tool for provenance determination.

Best discrimination between the different sample localities was achieved with Ba/Sr ratios vs B concentrations [5]. While Chinese freshwater pearls have higher and more variable Ba/Sr ratios, those from the Japanese lakes each occupy rather confined fields at lower Ba/Sr ratios. The field for pearls from Lake Biwa (Japan) overlaps with the Chinese sample population but Biwa pearls trend to lower boron concentrations than Chinese samples. Sr isotopic ratios range between 0.70759 and 0.71237. Lake Biwa samples show the most radiogenic compositions, while those from Lake Kasumigaura have the lowest $^{87}Sr/^{86}Sr$ ratios.

Origin of the Revelstoke carbonate-hosted gem corundum occurrence, British Columbia, Canada

Dzikowski, T.J.[1*], Groat, L.A.[1], Dipple, G.M.[1] & Marshall, D.[2]
[1]Dept. of Earth and Ocean Sciences, University of British Columbia, Vancouver, Canada ([*]tdzikowski@eos.ubc.ca)
[2]Dept. of Earth Sciences, Simon Fraser University, Burnaby, British Columbia, Canada

The Revelstoke sapphire and ruby occurrence in southeastern British Columbia occurs in micaceous laminations within marble that is surrounded by calcareous schist within the Paleozoic Monashee cover sequence northwest of the Frenchman Cap dome. These laminations were once calc-schist lenses that were incorporated into the marble either during deposition or tectonism and were subsequently stretched by intense deformation. The thin, micaceous corundum-bearing laminations have metamorphic assemblages of corundum + calcite + muscovite + plagioclase + K-feldspar ± diopside.

The composition of fluid inclusions within corundum was determined by microthermometry to be composed of CO_2 with minor amounts of CH_4 and/or N_2. The intersection of fluid inclusion isochores with temperatures estimated from $\Delta^{18}O_{cal\text{-}cor}$ RAM thermometry indicate that corundum crystallized at pressures of 1.7-2.1 kbar and temperatures of 575-600 °C. Corundum formed during retrograde metamorphic conditions on the high temperature side of the muscovite → corundum + K-feldspar + H_2O reaction. In relation to the regional P-T-t path, corundum formed after rapid exhumation and cooling as a result of uplift along the Okanagan-Eagle River and Columbia River Faults between 52 and 47 Ma [1].

Exploration strategies for this type of corundum occurrence may be based on the genesis of corundum, but also on the preservation of corundum. When corundum is in association with K-feldspar and hydrous fluids are introduced, corundum will be altered to muscovite. This has implications for developing exploration strategies that include not only how corundum is formed, but also how it is preserved.

Provenance determination of alexandrite

Malsy, A.K.[1,2*] & Armbruster, T.[2]
[1]Gübelin Gem Lab Ltd, Lucerne, Switzerland
([*]a.malsy@gubelingemlab.ch)
[2]Mineralogical Crystallography, Institute of Geological Sciences, University of Bern, Switzerland

Alexandrite is the Cr-bearing variety of chrysoberyl ($BeAl_2O_4$) and renowned for its colour change property. "Gem-quality" alexandrite specimens from Brazil, India, Madagascar, Russia, Sri Lanka, and Tanzania have been investigated for their microscopic features and chemistry. Over 170 samples were tested for trace elements by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). With spot analysis of 100 µm in diameter and by adding small amounts of hydrogen (13 ml min^{-1}) to the carrier gas [1], the sensitivity could be improved for most elements. A set of 4 individual spot analyses was performed on each samples girdle or polished face.

In addition to the chromophore (Cr, ± Fe) elements, B, Mg, V, Ga, Ge, Nb, Sn, and Ta were found to be most indicative for the recognition of alexandrite sources. The distribution pattern of the latter trace elements is specific for most alexandrite sources. Alexandrite samples from the Hematita mines (Brazil) have typically high Sn (up to 2294 ppm) concentrations, whereas samples from Orissa (India) show distinctly high V concentrations (up to 0.15 wt% V_2O_3) and low Sn contents (Fig. 1). Germanium was found to be the key element in identification of alexandrite from the Ural Mountains (Russia). For samples from Sri Lanka and Ilakaka (Madagascar), trace element pattern overlaps for all elements and a proper distinction by chemistry is not feasible.

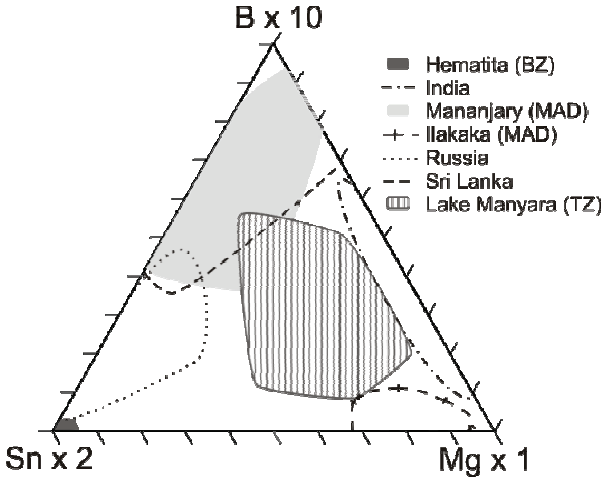

Fig. 1: Ternary B-Mg-Sn-diagram, showing LA-ICP-MS data [ppm] for alexandrites from Brazil (BZ), Madagascar (MAD), Russia, Sri Lanka, and Tanzania (TZ). Source fields are defined by the outline of individual plotting points.

Microscopic features generally yield only limited information on the provenance of alexandrite, as "diagnostic" inclusions (features that are unique for a specific mine or mining area) are mostly absent.

Thus, LA-ICP-MS provides new solutions for provenance analyses of alexandrite, where "standard" gemmological testing is facing its limitations.

Ruby and sapphire rimmed by spinel from the Luc Yen - Yen Bai gem mining area, Vietnam

Häger, T.[1*], Nguyen Ngoc Khoi[2,4], Duong Anh Tuan[3,4], Le Thi-Thu Huong[2] & Hofmeister, W.[1]
[1]Centre for Gemstone Research, University of Mainz, Germany ([*]haeger@uni-mainz.de)
[2]Faculty of Geology, Hanoi University of Science, Hanoi, Vietnam
[3]Inst. of Material Sciences Hanoi, Vietnam
[4]Doji Gold and Gems Group, Hanoi, Vietnam

Since the first ruby was found in February 1987 in Luc Yen (a small city in Yen Bai province, N- Vietnam), this country is an important source for gemstones in Southeast Asia. The quality and colour of rubies are comparable to the famous rubies from Burma.

On the way from the capital of the province, which is also named Yen Bai, to Luc Yen, a new star-ruby, red spinel and garnet mine has recently been opened by the Vietnamese company Doji. Beside idiomorphic ruby and corundum crystals, also rubies and corundum were found surrounded by a second phase. The second phase follows the morphology of the corundum crystals. The rim of the corundum crystal is spinel (determined using Raman spectroscopy and X-ray powder diffraction). The spinel formation can be explained by an overgrowth of spinel on the corundum or with the corundum consuming reaction:

corundum + dolomite = spinel + calcite + CO_2

The edges of the internal corundum and the second phase are slightly rounded, suggesting some disequilibrium between the two phases and favouring therefore the latter explanation.

A cross section of such a ruby crystal with spinel rim has been analysed with SEM. Fig. 1 shows the border between ruby and the spinel rim.

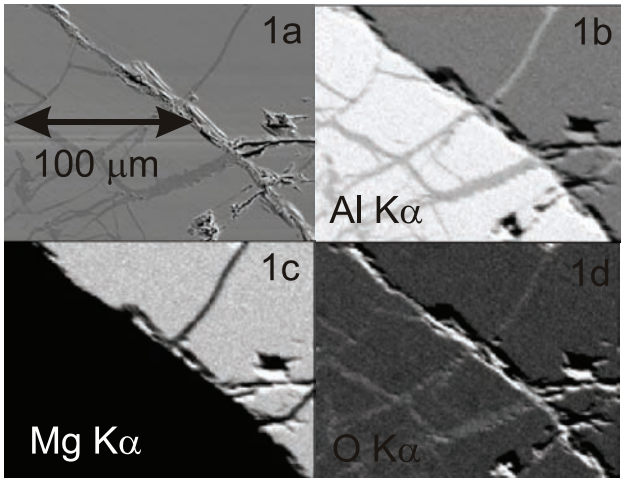

Fig. 1: BSE image of a typical corundum spinel border (1a). The cracks between corundum and spinel are filled with diaspore. Fig. 1b-d show element distribution maps of Al (1b), Mg (1c) and O (1d). High brightness displays high element content.

In the element-distribution maps shown in Fig. 1 it can bee seen clearly that the spinel is in the upper right corner and the corundum in the lower left corner. Both phases are cracked and the resulting fractures are healed and filled with a third phase. This third phase has lower Al content than corundum but a higher Al content than spinel. This observation suggests that the facture filling might consist of AlOOH. Using Raman spectroscopy, this third phase (which was obviously formed during retrograde metamorphism in the third stage) was identified as diaspore.

Emerald mineralization at the Glinka occurrence, Middle Urals, Russia

Bidny, A.S.[1*], Koshenskaya, T.O.[1], Baksheev, I.A.[1] & Popov, M.P.[2]
[1]Dept. of Mineralogy, Lomonosov Moscow State University, Moscow, Russia ([*]alexei.bidny@gmail.com)
[2]Dept. of Mineralogy, Petrography and Geochemistry, Ural State Mining University, Ekaterinburg, Russia

The Ural emerald mines are the only top quality emerald deposits in Russia [1]. It has been assumed that these deposits could extend further toward the north and south. To verify this assumption we have studied a new occurrence of green beryl (i.e., emerald) from Glinka, located 80 km north of the well-known Emerald mines.

The beryl from the Glinka occurrence is hosted by glimmerite occurring among talc schists, located close to the Murzinka pluton. The emerald-bearing rocks are composed of phlogopite and variable amounts of talc, plagioclase, tremolite-actinolite, and chlorite. Accessory minerals include beryl, chrysoberyl, tourmaline, corundum, apatite, fluorite, relict chromium spinel, and zircon. The 248 Ma Rb/Sr age of the Glinka pegmatite is consistent with that of the Murzinka pluton but differs appreciably from the 207 Ma age of the emerald mines [2].

Phlogopite occurs as brown or black flakes up to a few mm in size. Its fluorine content ranges from 2 to 5 wt.%. The Fe/(Fe+Mg) value varies from 0.05 to 0.36, with a clear increase toward the pegmatite body. Phlogopite associated with talc is lowest in Fe whereas that associated with muscovite adjacent to pegmatite contains much more Fe. The Be content in phlogopite varies from 5.8 to 16.8 ppm and reaches 23.2 ppm in muscovite. Transparent and colourless or light green beryl crystals are prismatic and vary from 13 to 200 mm in size.

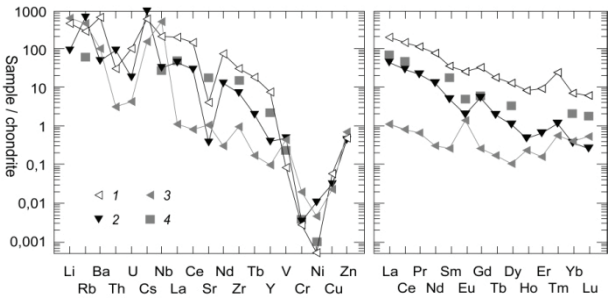

Fig. 1: Spider diagram of trace elements and REE distribution in (***1***) phlogopite-rich rock with high Be, (***2***) phlogopite-rich rock with low Be, and (***3***) muscovite of pegmatite from the Glinka occurrence, and (***4***) granite of the Murzinka pluton [3].

The geochemistry of the glimmerite from Glinka is shown in spider diagrams of trace elements and REE distribution (Fig. 1). The general distribution trends are similar to that of the Murzinka pluton granites. Notable differences include the enrichment of alkali elements (Li, Rb, Cs) and the depletion of Sr in glimmerite.

The results of our work show that mineralogical and geochemical features of the Glinka occurrence are similar to that of the Emerald mines. However, the ages of the two sources differ appreciably. The two occurrences therefore cannot belong to one extended deposit, even though their formation processes are widely similar.

Spectroscopy study of milky and rose quartz from the Borborema Pegmatitic Province (Brazil) irradiated with high gamma doses

Barreto, S.B.[1*], Guzzo, P.L.[2], Gonzaga, R.S.G.[2], Miranda, M.R.[2] & Khoury, H.J.[3]
[1]Dept. of Geology, Federal University of Pernambuco, Recife, PE, Brazil ([*]bsandra@ufpe.br)
[2]Dept. of Mining Engineering, Federal University of Pernambuco, Recife, PE, Brazil
[3]Dept. of Nuclear Energy, Federal University of Pernambuco, Recife, PE, Brazil

The origin of rose colour in polycrystalline quartz from granitic pegmatites was considered in numerous studies but no ultimate consensus was established until now [1]. In granitic pegmatities located in Borborema Pegmatite Province (BPP, Brazil), it is common to find areas of rose and milk quartzes randomly distributed inside the pegmatite cores. The rules defining the colour pattern into these quartz cores are unknown but we believe that proper characterization of samples taken from different areas can be useful to further discuss the origin of the rose colour. Thus, the aim of this work is to characterize the colour changing by gamma irradiation in milky and rose quartzes taken from the same core by means of electron paramagnetic resonance (EPR), optical, and infrared (IR) absorption spectroscopies. For this, milky and rose blocks of quartz samples collected from the Taboa pegmatite from the BPP were cut into small pieces and optically polished. The samples were irradiated with gamma rays (^{60}Co) with doses ranging from 0.5 to 96 kGy. The colour change was accessed by optical spectroscopy and the OH-related defects were analysed by mid-IR spectroscopy. Each irradiated sample was sectioned into two parts and 60 mg of powder in 75-150 µm size fraction was used to obtain the EPR signals using an spectrometer operating in the X-band. As a result, gamma radiation above 2 kGy induced smoky colour in both quartzes and optical bands near 230 nm and 460 nm, related to E' and $[AlO_4]^0$ centres, respectively, were observed. EPR spectra revealed several lines from 3500 to 3530 G at room temperature. Two sets of lines were assigned to $[GeO_4/Li]^0$ centre and E_1' centre perturbed by a substitutional Ge. It was observed that $[GeO_4/Li]^0$ signal increased with the increasing of gamma dose up to 4 kGy and then decreased. On the other hand, the signal related to E_1' appeared for doses higher than 16 and 32 kGy for milky and rose quartz, respectively. The onset of optical and EPR signals related to E' centers appeared at a higher dose for rose quartz. These results are summarized in Figure 1. In case of IR spectra, the rose quartz showed sharp bands assigned to $[H_40_4]^0$, Li-dependent OH and $[AlO_4/H]^0$ centers whereas the milky quartz only showed the typical broad OH band in the range of 3800 to 3000 cm^{-1}.

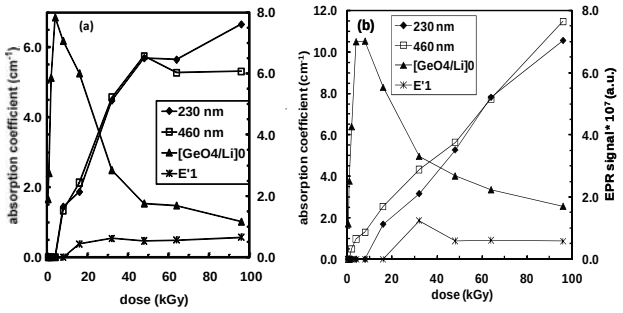

Fig. 1: Intensity of optical and EPR signals related to point defects induced by gamma rays in milky (a) and rose (b) quartz from BPP.

Incorporation of iron and chromium in pegmatitic tourmaline

Bordage, A.[1*], Rossano, S.[1], Fuchs, Y.[1] & Horn, A.H.[2]
[1]Laboratoire des Géomatériaux et Environnement, Université Paris-Est Marne-la-Vallée, France ([*]amelie.bordage@impmc.jussieu.fr)
[2]Universidade Federal Minas Gerais (UFMG), Belo Horizonte, MG, Brazil

The mechanisms of trace elements incorporation in minerals are a crucial problem in gemmology, since it has an impact on the physical and chemical properties of the mineral. For instance, the presence of an impurity modifies the colour of the mineral. The colouring impurity content of a gem and the incorporation process are also related to the geological history of the host-rocks where it was found. A detailed study of the electronic structure, crystallographic environment and optical properties can help to understand the physical and chemical properties of the gem and the history of its host-rock.

We present here a detailed study on tourmalines from the Minas Gerais region (Brazil). These pegmatitic minerals contain Cr and Fe as impurities. The partitioning of these two elements between co-genetic minerals (tourmaline and emerald) may provide information on the geological processes involved in the ore deposit formation and the general chemistry of pegmatites. Green and blue tourmalines, as well as tourmaline set in emerald, are studied by optical spectroscopy to characterize the general property of the mineral. Microprobe analyses have been performed to understand the elements partitioning of Cr and Fe between the tourmaline and emerald, to get insight on the ore formation.

X-ray Absorption Spectroscopy measurements have also been performed at the Cr and Fe *K*-edge of tourmaline on SuperXAS@SLS (Switzerland). The features in *K*-edge X-ray absorption spectra of transition metal cations provide indeed useful information about their crystallographic environment and electronic structure in minerals. In particular, the energy and relative intensities of the pre-edge features depend on the valence state and site symmetry of the absorbing atom. The Extended X-ray Absorption Fine Structure (EXAFS) measurements enable the neighbours of the absorbing atom to be characterized. To get a more complete knowledge of the site incorporation of Fe and Cr in tourmaline, the experimental XAS study has been coupled to a theoretical study: the X-ray Absorption Near-Edge Structure (XANES) spectra have been theoretically determined by *ab initio* calculations, based on Density Functional Theory (DFT). The comparison between the calculated and experimental spectra makes it possible to obtain accurate information about the crystallographic and electronic structures of Cr and Fe in tourmaline. These DFT calculations therefore substantially complete the information obtained by EXAFS on the Cr and Fe site incorporation. In particular, the XAS study provides quantitative information about the relaxation of the crystal structure around the impurity, a key parameter for understanding the mechanisms controlling the incorporation of colouring trace elements in minerals.

Unusual twinned diamond crystals

Hurlbut, J.F.
Denver Museum of Nature and Science, Denver, USA
(jfhu@earthlink.net)

Unusual diamond twin crystals from the micromount collection donated to the Denver Museum of Nature and Science by Paul Seel were studied. Paul Seel was an invited speaker to the first Kimberlite conference held here.

Paul Seel (1904–1982) was a prominent mineral collector and micromounter; he was born in Silesia, Germany, but in 1925, with a degree in engineering, he immigrated to the United States. In Brooklyn, New York he acquired his first micromounts and then he became an avid micromounter for the rest of his life. Paul Seel was received into the Micromounters' Hall of Fame in 1981.

His interest in diamond crystals started in the late 1940's, when he also built a substantial collection for study purposes. Each specimen "illustrated some morphological fact" and the collection as a whole was considered to be the finest and largest one then in existence [1]. Besides the collection itself, valuable are also his drawings of crystals viewed under the microscope, which are remarkably accurate. According to his will, his excellent diamond collection was donated to the Denver Museum of Natural Science. This collection gathers 1240 mounted specimens, 1 to 3 mm in diameter, and 278 of them are twins. Many of the twins have drawings made of them by Paul Seel.

Several drawings and pictures showing details of the growth features of some of the most unusual crystals from the Seel collection (Figs. 1,2) will be presented.

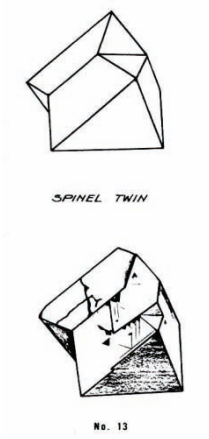

Fig. 1: Paul Seel, Multiple spinel twins (1954).

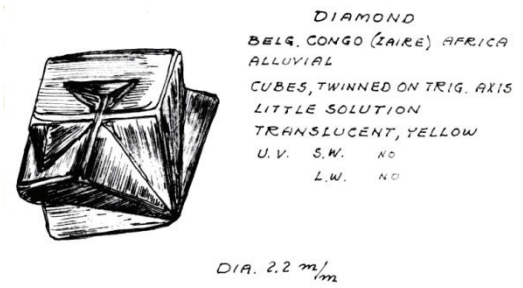

Fig. 2: Paul Seel, cubes twinned on trigonal axis (1959).

Such diamonds collections remain rare today, not only because of the high unit cost of good specimens, but also because the international diamonds market is not set up for providing collector-quality uncut diamond crystals.

Hydrothermal synthesis of quartz

Lenart, A.[1*], Šturm, S.[1] & Mirtič, B.[2]
[1]Dept. for Nanostructured Materials, Jožef Stefan Institute, Ljubljana, Slovenia ([*]alenka.lenart@ijs.si)
[2]Dept. of Geology, Faculty for Natural Sciences and Engineering, Ljubljana, Slovenia

Quartz was one of the first minerals to be synthesised with the hydrothermal method in a high-pressure reactor [1]. Due to its melting point of 1720°C and high chemical resistance, synthetic quartz crystals can only be produced in this way. Normally, the temperature-gradient method is used, which enables the growth of crystals on seeds [1]. Our experimental work aims at the controlled growth of micro- to nano-sized low-temperature quartz.

We used the isothermal method, which is suitable for powder synthesis, where in the whole volume of an autoclave a constant temperature is applied. Colloidal silica was used as the starting material, distilled water as the solvent and NaOH as the mineralizer. The morphology of the crystals was controlled by varying the pressure-temperature conditions and the composition of the solution. In the framework of our research we have shown that morphologically well-developed micron-sized quartz crystals can be obtained under p-T conditions, which are significantly lower than the generally accepted p-T regime for the synthesis of low-temperature quartz [1]. These experiments were performed in a basic medium, at 250°C, 40 bar and 55 % autoclave fill. The XRD pattern shows that the obtained products are pure α-quartz, with no other phases being present (Fig. 1). With the extension of the synthesis time, from 8 hours to 6 days, crystals with a different morphology and a large size range were obtained (Fig. 2). When a longer reaction time was applied, the solid product consisted of double-terminated, long-prismatic crystals of α-quartz. If the synthesis is sufficiently long, the crystals develop prismatic m $\{10\bar{1}0\}$ and rhombohedral r $\{10\bar{1}1\}$ faces, which are typical of the trigonal trapezohedral class, to which quartz belongs. Some crystals have a pseudohexagonal shape, which means that all the rhombohedral faces are nearly equally well developed.

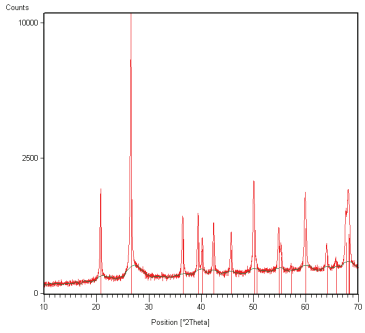

Fig. 1: The XRD analysis shows pure low-temperature quartz, with no other phases being present.

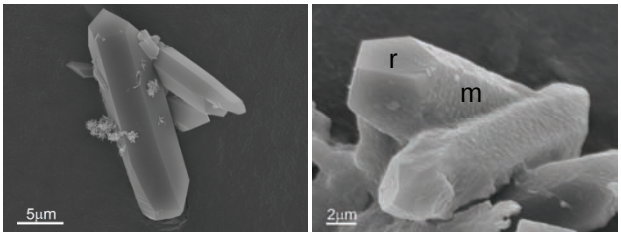

Fig. 2: SEM images of micron-sized quartz crystals obtained with hydrothermal synthesis at 250°C and 40 bar. The crystals have well-developed prismatic m $\{10\bar{1}0\}$ and rhombohedral r $\{10\bar{1}1\}$ faces.

Libyan glass gem formed at sea-water impact

Miura, Y.
Inst. of Earth and Planetary Material Sciences, Yamaguchi University,
Yamaguchi, Japan (dfb30@yamaguchi-u.ac.jp)

The Libyan Desert Silica Glass (LDSG) is a tektite composed of quenched silica glass with meteoritic inclusions that are assigned to an impact reaction [1,2], though other related impact data and its related impact crater are not reported so far. The purpose of the present paper is to elucidate impact material indicators on sea-water by using detailed features of carbon (C) and chlorine (Cl) of the LDSG determined by XRF and ASEM analyses.

The XRF bulk data (determined with EDX analysis) show significant amounts of C (ca. 4 wt% CO_2) in the LDSG samples. Carbon contents were checked also by IR bulk analysis. To avoid any contamination during thin section sampling, the analytical scanning electron microscopy (ASEM) was applied to obtain differences in composition and texture as follows [3,4]: Bulk XRF data indicate a high silica content with minor amounts of C, Na, K, Cl, Mg, Fe and Ca. The LDSG data of impact formation are different from that of volcanic obsidian samples, which have insignificant C and Cl contents. Bulk FE-ASEM data with elemental mapping method indicate high silica with minor amounts of Na, K, Cl and Ca, together with in-situ FE-ASEM analyses of inclusions C, Na, Cl, K, Cr and Fe (Fig. 1).

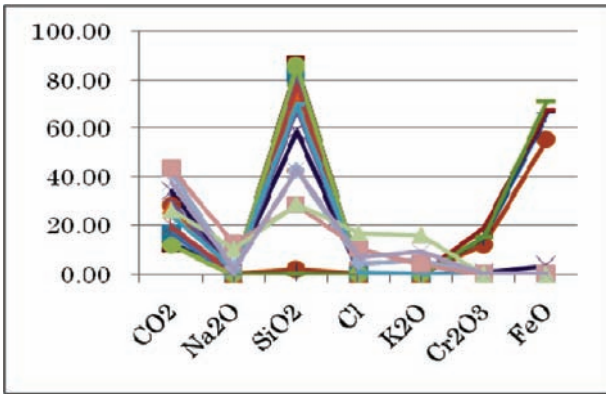

Fig. 1: The ASEM in-situ data of inclusions of the LDSG tektite sample with C, Mg, Al, K, Cr and Fe [4].

The highest C contents (ca. 43 wt% CO_2) with high silica (Fig. 1) are found in inclusions and radiated silica textures with minor contents of Na, Cl and K. The highest Cl contents (ca. 11 wt% Cl; Fig. 1) are mainly obtained in dendritic textures with high contents of Na, Si and O, and minor amounts of K. They are assigned to remnants of halite originating from the contact with sea water after impact. There are fine inclusions of Fe oxides in radiated textures.

The present analytical data can be explained as follows [3,4]. The LDSG tektite shows quenched textures with significant carbon (from limestone) and chlorine (from sea-water) contents which are new evidences of impact reaction on ocean (seawater) impact of the LDG sample. The XRF bulk data of the LDSG tektite and volcanic obsidian samples are different contents with major Si and minor C and Cl-Na elements.

Application of XANES analysis on blue sapphire samples from various geological environments

Monarumit, N.[1], Klysubun, W.[2] & Wathanakul, P.[1,3*]
[1]Dept. of Earth Sciences, Faculty of Science, Kasetsart University, Bangkok, Thailand
[2]Synchrotron Light Research Institute (Public Organization), Nakhonratchasima, Thailand
[3]The Gem and Jewelry Institute of Thailand
([*]fscipww@ku.ac.th)

Blue sapphire is a variety of gem corundum. This mineral has a chemical formula of Al_2O_3 and crystallises in the hexagonal system. Pure corundum is colourless; however colour of corundum can be generated by the introduction of trace elements into the structure. The blue colour of sapphire caused by iron (Fe^{2+}) and titanium (Ti^{4+}) is due to Fe^{2+}–O–Ti^{4+} charge transfer [1]. Even though blue sapphire can form in various geological environments, this corundum variety is mainly found in metamorphic (e.g., Sri Lanka, Madagascar) and basaltic deposits (e.g., Thailand, Australia, Laos) [2].

X-ray absorption near edge structure (XANES) spectroscopy is a powerful technique to study the electronic structure around the absorbing atom. The positions and shapes of lines in XANES spectra are highly sensitive to the valence state and symmetry of the surrounding, neighboring atoms [3].

XANES measurements were performed at the Synchrotron Light Research Institute, Thailand, using the X-ray absorption spectroscopy (XAS) beamline, BL-8, with synchrotron radiation from a bending magnet. Fe K-edge XANES spectra of blue sapphire samples were collected in fluorescence mode with a 13-element Ge detector. The Athena program was employed for the data reduction.

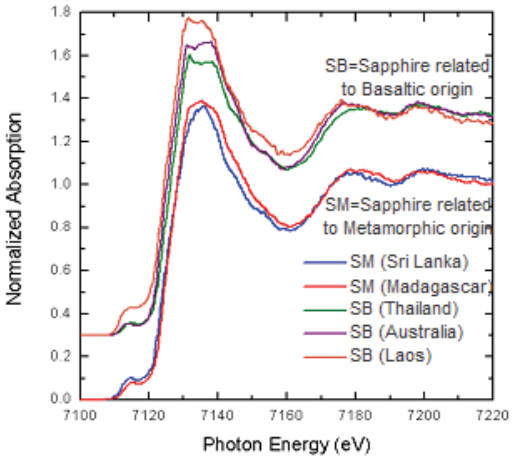

Fig. 1: Fe K-edge XANES spectra of blue sapphire samples from various geological environments.

The basaltic blue sapphire samples exhibit two convoluted absorption peaks followed by a broad shoulder feature overlaying on the high-energy side, which distinguish them from the metamorphic ones (see Fig. 1). This is possibly due to high Fe contents in basaltic hosted sapphires, i.e., Fe having a different atomic environment compared to those in metamorphic sapphire samples. Thus, this initial examination implies that the XANES technique may enable one to identify the geological origin of blue sapphire samples.

Crystal chemistry of a sarcolite gemstone

Pandolfo, F.[1*], Guastoni, A.[2], Nestola, F.[2] & Cámara, F.[2]
[1]Dept. of Scienze della Terra, University of Pavia, Italy
([*]francesco.pandolfo@dst.unipv.com)
[2]Dept. of Geoscience, University of Padova, Italy
[3]CNR-Istituto di Geoscienze e Georisorse, Unità di Pavia, Italy

An outstanding gem sarcolite gemstone, orange in color and weighing 2.55 carats, has been cut from a large fragment of a crystal hosted in xenolitic rock from the type locality of Monte Somma (Vesuvius, Italy) [1]. This sample was found in a metamorphosed volcanic ejecta in association with augite, gehlenite and nepheline. It represents the largest cut gemstone of sarcolite known so far. Sarcolite has an ideal chemical formula of $NaCa_6Al_4Si_6O_{24}F$ and is tetragonal with space group *I*4/*m*. Gemmological properties give refraction indices of ω = 1.604(1) and ε = 1.613(2) and a density of 2.91 g/cm^3 [2]. The crystal structure of sarcolite was solved using single crystal X-ray diffraction (SCXRD) by [3] who obtained an R value of 0.054. Chemical investigations of sarcolite were performed by [4] and [5].

We have performed a crystal-chemistry study using SCXRD and WDS electron microprobe analysis. The CHNS elemental analysis technique was also used for the determination of volatile elements. Crystallographic results give lattice parameters of a = 12.3678(5), b = 12.3678(5), c = 15.4777(10) Å, V = 2367.51 Å^3, and an R value of 0.0414.

CO_3 and PO_4 groups and Na(K) polyhedrons are situated along the 4-fold axis. C is 3-fold coordinated in planar CO_3 groups showing four alternative positions, thus having the CO_3 plane parallel to {110}. There are P tetrahedra with two alternative configurations, i.e., with two opposed edges parallel to (001), thus showing a local violation of the space group. Na is 5-fold coordinated and is locally split. Al is 5-fold coordinated; two polyhedra are connected through a common apex being F (or minor OH). Silicon is present as one disilicate group and four isolated tetrahedra per unit cell. There are three alkali sites: two Ca sites and a Na site, which can have half occupancy at maximum.

Electron microprobe analysis revealed an average composition of SiO_2 35.45 wt%, CaO 32.93 wt%, Al_2O_3 18.79 wt%, Na_2O 3.98 wt%, P_2O_5 3.23 wt%, F 2.86 wt%, Fe_2O_3 0.50 wt%, MgO 0.28 wt%, MnO 0.03 wt%, K_2O 0.85 wt%, TiO_2 0.04 wt%, Cl^- 0.02 wt%, and SrO 0.83 wt%. The CHNS yielded CO_2 1.99 wt%, SO_3 0.07 wt%, and OH^- 0.22 wt%. The chemical formula (a.p.f.u.) calculated for the sarcolite specimen by combining single crystal XRD, EMPA, and CHNS is $[(CO_3)_{0.46}(PO_4)_{0.47}\ (Na_{0.82}K_{0.18})]\ Na_{0.47}\ (Ca_{6.01}Sr_{0.08})_{\Sigma=6.09}\ (Al_{3.79}Fe^{2+}_{0.07}Mg_{0.07}Ti^{4+}_{0.01}Mn^{2+}_{0.01})_{\Sigma=3.94}\ (Si_2O_7)\ (Si_{1.02}O_4)_4\ [F_{1.52}(OH)_{0.21}Cl_{0.01}]_{\Sigma=1.74}$.

Effects of heat treatment on synthetic gem corundum: an AFM approach

Pongkrapan, S.[1], Wongkokua, W.[2] & Wathanakul, P.[1,3*]
[1]Dept. of Earth Sciences, Faculty of Science, Kasetsart University, Bangkok, Thailand ([*]fscipww@ku.ac.th)
[2]Dept. of Physics, Faculty of Science, Kasetsart University, Bangkok, Thailand
[3]The Gem and Jewelry Institute of Thailand (GIT), Bangkok, Thailand

Untreated gemstones with high-quality colours and clarity are hard to find. These naturally born beauties are therefore very expensive when compared to artificially enhanced ones. Heat treatment is the most popular technique to improve the quality of gemstones [1]. While traditional heat treatment on gem corundum (α-Al_2O_3) is still practiced, a technique developed by Thai gem burners, called beryllium (Be) diffusion [2], has become increasingly popular during the past decade. Gem testing laboratories have oftentimes faced difficulties in non-destructively differentiating heat-treated gemstones from untreated ones, especially for those that experienced either low-temperature heat treatment or Be diffusion.

The still on-going research presented here aims at developing an AFM innovation to identify the heat treatment of gem corundum that is not clearly determinable by other spectroscopic techniques employed in standard gem testing laboratories. Tapping-mode AFM observation in ambient condition showed that the surface perpendicular to the *c* axis of a synthetic gem corundum sample has developed a significantly faceted terrace-and-step morphology after treatment at 1650 °C. Mechanisms of such sharp-edged formation are thoroughly discussed.

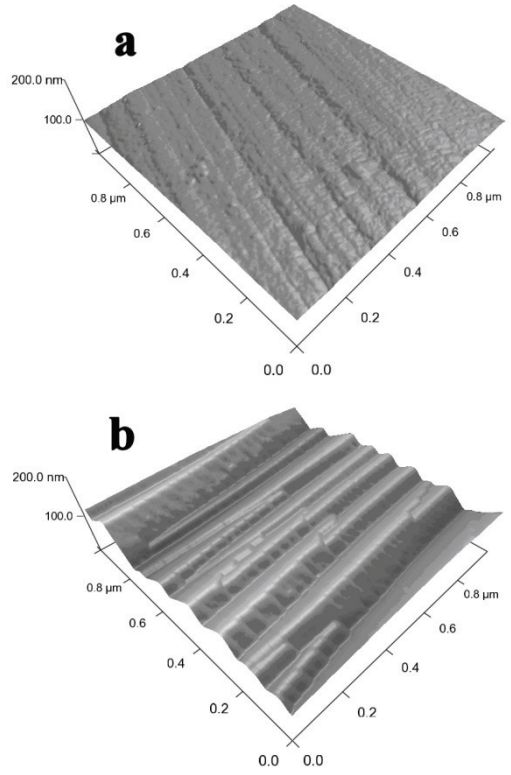

Fig. 1: AFM topographic images (1 µm × 1 µm) on the surface roughly perpendicular to the *c* axis of a synthetic gem corundum (a) before heat treatment, and (b) after heat treatment at 1650°C. The z-axis scale is 100 nm/division for both images.

Influence of geological formation on the quality of ruby from Myanmar, Sri-Lanka, and Thailand

Sorokina, E.S.[*] & Ozhogina, E.G.
Fedorovsky All-Russian Research Institute of Mineral Resources, Moscow, Russia ([*]elensorokina@mail.ru)

The most beautiful chrome-coloured gem corundum (ruby) is mined in alluvial deposits that originate from the weathering of primary rocks, in particular marbles and basalts. In this study, more than 300 samples of natural, non heat-treated and heat-treated rubies were investigated. These samples originate from deposits in Myanmar, Sri Lanka (both related to metamorphic origin), and Thailand (basaltic origin). Samples came from the collections of the A.E. Fersman Mineralogical Museum (Russian Academy of Sciences) and the Gemmology Chair of the Russian State Geological Prospecting University (RSGPU).

The quality of the raw material seems to depend strongly on the type of formation. The metamorphic ruby samples from in Myanmar and Sri Lanka often show the bright red colour (commonly referred to as "pigeon blood" red; more often found in Myanmar than in Sri Lankan stones) with slightly purple shade and are hence more expensive. In contrast, basaltic ruby from Thailand is often characterized by dark red and more often purplish red colours, which require additional heat treatment.

Stones belonging to the two types of formation can be distinguished based on their chemical composition, luminescence peculiarities, and the presence/absence of certain mineral inclusions (investigated earlier by [1,2] and many others). We report the discovery of Fe–Ti inclusions (probably ilmenite) in ruby from Myanmar, which, to the best of our knowledge, has not been reported thus far.

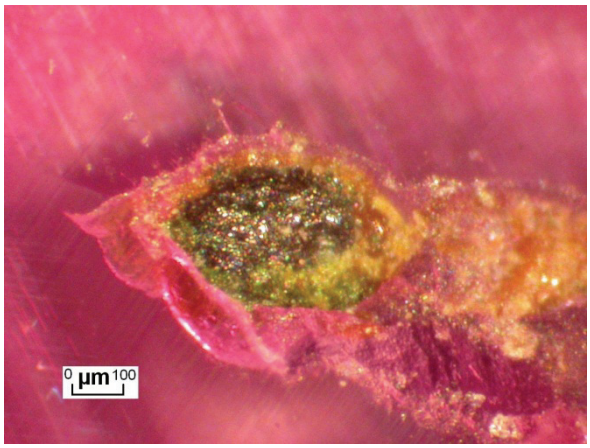

Fig. 1: Inclusion (probably ilmenite) in ruby from Myanmar, surrounded by rutile needles (sample №7734; Fersman Mineralogical Museum, RAS).

All investigated ruby samples from Thailand are presumably heat-treated. They show negative crystals within whitish cavities that are filled with a Si-rich material (all values in wt%: SiO_2 (78.0), Al_2O_3 (5.10), Cr_2O_3 (3.55), CaO (1.68), FeO (1.14), K_2O (0.91)), whereas there are virtually no inclusions in these stones (excluding, probably, well-shaped boehmite needles). Stones from Myanmar and Sri Lanka, in contrast, did not show any heat treatment. Our results allow us to contribute to a provenance assignment for unknown stones, and to assist in the prediction of the quality of raw materials depending on formation type.

Acknowledgements: We are indebted to Dr. O.V. Balitskaya, colleagues from the Fersman Mineralogical Museum, RAS, and the Gemmology Chair of the RSGPU.

Crystal chemistry of pyralspite garnets from Shavaryn Tsaram, Mongolia

Soumar, J.[1*], Skála, R.[1,2] & Matějka, D.[1]
[1]Inst. of Geochemistry, Mineralogy and Natural Resources, Charles University, Prague, Czech Republic ([*]jansoumar@centrum.cz)
[2]Inst. of Geology, Academy of Sciences of the Czech Republic, Prague, Czech Republic

Garnets from the classic localities in Northern Bohemia (Czech Republic) and Shavaryn Tsaram (Mongolia, 48° 12´ N, 100° E), of mostly dark red (in some cases dark orange) colour, were studied by means of electron microprobe and X-ray powder diffraction analysis, with the aim to compare the mineralogical compositions of the two sample sets. BSE images were taken to check for potential zoning of the samples.

Table 1: Chemical composition of a pyrope-almandine from Mongolia (Cameca SX 100, National Museum, Prague, Czech Republic)

Pt.	SiO_2	TiO_2	Al_2O_3	FeO	MnO	MgO	CaO	BaO	Total
1	40.15	0.57	22.15	15.51	0.41	13.91	5.2	1.11	99.25
2	40.78	0.6	22.14	15.81	0.37	14.05	5.65	1.17	99.96
3	40.48	0.63	22.18	15.71	0.32	14.09	5.78	1.14	99.97
4	40.69	0.6	22.3	15.91	0.38	14.14	5.93	1.19	100.73
5	39.91	0.66	22.07	16.04	0.37	14.33	5.96	1.28	100.14
6	39.63	0.64	22.27	16.31	0.4	14.31	5.83	1.32	100.13
7	39.1	0.64	22.2	15.29	0.41	13.99	5.94	1.32	98.51
Av.	40.11	0.62	22.19	15.80	0.38	14.12	5.83	1.22	100.26

No obvious zoning was observed in the BSE images of polished grains; this is also consistent with the relatively uniform chemical compositions measured (Table 1). Other elements were below the detection limit of the electron probe micro-analyser used. The average empirical formula (based on 12 oxygens per formula unit, full occupancy of all sites, and maintaining charge balance) is

$$(Mg_{1.56}Fe^{2+}_{0.92}Ca_{0.46}Ba_{0.04}Mn_{0.02})_{\Sigma 3.00}(Al_{1.91}Fe^{3+}_{0.08}Ti_{0.03})_{\Sigma 2.00}(Si_{2.97}Al_{0.04})_{\Sigma 3.00}O_{12}$$

This corresponds to the simplified end-member composition $Pyr_{53}Alm_{31}Gr_{12}And_4$. X-ray powder diffraction confirmed the identity of the studied material to the pyrope–almandine garnet series.

Comparing the data with results of a previous study [1] shows the possibility of the Mongolian garnets to have a similar use as the Czech ones.

Spectroscopic features due to Ni- and Co related defects in gem-quality natural diamonds

Tretiakova, L.
Diamond Research Ltd, Fort Lee, NJ, USA
(Ltretiakova@yahoo.com)

Ni- and Co-related defects observed in some nitrogen-containing synthetic diamonds grown from a Ni- or Co-containing catalysts have been studied well enough [1-3], but a little known of Ni- and Co-related defects in natural diamonds.

Natural gem-quality faceted diamonds (ND) were analyzed of non-destructive techniques including Infrared (IR) and laser-induced photoluminescence (PL) spectroscopy.

Detailed study of spectroscopic features (IR and PL) of ND has made possible to detect various kinds of impurities (N, H, Ni, Co, Si, CO2, lonsdaleite) containing in these diamonds.

The behavior of Ni and Co impurities in ND containing various levels of nitrogen aggregation and different concentration of IR-active hydrogen has been studied and temperatures, which Ni- and Co-related systems create, exist and vanish in ND, have been determined.

At the first time Co-N and Co-C defects (weak lines at 519.3, 523.6, 542.5, 544.1, 561.6, 669.4 nm) have been observed in PL spectra (PLS) of ND. These systems exist at temperatures around 1750-2050 K.

Prominent 694, 535.2, 700.6 nm Ni-related systems and a lot of low intensity Ni-related defects are observed in PL spectra (PLS) of studied ND. Low intensity defects were attributed to Ni-N complexes that exist at temperature range around 1600-2200 K and, displaying a transitory behavior, giving rise to other Ni-N complexes such as the 694, 535.2, and 603.5, 640.5, 700.6 nm.

Spectroscopic features of the 694 nm PL system in mixed (IaAB irregular + Ib) type ND, containing nitrogen in the A (dominant), B, C, N+ forms and high concentration of IR-active hydrogen, have been described and this defect tentatively attributed to Ni-N-H complex that exists at temperatures around 1600 - 2350 K.

At the first time the 535.2 nm defect has been observed in PLS of mixed (IaAB regular + Ib) type ND where nitrogen presented in the A, B, B', C, N+, N3 forms, B' defect is shown strong peaks at the range 1370 - 1360 cm-ą and in some stones splitted up to six components. The 535.2 nm defect is tentatively ascribed to Ni-N complex that exists at temperatures around 1950-2500 K and determined as additional feature for the identification of the treatment of greenish-yellow diamonds.

The origin of the 603.6, 640.5, 700.6 nm PL defects are some complicated interstitial type defects (Ni-N-V complexes) [4] possibly comprised hydrogen atom(s) [5] and associated in the type Ia ND of mixed cubo-octahedral shape [4]. These systems exist at wide temperature range around 1950 - 2500 K.

Any knowledge of the origin and behavior of defects in ND help in the reconstruction of diamond growth conditions and origin, as well as the identification of diamond treatment.

Annealing of metamict zircon from Ratanapura, Sri Lanka

Wanthanachaisaeng, B.[1*], Bunnag, N.[1], Pattarawarin, P.[1], Ounorn, P.[3], Sutthirat, C.[2,3] & Pisutha-Arnond, V.[2,3]
[1]Faculty of Gems, Burapha University, Chanthaburi, Thailand
([*]bhuwadol@yahoo.com)
[2]Dept. of Geology, Chulalongkorn University, Bangkok, Thailand
[3]The Gem and Jewelry Institute of Thailand, Bangkok, Thailand

A green metamict zircon sample (no. GRAT 21) from Ratanapura, Sri Lanka, was investigated in this study. The sample was annealed in air at 600, 700, 800, 900 and 1000°C in an electric furnace with around 3 hours of dwelling at each target temperature. The specific gravity (SG) value and the Raman spectroscopic technique were used to monitor the decrease of the degree of metamictization of the zircon sample (compare [1]).

As shown in Fig. 1, the SG values of the sample show a continuous increase from 3.8 g/cm^3 recorded before treatment to 4.24 g/cm^3 after annealing at 1000°C, which however is well below the SG of 4.68 g/cm^3 for well-crystallised zircon [2].

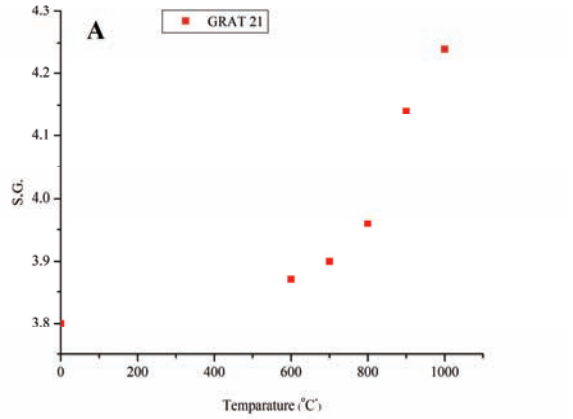

Fig. 1: Plot showing the continuous increase of SG values of a zircon sample (GRAT 21) from Ratanapura, measured before treatment and after annealing at 600, 700, 800, 900, and 1000°C.

The Raman spectrum of the sample before heating shows dramatically broadened Raman bands. This indicates a very high degree of metamictization of the original sample, which is perhaps close to the amorphous state. The sample's structure, however, started to improve after annealing at 700°C, as indicated by the appearance of some recovery bands and a general decrease of the band broadening. At higher annealing temperature, the structural recovery proceeds significantly. After annealing at 1000°C, the main υ_3 (anti-symmetric SiO_4 stretching) band lies at ca. 1006 cm^{-1} and has a full width at half maximum (FWHM) of ca. 15 cm^{-1}, indicating significant but still incomplete structural reconstitution. Based on the above SG and Raman spectroscopic results it is therefore concluded that the zircon structure was significantly recovered from a nearly amorphous state to almost crystalline state after dry annealing in air at 1000°C.

Characterization of beryl samples from a novel deposit in the Erongo massif, Namibia

Wildner, M.[1*], Giester, G.[1], Hammer, V.M.F.[2], Niemetz, W.[3] & Lehrl, M.[4]

[1]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria ([*]manfred.wildner@univie.ac.at)

[2]Staatliches Edelsteininstitut, Naturhistorisches Museum Wien, Vienna, Austria

[3]Österreichische Gemmologische Gesellschaft, Vienna, Austria

[4]Esme Fine Gemstones, Omaruru, Namibia

The described beryl claim belongs to the Erongo massif of the Damara orogen, Namibia, which is part of the Pan-African orogenic belt. This area is famous for spectacular findings (in 2000 and 2002) of aquamarine, associated with schorl, feldspar and fluorite. In 2009, the new deposit at Davib-Ost farm, Karibib District, was discovered. Miarolitic cavities within granite house loose beryl crystals of light blue to yellowish-green color, often intergrown with feldspar and colorless topaz. The pipes sometimes extend up to 100 m in length. Further associated minerals are e.g. quartz, apatite, fluorite, schorl, jeremejevite, bertrandite, siderite, goethite, and muscovite.

A faceted light blue aquamarine (~44 ct) with yellow-green hue shows overlapping healing fissures. Their boarders are very sharp and sometimes show "folds". The fissures consist of two- and three-phase inclusions. Along the *c*-axis fine needle-like growth tubes with milky appearance are observed. Single muscovite flakes may prove a granitic or pegmatitic origin. Such clear aquamarine crystals have not been known from other deposits of the Erongo massif so far.

Two further beryl samples, a pale blue and a more greenish-blue one, were characterized by single crystal X-ray diffraction and optical absorption spectroscopy. Lattice parameters are in the range a = 9.219–9.220 and c = 9.195–9.196 Å, as commonly observed for "normal" beryl. Structure refinements in space group *P6*/*mcc* yielded R_1-values of 2.8 %; residual electron densities within the channels are 1.7 and 1.3 $e^{-}Å^{-3}$, respectively. The optical spectra (Fig. 1) are dominated by a band centered at ~810 nm, which is strongly polarized perpendicular to the *c*-axis and assigned to the spin-allowed $^5E(D)$ crystal field state of Fe^{2+} in octahedral coordination. Minor features at 425 and ~370 nm are related to spin-forbidden levels of octahedral Fe^{3+}. In the NIR range, several overtone and combination modes of channel H_2O-molecules type I and II are observed. In the greenish blue sample the aforementioned band at 810 nm is broadened in polarization parallel to the *c*-axis due to additional components around 620 and 1000 nm, probably caused by Fe^{2+}–Fe^{3+} charge transfer (however, the detailed origin of these features is still a matter of controversial debate in the literature). The shift of the UV absorption edge towards the visible range has a further color-modifying effect as compared to the pale blue sample.

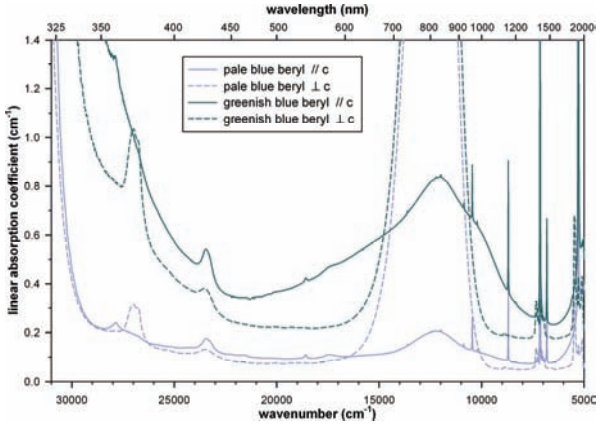

Fig. 1: Polarized optical absorption spectra of two beryl samples from the new deposit at Davib-Ost farm, Karibib District, Namibia.

The vibrational behavior of SiO_2 at the glass transition: some *ab-initio* vibrational calculations and their thermodynamic implications

Ottonello, G.*, Vetuschi Zuccolini, M. & Belmonte, D.
DIPTERIS, Università di Genova, Genoa, Italy
(*giotto@dipteris.unige.it)

We investigated with *ab-initio* procedures the structure-energy and vibrational properties of silica clusters incorporated in a continuum with appropriate permittivity (dielectric constant ε=3.8) through DFT/B3LYP gas phase calculations coupled with a Polarized Continuum Model approach, and, in the framework of the Block theorem [1], those of the periodical structure D_{6h} which leads to the α-cristobalite polymorph of silica when subjected to symmetry operations. The obtained energy properties and vibrational features indicate that none of the investigated moiety, when taken alone, justifies the observed energy and vibrational properties of the silica glass while, based on the computed energies and vibrational features, an aggregate of the D_{6h} network and the monomer locally ordered in the short-medium range present in the glass in a mutual arrangement lacking of spatial continuity reproduces satisfactorily both the experimentally observed low T heat capacity and the deviation from the Debye T^3 law, which, contrarily to what previously assumed, is largely due to low frequency internal modes, and only partly to coherent low frequency acoustic motions. The heat capacity of the glass at all temperatures below T_g is consistent with the (84) internal modes of 2 D_{6h} units variably linked with a $[SiO_4]^{4-}$ monomer plus the 3 (experimentally observed) acoustic modes [2,3] and an excess acoustic-like (i.e. coherent) mode of low frequency [4]. At T_g, the observed sharp increase in the isochoric heat capacity [5] is due to the onset of rotational and translational motions which replace the coherent (acoustic-like) motions of all atoms in the ensemble. The process is kinetically mediated by the number of bonds which are effectively broken at the various T above T_g and ceases out at the mode-coupling temperature T_{MC} where hybridization of acoustic-like and internal modes occur [6]. The hybridization process involves a substantial decrease of the force constant of the bond ϕ and an increase on the reduced mass m. The coupled effects would result in an overall increase of the ϕ/m ratio at T_{MC} of a factor $\sim 5\times10^2$, which suggests the onset of RUM-like stretching motions between rigid D_{6h} units intermingled with $[SiO_4]^{4-}$ bridging units. Our calculations indicate that, although for simple computational purposes one may eventually treat the glass transition as a (reversible) thermodynamic process occurring at T_g without incurring in substantial errors, it cannot be considered of high order because it involves discrete, though limited, transition entropy ΔS_{Tg} = 1.304 J/(mol×K) and transition enthalpy ΔH_{Tg} = 1.930 kJ/mol contributions.

The fate of CO_2 in silicate melts: a computer simulation study

Guillot, B.* & Sator, N.
Laboratoire de Physique Théorique de la Matière Condensée (UMR 7600), Université Pierre et Marie Curie, Paris, France
(*guillot@lptmc.jussieu.fr)

The distribution, recycling and storage of carbon in the Earth are of fundamental importance to understand the global carbon cycle between the deep Earth and near surface reservoirs. Degassing of CO_2 at mid-ocean ridges may give information on the source region but the very low solubility of CO_2 in tholeïtic basalts (~0.5 ppmw/bar) has for consequence that near all MORB glasses exsolve their CO_2 rich vapor at shallow depth as they approach the ocean floor. Hence their CO_2 contents mostly represent the pressure at eruption and not the source region. Recent petrological investigations [1] have shown that the presence of carbonates at depth in the upper mantle has a large effect on the solidus of carbonated silicates (e.g. peridotite) by inducing incipient melting at much lower temperature. So the role of carbon-rich melts at great depth is now becoming a credible scenario to explain the extraction of CO_2 from the source region to the surface. During the last three decades many studies have been devoted to measure the solubility of CO_2 in silicate melts of various compositions. But due to experimental difficulties these studies were generally restricted to low and moderate pressures (below ~20 kbar). IR spectroscopy has emphasized the importance of CO_2 speciation which may exist either as molecular CO_2 or as carbonate ion (CO_3^{2-}), the molecular form being favored in polymerized (silicic) melts while the carbonate ion is dominant in depolymerized (basic and ultrabasic) melts. However it has been demonstrated recently [2] that the CO_2 speciation observed in quenched glasses by IR spectroscopy may not be representative of that in silicate melts equilibrated at high temperature: in particular, the abundance of molecular CO_2 is underestimated in the liquid at magmatic temperatures.

By performing a series of molecular dynamics simulation where a supercritical CO_2 phase is in contact with a silicate melt of various composition (from felsic to ultrabasic) at different temperatures (1473-2273K) and pressures (20-150kbar), we have been able to evaluate the solubility of CO_2, the population of molecular and carbonate species, their diffusivity through the melt and the local structure. We will show that this kind of molecular simulation is a useful theoretical guide to better understand the behavior of CO_2 in magmas at depth.

Evolution of microstructure and composition of refractories at their interaction with metallurgical melts

Shchekina, T.I.*, Gramenitskiy, E.N. & Batanova, A.M.
Dept. of Petrology, Moscow State University, Moscow, Russia
(*t-shchekina@mail.ru)

This work is a study of the deterioration mechanism of Martin furnaces hearth, which are used for stuffing the magnesia-dolomite ramming mixture of various marks: Ankerharth (Austria), Jehearth (Slovakia) and PPM 85 (Satka, Russia). Our purpose is to reveal the factors affecting the stability of the refractory materials during their service. Chemical corrosion during the service is the main reason of lowering fire-resistant materials stability.

Chemistry, phase composition and structure of samples from various hearth sites of Martin furnaces pre- and after service in zones at interaction of fire-resistant materials with metallurgical melts, were studied. The comparative analysis of the changes and parameters depending on refractory mark was carried out. The main result of this study is detection of diffusive zoning at the contact between metallurgical melts and a fire-resistant material, similar to natural metasomatic processes. [1]. Due to diffusive interaction of fire-resistant material with melts of steel and slag, new phases with technogenic origins are formed as unusual isomorphic replacement in minerals of calcium ferrites, aluminates, perovskite groups [2].

Chemical corrosion during the service is the main reason of lowering fire-resistant materials stability. Phase composition and the microstructure of samples change significantly in zones arising at interaction between fire-resistant materials and metallurgical melts. The composition of all fire-resistant materials used in Martin manufacture bear similarities, although the ratios vary: periclase MgO (80-90%), lime CaO (8-20%), impurities of the phases containing SiO_2, Fe_2O_3, Al_2O_3 (3-5%).

In the reactionary columns about 5 zones can be separated, from moderately changed zone 1 (closed to initial refractory material on phase composition) to most cardinal changed zone 5 (almost completely combined by new-formed phases). General thickness of reactionary columns reaches tens centimeters, while thickness of its most changed parts is about 5-7 mm.

The main change of material chemistry consist of carrying out Mg and introducing Fe and Si, thus the role of Fe^{3+} in relation to Fe^{2+} increases, as approaching the contact of the refractory - the melt. Mineral composition changes also. Periclase registers an increasing of ferruginosity up to 30% until its full replacement by magnesioferrite, magnetite and wustite. The aluminates form in moderately changed zones, while silicates of calcium, merwinite and ferrite of calcium – in more changed zones. The phase composition becomes similar for all refractory material closest to the contact with metallurgical melts. Periclase remains only as relict grains with high ferruginosity up to 30 %. Magnesioferrite, forming large crystals, becomes the main mineral in Ankerharth material. Smaller amounts of magnetite, ferrite of calcium and dicalcium silicate fill the space between high ferrrous phases. The main feature of structure of 5th zone on Jehearth material is occurrence of ferrous oxide melt. Ti-containing brounmillerite in accretions with calcium aluminates form the final zone in Satka material. About 30 % of iron position in brounmillerite is occupied with titan. Microstructure of this material is assumed to formation of appropriate melt at conditions of metallurgical process. Formation of such melts promotes a softening of the refractory material surface and its erosion.

In-situ structural investigation of hydrous and anhydrous $NaAlSi_3O_8$ melt at high pressure

Yamada, A.[1*], Inoue, T.[1] & Kikegawa, T.[2]
[1]Geodynamics Research Center, Ehime University, Matsuyama, Japan (*a-yamada@sci.ehime-u.ac.jp)
[2]Photon Factory, High Energy Accelerator Research Organization, Tsukuba, Japan

Microscopic structure of molten silicate at high pressure gives important insights into the fundamental understanding of the physicochemical properties of magma in the Earth's interior. In particular, *in-situ* observations of liquid are necessary for the realistic response of the structure to pressure because the information through the glass is always under-estimated due to the kinetic effect and the reversible property of the structure during decompression. A local structural change in AlO_4 tetrahedra is thought to happen at much lower pressures than in the SiO_4 tetrahedra, which influent to various properties of aluminous silicate melt. In addition, it is widely known that water changes the structure and properties of silicate melt dramatically. Here, we investigate the difference in local structure between hydrous and anhydrous albite ($NaAlSi_3O_8$) melt with high-pressure X-ray diffraction.

A sample of anhydrous albite was prepared with a mixture of $NaCO_3$, Al_2O_3, and SiO_2. The mixture was decarbonized at 1000°C for 9 hours, then melted at 1200°C, and finally quenched at room temperature to make a glass. Hydrous albite was made from sodium silicate glass ($Na_2Si_6O_{13}$) plus $Al(OH)_3$ gibbsite, which has 9.3-wt% water content. High-pressure X-ray diffraction experiments have been conducted at NE5C beamline in PF-AR, Tsukuba, Japan. A DIA-type press was used for the high-pressure and temperature experiments. A hydrous sample was encapsulated in single-crystal diamond tubing with platinum lids (e.g., [1]). Anhydrous melt was put in graphite or boron nitride containers. Diffractometry of the molten sample for the structural analysis was performed with polychromatic X-rays with the energy-dispersive method. Diffraction patterns of the sample were collected from $2\theta = 3°$ to 30° to cover a wider range of Q ($Q = 4\pi E \sin\theta/12.398$ [Å^{-1}], where E and θ are the energy of the X-rays and the Bragg angle, respectively). To obtain S(Q), software developed by Funakoshi (1997)[2] was exploited.

S(Q) and G(r) for hydrous albite melt are shown in Fig. 1.

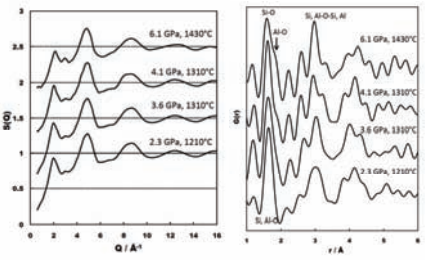

Fig. 1: Structure factor, S(Q), (left) and radial distribution function, G(r), (right) for hydrous $NaAlSi_3O_8$ melt.

The pressure dependence of the peak-shift of the first peak in S(Q) for the hydrous melt is much smaller than for the anhydrous melt although the position of the peak is located on the higher-Q side. The shoulder peak on the right side of the Si-O peak in G(r) appears from 4.1 GPa in the hydrous melt (allow in right figure), which becomes intense with pressure. This shoulder peak can be assigned to a highly coordinated Al-O atomic pair. This striking peak, which reflects the appearance of AlO_n polyhedra, was not seen in the anhydrous melt up to 6.2 GPa. Further discussion will be presented in the presentation.

Effect of alkali content and Fe oxidation state on the S oxidation state and solubility in silicate glasses

Giuli, G.[1*], Paris, E.[1], Alonso Mori, R.[2], Glatzel, P.[2], Cicconi, M.R.[1], Scaillet, B.[3] & Eeckhout, S.G.[2]
[1]Dip. di Scienze della Terra, Universita' di Camerino, Italy ([*]gabriele.giuli@unicam.it)
[2]European Synchrotron Radiation Facility (ESRF), Grenoble, France
[3]Inst. de Sciences de la Terre D'Orleans, UMR, CNRS-UO, Orleans, France

The Fe oxidation state, coordination geometry and <Fe-O> distances have been determined by Fe K-edge XANES and EXAFS for a set of sulphur bearing silicate glasses of rhyolite composition in the aim of determining:

1) the effect of bulk composition on the iron oxidation state and local structural environment;

2) the effect of Fe oxidation state on sulphur behaviour in the corresponding magmas/melts.

Glass compositions have been chosen so as to represent S-Cl-F bearing rhyolitic magmas with low to high alkali content. These glasses have been equilibrated at a range of different oxygen fugacity conditions typical of magmatic conditions and ranging from –15.4 to –10.75 log units (at 800 ° C, 1.5 kbar).

Comparison of the pre-edge peak data with those of Fe model compounds with known oxidation state and coordination number allowed to determine the Fe oxidation state and coordination number for all the glasses analysed. The $Fe^{3+}/(Fe^{3+} + Fe^{2+})$ ratio varies from 0.25 to 0.80 (±0.05) in the glasses studied. Moreover, pre-edge peak data clearly indicate that Fe^{3+} can be present in [4] and/or [5] coordination according to the alkali content of the glass, whereas Fe^{2+} is present in [5] coordination units for these compositions. The presence of minor amounts of [6] coordinated Fe cannot be ruled out by XANES data alone. EXAFS derived Fe-O distance in the most oxidised sample (Fe-O=1.85 Å) indicates that Fe^{3+} is in tetrahedral coordination.

For these glass compositions, going from reducing to oxidising condition results in higher fraction of network forming $^{[4]}Fe^{3+}$, thus increasing the polymerisation of the tetrahedral network.

Alkali content has been found to have a very strongly effect on the Fe oxidation state: at a given oxygen fugacity, Fe oxidation state increase noticeably with increasing alkali content.

A direct proportionality has been found between the S^{2-}/Fe^{2+} molar fractions.

As Fe oxidation state is known to affect the solubility of S^{2-} species in silicate melts, Alkali content is expected to play a major role together with oxygen fugacity in the S geochemical behaviour in silicate magmas.

Investigation of boron coordination in borate and borosilicate glasses and minerals using high resolution O *K*-edge XANES

Dong, D.[1], Henderson, G.S.[1*], Blyth, R.[2] & Regier, T.[2]
[1]Dept. of Geology, University of Toronto, Toronto, Canada ([*]henders@geology.utoronto.ca)
[2]Canadian Light Source Inc., University of Saskatchewan, Saskatoon, Canada

Oxygen *K*-edge XANES is sensitive to the coordination of the cations bound to the oxygen atoms. O *K*-edge XANES spectra 1have been collected for a number of crystalline reference compounds (B_2O_3, H_3BO_3, HBO_2-II, HBO_2-III, $Na_2B_4O_7$, CaB_2O_4, BPO_4), as well as, for a series of borosilicate and sodium borosilicate glasses. Crystalline phases (B_2O_3, H_3BO_3, HBO_2-II, and HBO_2-III) in which B bonds to 3 oxygens ($^{[3]}B$), exhibit a relatively narrow peak at around 537 eV, with a broad weak shoulder at around ~542 eV and a strong broad shoulder at ~545 eV. In crystalline phases containing only 4-fold B ($^{[4]}B$) (BPO_4) the spectra are characterised by 4 distinct features: a relatively sharp peak around ~539.5eV with 3 further peaks at ~538, ~541.5 and ~542.5 eV. A pre-edge feature is found around 533 eV in the spectra of both the $^{[3]}B$ and $^{[4]}B$ phases. Introduction of H as H_3BO_3, HBO_2-II, and HBO_2-III affects the intensity of the pre-edge feature but does not influence strongly the main XANES features. The spectra of calcium metaborate (CaB_2O_4) with nominal 100% $^{[3]}B$ suggest that there is a substantial amount of 4-fold B present similar to other studies. We suspect that the $^{[4]}B$ forms during sample preparation. The O *K*-edge spectra are clearly distinct for phases containing only $^{[3]}B$ and only $^{[4]}B$ and have the potential to be used to quantify the relative proportions of the different B coordination environments. Currently, we are analyzing the results for a series of borosilicate and alkali borosilicate glasses which will be reported upon.

Structure of glasses and melts in the Ca-Mg pyroxene join

Cormier, L.
Inst. de Mineralogie et Physique des Milieux Condensés, CNRS, Université Pierre et Marie Curie, Université Paris Diderot, IPGP, France (cormier@impmc.upmc.fr)

The structure of silicate melts determines their macroscopic properties such as viscosity, density, diffusivity, entropy, etc. Their understanding is still limited by the technical difficulties to obtain measurements at elevated temperatures in the liquid state. Glasses are thus often considered to describe melt structure but the structural variations with temperature are often poorly understood.

In this study, we have investigated the structure of glasses and melts on the Ca-Mg pyroxene join ($Ca_{2x}Mg_{2-2x}Si_2O_6$) using X-ray and neutron diffraction. Data were obtained from room temperature up to the liquid state. The experimental data have been coupled with numerical simulations (Molecular Dynamics and Reverse Monte Carlo). We report a detailed investigation focussing to understand the evolution of important structural parameter (Mg and Ca coordination, Mg-Ca mixing and silicate topology) with the composition and the temperature.

A molecular scale approach of the structure and properties of glasses: the role of "chameleon" elements

Calas, G.*, Cormier, L., Dargaud, O., Ferlat, G., Galoisy, L. & Lelong, G.
Inst. de Minéralogie et Physique des Milieux Condensés, Universités de Paris 6&7, IPGP and CNRS, Paris, France (*Georges.Calas@impmc.jussieu.fr)

More disordered than nanomaterials, amorphous solids such as glasses and gels have recently benefited from molecular scale approaches, which have provided at the same time a deeper knowledge of their structural organization as well as giving potential tools to predict their properties. Glass stability is required for environmental applications, including the development of insulating materials or nuclear waste matrices. On the other hand, nanophase crystallization is favored in glasses to form glass ceramics. It is interesting that the same glass components, such as Zr, B or Fe are used to develop such different properties.

The talk will summarize recent advances in rationalizing the sites of and the medium range structure around these key glass components. These data are obtained by an adequate combination of experimental approaches, mostly based on the determination of interatomic distances in glasses (EXAFS, neutron and X-ray diffraction), and of numerical modeling/simulation tools.

An extensive data set exists on Zr crystal chemistry in glasses and crystals. Zr is known to decrease the solubility of simulated nuclear glasses. In these glasses, Zr occurs in octahedral coordination and has a reticulating role. At the glass-water interface, Zr coordination may change or nor not depending on alteration conditions. Under SiO_2-saturated conditions, Zr retains its reticulating role in the alteration gel with a small nanoporosity, providing a protective role. By contrast, during alteration under open conditions, Zr coordination changes from 6 to 7, showing the formation of a mixed hydrous zirconia-silica gel at the glass surface, with a poor protective role. In glass ceramics, such as Mg- or Li-aluminosilicate glasses in which high cation field strength increases the disorder of the glassy network, Zr is used for enhancing the nucleation of nanocrystals. Zr occurs in a peculiar local surrounding, explaining its structural instability during thermal treatment. Molecular scale transformations occur about 30°C below the onset of crystalline nucleation and cause the appearance of peculiar nuclei in which surface stress effects provides these nanophases a peculiar structure.

Other structure-property relationships will be illustrated on the influence of Fe^{3+}-clustering on optical and magnetic properties of glasses, or of B-coordination on radiation- and thermal-dependent glass/melt properties. They show that bond valence rules and principles governing mineral crystal chemistry are also active in glasses, emphasizing the interdependence between the local surrounding and chemical state of the various glass components.

Fe and melt viscosity

The rheology of magma and the viscosity of melts is a dominant control on the physical nature of magmatism and volcanism on Earth and other planets. Rheology is also a fundamental control on the efficiency of magmatic differentiation leading to the diversity of igneous rocks.

The physical description of melt rheology is well advanced and unexpected surprises in this field are likely able to be confined to extreme conditions of pressure, stress, and/or relaxation time.

The chemical description of melt rheology has also advanced rapidly in recent years. There are now a number of predictive models of varying power, both empirical and structure-based. General acceptance of a single, extrapolable, structure-based model of viscosity still lies however in the future.

Working towards a general model for melt viscosity, the influence of polyvalent elements in controlling melt viscosity is a special opportunity to understand structure-property relationships. Fe is the polyvalent element of major influence in terrestrial magmas. Its role in controlling melt viscosity is still unknown in detail.

Using a combination of viscometry, dilatometry, calorimetry and spectroscopy, the role of Fe and its redox state in controlling melt viscosity has been investigated. Compositions range from ferropicrite to pantellerite. The results reveal a (for us) surprising sensitivity of melt viscosity to Fe oxidation state. Scaling models for relating Fe-content to the magnitude of the redox effect are not yet clear. Based on these experimental determinations, we will speculate on the relationship between structure and viscosity in these systems and its implications.

Proton dynamics in hydrous silicates studied by high temperature high pressure quasielastic neutron scattering

Yang, F.[1*], Meyer, A.[1], Mamontov, E.[2] & Unruh, T.[3]
[1]Inst. of Material Physics in Space, German Aerospace Center (DLR), Cologne, Germany ([*]fan.yang@dlr.de)
[2]Spallation Neutron Source, Oak Ridge National Laboratory, Oak Ridge, Tennessee, USA
[3]Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM II), TU München, Garching, Germany

Dissolved water in silicate melts plays an important role in many geological processes, especially in active volcanism. The knowledge of the dynamics of water species represents a key for the understanding of these processes and to predict melt properties like viscosity. We present results from quasielastic neutron scattering (QNS) on hydrous silicate melts, which provide informations about microscopic hydrogen dynamics in the sample on picosends to nanoseconds time scales.

Measurements were done at temperatures up to 1250 K. A constant pressure of 200 MPa was applied to prevent degassing of the sample. A Nb1Zr cell was built as sample environment for such study, which is transparent for cold neutron beams.

Experiments were carried out on several synthetic hydrous silicate systems, including pure silica, sodium trisilicate and albite compositions, all with 10 mol% water concentration. By combining experiments on different neutron spectrometers, we are able to study dynamics on the time scale from of about 0.2 picosecond up to 1 nanosecond, spanning over nearly 4 decades. Also, taking advantage of the large difference in neutron scattering cross-sections of H and D, a contrast variation via H_2O/D_2O substitution gives access to the pure incoherent proton dynamics.

The QNS signal reveals that the proton dynamics has a different nature as compared to the alkali ions in the Si-O matrix, although the addition of the water and alkali oxides both leads to a dramatic decrease of the silicate melt viscosity. In hydrous silica and albite, the relaxation time of the protons is larger than 60 picosends at 1250 K. Therefore, the proton dynamics is slower than *i.e.* the sodium dynamics in the sodium silicates under similar conditions [1]. Thus, in contrast to sodium silicates, no evidence of fast diffusion via channel structures in hydrous silica and albite has been observed. In the hydrous sodium silicate it has been found that the sodium dynamics is not significantly accelerated upon water addition. Note that although in both silica and sodium silicate cases, the macroscopic melt viscosity has dropped by orders of magnitudes, which is commonly understood as the depolymerization of the Si-O network. The slower proton dynamics may be attributed to the strong bondings between proton and Si-O matrix.

In addition, an unusual dynamics of the protons has been observed in sodium silicate melt. The proton relaxation consists of a fast process and a slow process. The later one only comes into the time window on the order of 1 nanosecond at the experimental temperature of 1150 K. This will give a transport coefficient on the order of 10^{-11} m^2s^{-1} at this temperature. However, within the neutron scattering study, decoupling of the relaxation time scale due to different proton environments can be excluded. The fast process exhibits extreme stretching of the intermediate scattering function S(q,t), which might be interpreted under a glass-glass transition scenario [2].

Compositional dependent compressibility of dissolved water in silicate glasses

Malfait, W.J.[1*], Sanchez-Valle, C.[1], Ardia, P.[1,2] & Médard, E.[3]
[1]Inst. for Geochemistry and Petrology, ETH Zurich, Switzerland ([*]wim.malfait@erdw.ethz.ch)
[2]Dept. of Geology and Geophysics, University of Minnesota, USA
[3]Lab. Magmas et Volcans, Universite Blaise-Pascal-CNRS, OPGC, Clermont-Ferrand, France

Because of the lack of available experimental density data, and motivated by the compositional independent partial molar volume of water in silicate glasses at atmospheric pressure [1], current density models for hydrous magmatic liquids [2] assume a composition independent from compressibility of the water component. In order to test this assumption, we have determined the acoustic velocities and elastic moduli of a series of hydrous rhyolite, andesite and basalt glasses at ambient conditions using Brillouin spectroscopy.

The measured velocities and bulk moduli are in good agreement with previous data on glasses with similar compositions, when available [1]. For all glass series, the addition of water leads to a decrease in the shear modulus (G). The increase in Poisson ratio with increasing water content for the rhyolite glasses provides indirect evidence for the depolymerization of the glasses [3]. For the rhyolite glasses, the bulk modulus (K_S) is essentially unaffected by the addition of water, but K_S decreases with increasing water content for the andesite and basalt glasses. The results show that the partial molar bulk modulus of water in depends on glass composition. The compositional dependence of the partial molar K_S, hence compressibility ($\beta_S=1/K_S$), limits the applicability of the current density models, in particular at higher pressures and/or for melt compositions that deviate strongly from liquid albite. The results of this study emphasize that the construction of more robust density models for hydrous magmatic liquids requires additional data on the density and compressibility at relevant temperature and pressure conditions.

Viscosity of basaltic magma at high pressure

Suzuki, A.[1*], Ohtani, E.[1], Ando, R.[1], Terasaki, H.[1], Sakamaki, T.[1] & Funakoshi, K.[2]
[1]Dept. of Earth and Planetary Materials Science, Faculty of Science, Tohoku University, Sendai, Japan
([*]a-suzuki@m.tains.tohoku.ac.jp)
[2]JASRI, SPring-8, Japan

The viscosity of magma (silicate melt) is one of the fundamental properties that control the generation, transportation, and eruption of magmas. Because magmas are formed in the Earth's interior and ascend to the surface, knowledge of the pressure dependence of viscosity is crucial in understanding the igneous processes. Therefore, the viscosities of various silicate melts have been investigated at high pressure. The viscosity of silicate melts at high pressure was measured with the falling-sphere method by a quenching experiment using a piston cylinder apparatus. In recent years, X-ray radiography has been applied to measuring viscosity for the purpose of improving uncertainty of the measurement and extending the experimental range at higher pressure and lower viscosity. Mid-ocean ridge basalt (MORB) is the most abundant basalt composing the oceanic crust. Furthermore, it is suggested that the recycling MORB would be molten again in a heterogeneous mantle plume in the deep upper mantle. The recycled MORB may be related to the activity of oceanic island basalts and continental flood basalts. Therefore, it is important to clarify the viscosity of the basaltic melt at high pressure to understand the behavior of the melts in the upper mantle. The viscosity was measured using the radiographic falling–sphere technique at the beamline BL04B1 of the SPring–8 synchrotron radiation facility. High–pressure and –temperature experiments were conducted using a Kawai–type multianvil apparatus driven by a 1500 ton uniaxial press, SPEED1500. The X-ray shadow image was observed using a CCD camera with a YAG:Ce fluorescence screen. The viscosity (η) of the melt was calculated by the Stokes' equation with the Faxén correction for the wall effect. The viscosity of the dry MORB melt decreased gradually up to a pressure of 4.5 GPa. At higher pressure, an increase in viscosity was observed to 6.5 GPa. At higher pressure the viscosity decreased up to 13 GPa. The present study revealed that the viscosity of dry MORB reached a minimum near 5 GPa. It has been suggested that the pressure dependence of viscosity changes because of modification of the structure of the melt such as the change in T–O–T bond angles in the melt and formation of the higher-coordinated aluminum and silicon. This study suggests that the structure of the MORB melt changes drastically near 5 GPa.

Structure, properties and implications for the formation of tektite glasses

Neuville, D.R.[1*], Bressel, L.[2], de Ligny, D.[2] & Cochain, B.[3]
[1]CNRS-IPGP, Géochimie et Cosmochimie, Paris, France
([*]neuville@ipgp.jussieu.fr)
[2]LPCML, UMR 5620, Université Lyon 1, Université de Lyon, Villeurbanne, France
[3]Institute for Study of the Earth's Interior, Okayama University at Misasa, Misasa, Tottori, Japan

Tektites are natural glasses corresponding to enigmatic glasses, which fascinate scientists in a number of diverse disciplines about their formation conditions. It is generally accepted that they must have formed in enormously energetic impact created by a gigantic hypervelocity object penetrating the atmosphere and striking the Earth with undiminished velocity.

First, to understand tektite glasses, we have decided to investigate viscosity measurements and glass transition temperature, which can link to the geometrical form of the tektite glasses.

The structure of the glasses investigated by Raman spectroscopy can provide also information about the quenching rate and their formation.

And finally, by using in situ XANES spectroscopy at the Fe K-edge at high temperature we can determine the redox state of tektite at high temperature. These variations of Fe^{3+}/Fe^{tot} ratio at high temperature can be compared at the Fe^{3+}/Fe^{tot} ratio at room temperature on the glass and assuming that the oxygen fugacity of the tektite formation is almost the same than during our XANES experiments, we can propose a temperature of formation of tektite glasses.

Volcanic glass textures from pyroclasts of the AD 1913 rift-edge phreatomagmatic eruption, Ambrym Island, Vanuatu

Németh, K.[*] & Stewart, R.B.
INR-CS, Volcanic Risk Solutions, Massey University, Palmerston North, New Zealand ([*]k.nemeth@massey.ac.nz)

Thermohydraulic explosions produce fine ash fragments as a result of brittle melt fragmentation and high kinetic energy release due to the interaction of magma and water. Fine ash particles (<2 Phi) formed during the explosive fragmentation represent the particles directly been involved in the thermal to kinetic energy transition, and their shape and texture can be directly linked to the processes generating them. These particles are commonly referred as active particles because they play an active role in the phreatomagmatic explosion. While the phreatomagmatic fragmentation quickly vaporizes the adjacent water, the suddenly generated vapour expansion can deform the melt immediately surrounding the explosion locus, causing ductile deformation and consequently spalling particles into the expanding pyroclast mixture. Textural features of pyroclasts such as shape parameters characteristic for brittle or ductile melt deformation are therefore able to provide information about the melt fragmentation. Here we tested the ability of morphological analysis of pyroclasts to identify brittle and ductile processes involved in fine ash generation in the AD 1913 phreatomagmatic, maar-forming rift-edge eruption in west Ambrym. It appears that the eruption was initiated off-shore and magma erupted through a shallow marine, fringe reef environment. Various image analysis methods were used on light microscopy (LM), SEM and BSE images to identify and quantitatively measure surface morphological parameters of ash particles of base surge beds. Morphological parameters were measured to calculate circularity (C), rectangularity (R), compactness (Co) and elongation (E) then a CXE versus RXCo discrimination diagram was prepared to define the deformation mode as either ductile or brittle for each particle. In the coarse ash (-1 - 2 Phi) the CXE values were dominantly around 1 indicating ductile deformation as the main deformation mode of these particles. While these particles are glassy, of low vesicularity and bulky in appearance, they have smooth surfaces and rounded vesicles suggestive being still molten during their fragmentation. Platy glass peels appeared to commonly form a mosaic-like surface. The shape of these mosaic-like zones indicate brittle deformation, and their shape compares well with platy particles in the fine (>4 Phi) ash, suggesting that they may have formed during transportation in the pyroclastic density current by spallation from the coarser particles. A gradual shift toward more brittle fragmentation shape characteristics has been recorded in the >2 Phi grain size fractions. It has also been recognized that shape parameters measured on BSE images tend to fall toward the brittle field of the discrimination diagram while parameters derived from SEM and LM images were less characteristically brittle. A same tendency has been observed using automatic-to-semi-automatic thresholding on images versus manual particle boundary retracing. These observations highlight the importance of sample preparation and technical methods applied to derive particle shape data from volcanic ash. FTIR data shows total water contents in the glassy particles range from 0.17% to 0.43% with CO_2 below detection. The low H_2O and CO_2 is consistent with degassing under the summit and in the rift and suggests that the eruption was almost entirely driven by thermohydraulic explosions. This study gives evidence of the thermohydraulic magma/water interaction triggering fragmentation of the melt and distinguishes active, passive and abrasion-produced juvenile particles in individual beds. It seems that the proportion of these types of particles strongly depends on the physical conditions in the vent and the location of the deposit sampled relative to the vent.

Europium geochemical behaviour in silicate glasses

Cicconi, M.R.[1*], Giuli, G.[1], Paris, E.[1], Ertel-Ingrisch, W.[2], Dingwell, D.B.[2] & Ulmer, P.[3]
[1]School of Science and Technology – Geology Division, University of Camerino, Italy ([*]mariarita.cicconi@unicam.it)
[2]Dept. of Earth and Environmental Sciences, LMU München, Germany
[3]Inst. fur Mineralogie und Petrographie, ETH Zürich, Switzerland

Rare Earth Elements (REE) have demonstrated to be important geochemical indicators; in fact, the distribution of REE in igneous rocks are frequently used to constrain the mineralogy of the source materials, the degree to which magma composition has been modified by crystal fractionation, and to identify the mineral phases removed from the magma during differentiation. Moreover, the variation of the $Eu^{+2}/(Eu^{+2} + Eu^{+3})$ ratio can be used as oxygen fugacity indicators. As the Eu^{+2}/Eu^{+3} buffer is located at very low oxygen fugacity, the $Eu^{+2}/(Eu^{+2} + Eu^{+3})$ ratio can be used to constrain the formation conditions within a very large range of oxygen fugacity down to few log units below the Fe/FeO buffer. The $Eu^{+2}/(Eu^{+2} + Eu^{+3})$ ratio is therefore very useful in the study of meteoritic material and in studying planetary evolution and many authors had used the Eu partition coefficient vs. fO_2 to extrapolate redox conditions under which magmas have crystallized A complete understanding of transition and REE elements is important for the geochemical and petrological interpretations of magmatic processes and partition properties between melt and crystals.

To this aim, synthetic silicate glasses corresponding to compositions relevant for the Earth sciences were used to study the dependence of the redox states of a Rare Earth Element (Eu) on the bulk melt composition and at different values of oxygen fugacity (from air to IW-2).

The samples have been analyzed via Eu L_{III}-edge X-ray Absorption Spectroscopy (XAS) to study the Eu oxidation states and local environments. Eu L_{III}-edge XANES peak analysis allowed the semi-quantitative assessment of Eu redox ratio; literature data report a difference of 7 – 8 eV between Eu^{+2} and Eu^{+3} in the experimental spectra and this energy shift is evident enough to well differentiate between the two oxidation states and to determine the Eu oxidation state in the glasses under investigation. XANES spectra vary systematically with composition and with fO_2 (log fO_2 from 0 to –11.6) indicating changes in the Eu oxidation state. The intensity of the 2 peaks of the absorption maximum were quantified and used to determine $Eu^{+2}/(Eu^{+2}+Eu^{+3})$ ratio. Moreover, the local structural environment of Eu was determined by EXAFS (Extended X-ray Absorption Fine Structure) analyses, highlighting the different Eu behaviour as function of the fO_2.

This work has clearly demonstrated that for a better interpretation of the Eu anomalies observed in rocks and minerals, which are often used to constrain magmatic evolutions of igneous regions, the melt composition and the redox condition must be taken into consideration.

TEM-analyses of nanocrystals in obsidian

Kirste, J.[*], Schulze, N., Wagner, G. & Kloess, G.
Inst. of Mineralogy, Crystallography and Materials Science, Leipzig University, Leipzig, Germany ([*]kirste@uni-leipzig.de)

TEM analyses of nanocrystals in obsidians lead to a number of unexpected results. Using a Philips CM 200 HRTEM we combined bright field (BF) and dark field (DF)-imaging, Nano-EDX, and SAED (Selected Area Electron Diffraction). We found that:

1. The average chemical compositions determined by TEM-EDX on the one hand and XRF on the other hand show a perfect match. However, on a nano-scale we found strong fluctuations from 70 up to 90 wt.% in SiO_2 content.

2. According to susceptibility the predominating mineral phases are hematite nanocrystals and magnetite microcrystals. But in some cases the measurements showed exceptional compositions like wuestite or Al-bearing hematite.

3. In contrast to the expected process of devitrification we observed evidences for decrystallisation, especially at albite-like feldspars and hematites. The process of decrystallisation is accompanied with a decolourization of the red-brown obsidian.

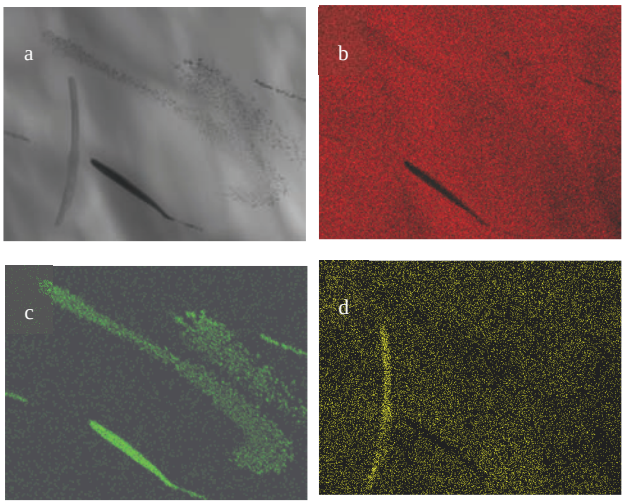

Fig. 1: STEM bright field image (a) and element distribution (b-d) in a section of Büyük Yayla obsidian; BF-image showing a dark hematite, vertical albite and cloudy nano-hematite crystals in the right; b – Si-distribution; c – Fe-distribution; d – Na-distribution.

The study deals with obsidians that stem from the Büyük Yayla Area, Eastern Pontides, Turkey. Showing unique layering structures in parts of the locality, the obsidian of Büyük Yayla is a rarely variety of obsidian.

Structure and properties of melts in the system Na_2O-K_2O-Al_2O_3-SiO_2

Le Losq, Ch.[1], Neuville, D.R.[1*], Florian, P.[2], Montouillout, V.[2] & Massiot, D.[2]
[1]CNRS-IPGP, Géochimie et Cosmochimie, Paris, France
([*]neuville@ipgp.jussieu.fr)
[2]CNRS-CEMHTI UPR3079 & Université d'Orléans, France

Rheological properties of silicate melts govern both magma ascension from the mantle to the surface of the earth and volcanological eruptions styles and behaviors. In this mind, it is very important to understand which parameters influence these properties. Up to now, we know for example that viscosity of silicate melts is dependent of temperature, pressure and chemical composition [1,2]. In this work, we will focus on the Na_2O-K_2O-Al_2O_3-SiO_2 system, which is of a prime importance because it deals with a non-negligible part of natural melts like silica rich alkali magmas. We will first present our viscosity measurements and some modelisation concepts based on the Adam and Gibbs theory. Also, while rheological properties are directly linked with structural properties of aluminosilicate melts, we will present our results obtained with Raman spectroscopy and NMR investigations at room and high temperature. These spectroscopies provide important structural informations on the polymerization of the glasses and melts and also on the environment of tetrahedral coordinated cations. It allows us to relate the rheological properties to the polymerization.

Electroatmogenous apodolerite glasses (petrofulgurites from Norilsk area, Russia)

Lysyuk, A.
Institute of Geology, UB RAS, Syktyvkar, Russia
([*]andra227@yandex.ru)

Fulgurites are geologic bodies formed as a result of lightning strike to dry rocks; according with the target, they are classified into three types: clastofulgurites (aleuro- and psammito-), petrofulgurites and phytofulgurites.

Petrofulgurites are commonly found on small hills in the area of Norilsk copper-nickel deposit, Russia. They form fulgurite crusts covering the surface of small crystalline gabbro-dolerite bodies, or drop-like structures and black glass balls in shallow craters. In the highly porous glass the relic inclusions of target material (titaniferous magnetite, ilmenite) and newly formed mineral inclusions (magnetite, Fe-Ni alloys, high-silica glasses, silica) are observed.

The comparative analysis of chemical compositions shows that the content of elements in the initial gabbro-dolerite and products of its electroatmogenous transformation is only slightly different, but certain trends in the substance differentiation are observed. Thus, in fulgurite, in comparison to gabbrodolerite, the content of Al_2O_3, Fe_2O_3, CaO, P_2O_5 decreases, but SiO_2 increases. Among admixtures in fulgurites elements-hydrolyzates La, Ce, Nd, Zr and also Br are slightly accumulated. Ba, As, Sb, Cr, Ni are removed. Sr, Eu, Se, Th and U are characterized by various trends. Strontium and europium are accumulated in massive fulgurite, but brought in from glass drops. Selenium, thorium and uranium are also accumulated in fulgurite, but their contents in glass are practically unchanged. At last caesium is sharply accumulated in glass (which is known also for volcanic glasses).

The analysis showed that figures of cerium anomaly $A(Ce)=Ce_N/Ce_N*$ form sequence:

1.56 (initial rocks) ⇨ 0.55 (fulgurite) ⇨ 0.60 (glass),

that is, thermal impact alteration of the gabbro-dolerite transforms "positive" cerium anomaly into "negative" one.

The figures of europium anomaly $A(Eu)=Eu/Eu_N/Eu*_N$ form sequence:

0.78 (initial rocks) ⇨ 0.89 (fulgurite) ⇨ 0.32 (glass).

The behavior of europium anomaly repeats differentiated distribution of europium itself: its content increase in fulgurite is accompanied by the increase of the anomaly, and decrease of Eu content in glass – decrease of the anomaly, it becomes more "negative".

The determined changes trends of content of Norilsk gabbro-dolerite resulted from atmospheric electrical discharges on its surface are characterized by instantaneous local effect of superhigh temperatures and pressures, they are connected with passing of the target through gas stage and explained by degassing, successive-selective rock melting and somewhat different conditions of glass alloy solidification on the rock surface and in scattered drops. The processes of fulgurite formation are accompanied by reducing of all phases to the utmost reduced condition.

Acknowledgements: RFBR and RAS program 09-П-5-1026 support).

Study of complex silicate melts and glasses of geological interests by X-ray absorption spectroscopy, time resolved X-ray diffraction and molecular dynamics simulations

Madjer, K.[1], Rossano, S.[1*], Hennet, L.[2], Malavergne, V.[1], Reguer, S.[3], Wilke, M.[4], Harfouche, M.[5], Bytchkov, A.[6], Bordage, A.[1] & Leydier, M.[2]

Mg-rich silicate materials are the major components of the Earth, from the very first stage of its formation to Archaean age. In this study, we focus on two different systems: CI and enstatite chondrites which, according to recent studies could be the building blocks of the Earth, and komatiites which are high-temperature, Mg-rich lavas typical of the Archaean age**.** The main aim of this study is to enlighten the relationship between the composition and structure of melts and the chemistry and mineralogy of the primitive and current mantle.

The samples consist of a simplified CI chondrite, a simplified composition of the silicate part of an enstatite chondrite, two simplified komatiites and, for future comparison purposes, a synthetic basaltic Martian glass EG. Their structure is investigated using Fe *K*-Edge EXAFS measurements, time resolved X-ray scattering and Molecular Dynamics (MD) simulations (DL_POLY code). The EXAFS measurements are performed on the Diffabs beam line at the Soleil Synchrotron facility and on the SuperXAS beam line at the SLS Synchrotron. The X-ray scattering experiments are conducted on the ID11 beam line at the ESRF. In order to achieve containerless melting, an elaborate installation is set up, including a confinement chamber, a heating laser and a gas operated levitation system. This allows the melting of the material under controlled atmosphere, using O_2, N_2 or Ar as the flowing gas. Time resolved X-ray scattering measurements are performed while controlling the cooling rate, giving access to the whole thermal history of the samples: in the liquid, during the glass transition and in the solid state. The experimental structure factors, radial distribution functions and local environments are compared to MD simulations results.

Aluminum coordination in hydrous rhyolite glasses: ^{27}Al NMR spectroscopy at 20 Tesla

Malfait, W.J.[1*], Verel, R.[2], Ardia, P.[1,3] & Sanchez-Valle, C.[1]

In this study, we investigate the Al environment in realistic analogs to natural granitic melts, *i.e.* glasses in the H_2O-Na_2O-K_2O-Al_2O_3-SiO_2 system quenched from pressures relevant to igneous crustal processes. More specifically, we investigate the effect of pressure (up to 2.5 GPa) and water content (up to 5.24 wt% H_2O) on the Al coordination. The ^{27}Al NMR measurements were performed at a high magnetic field of 20 Tesla to reduce broadening effects caused by the quadrupolar interaction, resulting in well resolved NMR bands for ^{IV}Al and ^{V}Al. For all measured glasses, the abundance of ^{V}Al was smaller than 0.5%, whilst no ^{VI}Al was detected. As expected, the amount of ^{V}Al increases with increasing pressure (Fig. 1a). However, the proportion of ^{V}Al seems to decrease with increasing water content (Fig. 1b). This is in contrast to what was observed for simplified basaltic glasses, where increasing the water content favored the formation of higher coordinated Al [1]. Taking into account the ^{V}Al-^{V}Si exchange reactions [2] and the temperature dependence of the ^{V}Al abundances [3], our results on the Al coordination in glasses constrain the ^{V}Al and ^{V}Si to a maximum of 1.5 and 0.015% respectively for granitic magmas at crustal pressure and temperature conditions.

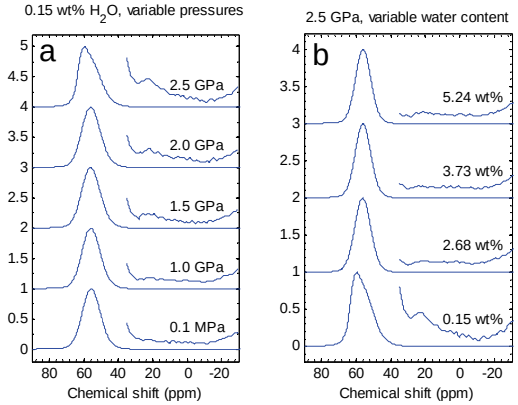

Fig. 1: ^{27}Al NMR spectra of hydrous rhyolite glasses; the intensities in the region between -25 and 35 ppm are magnified by a factor of 50 to visualize the contribution of ^{V}Al near 20 ppm. a) Spectra as a function of pressure for the nearly anhydrous glass. b) Spectra as a function of water content at a constant pressure of 2.5 GPa.

Quantifying Si-OH and Al-OH abundances in hydrous aluminosilicate glasses by ^{1}H, ^{27}Al-^{1}H and ^{29}Si-^{1}H NMR spectroscopy

Malfait, W.J.[1,2*] & Xue, X.Y.[1]
[1]Inst. for Study of the Earth's Interior, Okayama University, Okayama, Japan
[2]Inst. for Geochemistry and Petrology, ETH Zurich, Switzerland ([*]wim.malfait@erdw.ethz.ch)

The combined results of ^{27}Al-^{1}H and ^{1}H-^{29}Si-^{1}H cross polarization NMR experiments for hydrous glasses (containing 0.5 to 2 wt% water) along the SiO_2-$NaAlSiO_4$ join confirm that the dissolution mechanism of water in aluminosilicate glasses is fundamentally the same as for Al-free systems [1,2], i.e. the dissolved water ruptures oxygen bridges and creates Si-OH and Al-OH groups, in addition to forming molecular water (H_2O_{mol}).

The partial ^{1}H NMR spectra for Al-OH for the different glasses were derived from the ^{27}Al-^{1}H cross polarization spectra without any a priori assumptions about their lineshape [3]. The abundance of Al-OH was then determined from the fit of these partial spectra to the quantitative ^{1}H spectra.

The fraction of Al-OH increases non-linearly as the Al content increases with up to half of the OH groups as Al-OH for compositions close to $NaAlSiO_4$ (Fig. 1a). The relative abundances of the different species are controlled by the degree of Al-avoidance and the relative tendency of hydrolysis of the different types of oxygen bridges, Si-O-Si, Si-O-Al and Al-O-Al. A set of homogeneous reactions is derived to model the measured Al-OH/Si-OH speciation:

Si-O-Si + Al-O-Al = 2 Si-O-Al (1)

Si-O-Si + Al-OH = Si-O-Al + Si-OH (2)

The values of the corresponding equilibrium constants can be obtained by fitting reactions (1) and (2) to the experimentally derived Al-OH/OH_{tot} ratios (Fig. 1a). The result for K_1 is in agreement with literature data on the degree of Al-avoidance (Fig. 1b).

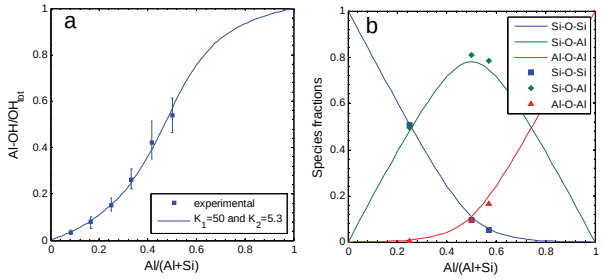

Fig. 1: a) Abundance of Al-OH as a function of the Al-content of the glass. Reactions (1) and (2) reproduce the experimental data well. b) Degree of Al-avoidance: symbols correspond to results from ^{17}O NMR [4]; the Al-avoidance corresponding to K_1=50 (lines), determined from the fit of reactions (1) and (2) to the experimentally determined Al-OH speciation (Fig. 1a), agrees with the ^{17}O NMR data.

With the values for K_1 and K_2, and literature data for the OH/H_2O_{mol} speciation in hydrous albite glasses [5], the abundance of the different oxygen species, i.e. Si-O-Si, Si-O-Al, Al-O-Al, Si-OH, Al-OH and H_2O_{mol}, can be predicted for the entire range of water and Al contents.

High temperature topological transitions in the feldspar melts with composition $MAl_2Si_2O_8$ (M=Ba,Ca)

Simakin, A.[1], Salova, T.[1], Kucherinenko, Ja.[2], Eremyashev, V.[3] & Zakrevskaya, O.Ju[1*]

[2]Moscow State University, Moscow, Russia
[3]Institute of Mineralogy, UB RAS, Miass, Russia

Proportion of the non-bridging oxygen (composition based NBO/T parameter) is usually considered as a measure of the polymerization degree. Recently conception of three coordinated oxygen introduces a factor independent of the composition [1]. At the same time layered polymorphs of the typical 3D connected feldspars give another mechanism of depolymerization. Indeed in respect viscosity there is no large difference is network locally interrupted along sheet of Q3 units ($Na_2Si_2O_5$) or along double sheet of $MAl_2Si_2O_8$ (M=Ca, Sr, Ba) composition.

Structural similarity of the hexagonal phylosilicate $BaAl_2Si_2O_8$ and its glass was probably first time suggested in [2]. We present IR spectra of $BaAl_2Si_2O_8$ glass and synthesized from the melt hexa-phase supporting this idea. Glass was prepared by the quenching on the metal plate. Due to the high affinity for Ba hexa-celcian crystallization pure glass was formed only on the outer drop rim. IR spectrum of the glass has bands set with maxima around 450, 670 and 967 cm^{-1} typical for known hexa-modifications of feldspars (Fig. 1).

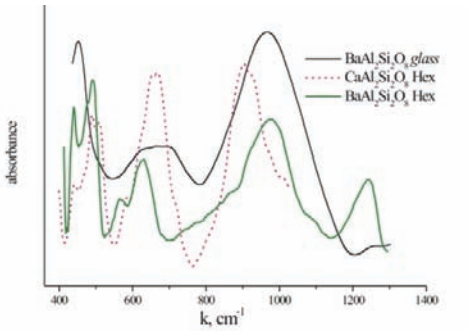

Fig. 1: IR spectra of the layered modifications of feldspars and glass.

Layered modification is stabilized with earth alkali ions radius (Ba>Sr>Ca) and temperature increase. We suggest that in anorthite ($CaAl_2Si_2O_8$) melt fraction of the layered type continuously increases with temperature while in the quenched glasses it returns practically to zero. Viscosity of anorthite melt can be described through the fraction of the layered type as a function of temperature [3]. Estimated energy of transformation $anorthite_L$ -> $hexa\text{-}anorthite_L$ is ca 50.6 kJ/mol that is substantially less than anorthite melting enthalpy of 133 kJ/mol.

Iron redox and structural state in granitoidic melts according to experimental data

Volovetsky, M.V.[1*], Lukanin, O.A.[1], Rusakov, V.S.[2] & Kargaltsev, A.A.[1]
[1]Vernadsky Inst. of Geochemistry and Analytical Chemistry, Moscow, Russia (*volovetsky@gmail.com)
[2]Lomonosov Moscow State University, Moscow, Russia

Iron is widely distributed element with variable valence which is presented in natural acid melts of volcanic and impact origin. Redox state of iron in melts depends on a set of parameters: temperature, oxygen fugacity and melt composition. Knowledge of these parameters gives an opportunity to determine redox conditions during melt forming. Despite this problem were regarded in many previous experimental studies T-fO_2 influence on Fe^{2+}/Fe^{3+} ratio in acid melts is still poorly known.

Experiments were performed to study T-fO_2 influence on iron redox and structural state in acid melts (~70 % SiO_2). Two granitic compositions were chosen as initial glasses: 1) granite – I2; 2) pantellerite (alkaline granite) – P9. Glasses were obtained in a set of experiments under temperatures from 1120 to 1420°C and in a wide range of fO_2: from $10^{-0.7}$ (air) до 10^{-13} (buffer IW) bar using high-temperature furnace with controlled oxygen fugacity. Alumina crucibles were used as containers. Microprobe analysis has revealed that chemical composition of melts changes with increasing temperature (in particular Na volatilizes).

Valent and structural state of iron was investigated using Mössbauer spectroscopy. Mössbauer data analysis has shown that iron redox-ratio depends on oxygen fugacity in accordance to the equation $\lg(Fe^{3+}/Fe^{2+}) = a \cdot \lg(fO_2) + b(T)$ (Fig. 1). On the figure it is shown that $Fe^{3+}/\Sigma Fe$ ratio in pantelleritic melts is higher than in granitic on 10-20%. It is also noteworthy that redox-ratio decreases with increasing temperature.

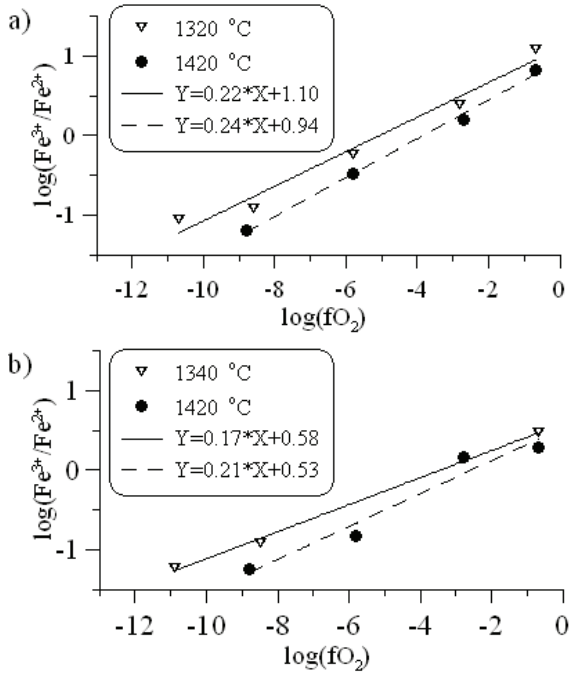

Fig. 1: Relationship between logarithms of Fe^{3+}/Fe^{2+} ratio and fO_2: a) pantelleritic composition (P9); b) granitic composition (I2).

Iron coordination state was determined from average Mössbauer line shifts of corresponding subspectra. Fe^{3+} ions were revealed to change coordination from octahedral to tetrahedral with increasing of iron redox ratio (beginning from $Fe^{3+}/\Sigma Fe>0.6$). At the same time a large amount of ions occupies five-fold positions. Fe^{2+} ions do not change coordination much and occupy five-fold and octahedral positions.

Elastic behaviour and HP-induced phase transitions in MFI-type zeolites

Quartieri, S.[1*], Montagna, G.[2], Arletti, R.[3] & Vezzalini, G.[1]
[1]Dept. of Earth Sciences, University of Messina, Italy
([*]squartieri@unime.it)
[2]Dept. of Earth Sciences, University of Modena and Reggio Emilia, Modena, Italy
[3]Dept. of Earth Sciences, University of Ferrara, Italy

High pressure applied to microporous materials can induce profound structural changes, which could give rise to modifications of the physical properties and of the accessibility to the zeolite catalytic sites by the molecular species entering the porous material.

The response to compression of different natural and synthetic zeolites with MFI topology, but with different framework and extraframework chemical composition (Mutinaite, H-ZSM5, silicalite), was explored by in-situ synchrotron X-ray powder diffraction (XRPD), using silicon oil as non-penetrating pressure transmitting medium. Two silicalite samples [s.g. $P2_1/n$] with different Si/Al ratios (1240 for silicalite1 and 1850 for silicalite2) and water content (8.9 and 2.3 molecules for silicalite1 and 2, respectively) were studied. Their pore system does not contain cations and their Si/Al ratios are much higher than in H-ZSM5 (10) and in mutinaite (7.6).

The main result of this study is the evidence of a *P*-induced phase transition in silicalite, from the monoclinic $P2_1/n$ (P_{amb}) to the orthorhombic Pnma (H*P*) (Fig. 1). In particular, silicalite1 becomes orthorhombic between P_{amb} and 0.3 GPa, while silicalite2 undergoes the same transition between 0.4 and 0.9 GPa. Otherwise, mutinaite and H-ZSM5 remain orthorhombic in all the studied *P*-range. Both the original s.g. and the unit cell parameters are recovered, for all the studied phases, upon decompression.

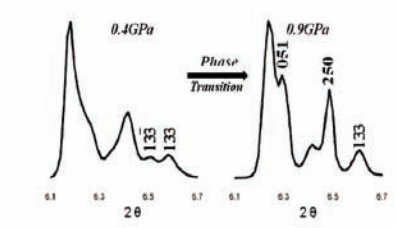

Fig. 1: XRPD patterns of silicalite2 as a function of pressure.

The cell volume decreases observed for the different phases in the P_{amb}–6 GPa range are reported in Fig. 2.

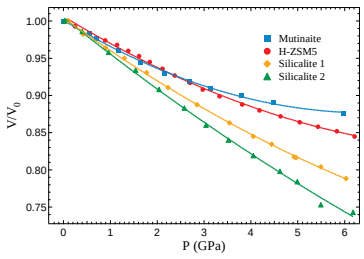

Fig. 2: Normalized unit cell volume vs. pressure behaviors for the studied phases.

Ion-exchange behavior of zeolite A

Lührs, H.[*], Derr, J., Gumbert, J. & Fischer, R.X.
Fachbereich Geowissenschaften, Universität Bremen, Germany
([*]hluehrs@uni-bremen.de)

Zeolites, especially Linde Type A zeolites ($Na_{12}Al_{12}Si_{12}O_{48} \cdot 27H_2O$, Na-A), have a high potential as cation exchangers with high selectivities. These properties are due to their uniform network of channels and pores, formed by the aluminosilicate framework, occupied by exchangeable cations and water molecules. Zeolite A represents one of the most extensively studied zeolites. We present here some additional information on its Ca, K, and Ba exchanged forms and its characterization by X-ray diffraction methods and thermal analyses.

Full cation exchanges of Ca, K and Ba were performed on Na-A using 0.1 and 1.0 molar solutions of the respective chloride salts. Experiments were carried out at room temperature and at 90°C, for periods between 30 minutes and seven days. For the Ca exchange, two different sources of Na-A materials were used. By static exchange methods a series with varying compositions between Na-A and Ca-A was synthesized.

The cation exchanged samples were characterized by X-ray powder diffraction (XRD) methods, including Rietveld refinements in space group $P\,m\,\bar{3}\,m$. In addition, scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX) techniques were performed on selected samples.

Na-A was completely Ca, K and Ba exchanged, all exchanges resulted in changes of lattice parameter *a*. For the Ca and Ba experiments these are clearly visible as peak shifts in the respective diffraction patterns. Rietveld refinements for the Ca exchanged samples revealed a linear dependence of lattice parameter *a* on the degree of exchange. For high Ca-contents, *a* is significantly smaller for Ca-A than for Na-A, which is in accordance with [1]. A trend towards larger values for *a* can be observed with decreasing degree of exchange. At very low Ca contents, *a* tends to become even larger than the corresponding value for Na-A. The K exchanged samples show a similar behavior. However, variation of *a* is distinctly smaller than for Ca-A which is in accordance with literature data [2]. Thermal analysis of the Ca-A series yielded a linear relationship between the degree of exchange and the water content.

The refined lattice parameters for Na-A and Ba-A are somewhat smaller than the ones reported in literature [3,4]. For the Ba exchanged samples, Rietveld refinements yielded significantly smaller lattice parameters *a* compared with the Na-form. The reduction of intensities in the X-ray diffraction data of the Ba-exchanged samples compared with the original Na-A zeolite is entirely due to the absorption effects introduced by Ba replacing Na, resulting in a reduction of the volume of the sample exposed to the X-ray beam. Thus, the loss of intensity does not indicate any destruction or amorphization of the crystalline zeolite.

Acknowledgements: We thank Wolfgang Schmidt (MPI, Mülheim a.d. Ruhr) for providing powdered samples of Na-A, Petra Witte (Bremen) for the EDX analyses.

The (Al,Si)-ordered zeolites of the Bellerberg, Eifel area (Germany): the particular flörkeite case

Lengauer, C.L.[1*], Kolitsch, U.[2] & Tillmanns, E.[1]
[1]Inst. für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria ([*]christian.lengauer@univie.ac.at)
[2]Mineralogisch-Petrographische Abteilung, Naturhistorisches Museum, Vienna, Austria

Flörkeite, $K_3Ca_2Na[Al_8Si_8O_{32}]\cdot 12H_2O$, is a new phillipsite-type zeolite, which was found in a Ca-rich xenolith from a quarry at the Bellerberg volcano near Ettringen, East Eifel volcanic area, Germany [1]. Prior to the finding of flörkeite, the Bellerberg volcano was also known as the type locality of the rare zeolites willhendersonite, bellbergite and tschörtnerite. Similar to flörkeite, all these zeolites exhibit (Al,Si) ordering [2]. Up to now no structurally related compound is known for tschörtnerite. Willhendersonite and bellbergite, however, represent the (Al,Si)-ordered analogues of chabazite and synthetic zeolite TMA-E [3], respectively.

The unit-cell parameters of flörkeite with space group *P*1 in the phillipsite-type cell setting are: a = 19.965(1), b = 14.274(1), c = 8.704(1) Å, α = 88.37(1), β = 125.08(1), γ = 89.57(1)°. In comparison to phillipsite with $P2_1/m$ symmetry (a ~ 9.9, b ~ 14.3, c ~ 8.7 Å, β ~ 124.5°), it is apparent that flörkeite exhibit a pseudomonoclinic, triclinically distorted unit-cell metric accompanied by a doubling of the *a*-parameter. The most significant change in the framework of flörkeite is the (Al,Si) ordering at the *T*-sites. As a consequence, *i.e.* the loss of the mirror planes and the pseudo-monoclinic distortion of the framework, the topochemical symmetry [5] of flörkeite is reduced to *B*2/*b*. The doubling of the *a*-parameter is induced by an ordering of the extra-framework constituents in the channel system along **a**. Basically responsible are alternating sequences of atom pairs with non-equivalent scattering factors and $\Delta \sim a/2$: Ca1–□–Ca1, Ca2–Na1–Ca2 and K3–OW2–K3. In contrast, K1 and K2 and their bonded ligands follow a phillipsite-type ordering with $a/2$.

Among the special extra-framework sites of zeolite-type compounds the centre of 8-rings is known to be a favoured site for the emplacement of large cations. As a further inference, one can state that a high K content in the crystallization environment is the predominant controlling variable during the formation of flörkeite and high-K batches will be required for possible syntheses routes of flörkeite-type tecto-aluminosilicates. Additionally, the observed (Al,Si) ordering can be attributed to the unusual, low-thermal conditions of formation within the Ca-rich xenolithic host, as it is also indicated by the co-occurrence of the already mentioned (Al,Si)-ordered zeolites.

From minerals to materials: tetrahedral sheets with $4^1 8^1$ and $4^1 5^1 6^1 8^2$ topologies as bricks to build heteropolyhedral microporous silicates

Cadoni, M. & Ferraris, G.[*]
Dipt. di Scienze Mineralogiche e Petrologiche & Nanostructured Interfaces and Surfaces (NIS), Centro di Eccellenza, Università di Torino, Italy
([*]giovanni.ferraris@unito.it)

A *ring symbol* is defined as a sequence $p_1^{r1}p_2^{r2}...p_n^{rn}$, where p_1, $p_2...p_n$ are numbers of nodes in a ring and r_1, $r_2...r_n$ are relative numbers of the corresponding rings in a graph [1]. If the nodes represent TO$_4$ tetrahedra, one obtains two-dimensional sheets that occur in (alumino)silicates and not necessarily are strictly planar. Some geometrical aspects of these sheets have been analysed [2, 3] emphasising the presence of wollastonite-type chains that condense to form xonotlite-like double chains containing eight-rings. The condensation of the double chains leads to $p_1^{r1}p_2^{r2}...p_n^{rn}$ sheets. A detailed nomenclature to classify the tetrahedral sheets, in particular naming tertiary, quaternary and non-tertiary those tetrahedra sharing three, four and less than three vertices, has been introduced [2]. The most common $p_1^{r1}p_2^{r2}...p_n^{rn}$ silicate sheet is 6^1 that occurs in layered silicates like micas, where all tetrahedra are pointing to one direction being generated by periodic repetition of a pyroxene-like chain. Mixed up- (*u*) and down-pointing (*d*) tetrahedra allow the formation of geometrical isomers. If only tertiary tetrahedra occur T/O = 2/5, as in micas and in the REE compounds described here [4]; the presence of non-tertiary tetrahedra implies T/O < 2/5; finally, quaternary tetrahedra require T/O > 2/5 and the sheet must be either branched or doubled to form microporous layers, as in the rhodesite series [5,6].

The sheets can act as building bricks (modules) either of *s.s.* layered structures, where the strong bonds are confined within layers that are interconnected by weak bonds (typically phyllosilicates), or of heteropolyhedral frameworks. The latter are obtained when the silicate sheets are interconnected by strong bonds *via* five-, six-, or seven-coordinated polyhedra and often are crossed by channels. Heteropolyhedral microporous structures are modular structures [7] and those occurring in the mineral realm [8] often were the incentive for the synthesis of compounds for technological applications. In heteropolyhedral structures the non-tetrahedral coordination polyhedra (typically octahedra) can host a variety of cations; thus, the frameworks offer a range of crystal-chemical opportunities far wider than in pure tetrahedral frameworks like zeolites.

The synthesis and structural characterisation of new heteropolyhedral microporous silicates [four with formula $A_3REESi_6O_{15}\cdot 2.25H_2O$, based on $4^1 5^1 6^1 8^2$ sheets (A = Na, K, H_3O; REE = Ce, La, Eu), and four members of the rhodesite mero-plesiotype series, based on $4^1 8^1$ sheets] will be presented. In the first group heteropolyhedral channels with an effective channel width (*e.c.w.*) ~ 4.5 x 2.8 Å occur; the second group shows tetrahedron-delimited channels with *e.c.w.* ~ 3.5 x 3.8 Å.

Analcime formation from alkaline hydrothermal alteration of bentonite

Fernández, R.*, Vigil de la Villa, R. & Cuevas, J.
Dept. of Geology and Geochemistry, Faculty of Science,
Autonomous University of Madrid, Spain
(*raul.fernandez@uam.es)

Analcime is one of the most common rock-forming zeolites. It forms in a wide range of geologic environments, from diagenesis of volcanoclastic sediments to precipitation in alkaline saline lakes at the surface of the earth. In all settings, the formation of analcime is very sensitive to chemical potential of SiO_2.

The interaction of cement pore fluids with bentonite is studied within the context of radioactive waste disposal due to the long term stability required for the materials used as engineered barriers. Calcium silicate hydrates and zeolites are the main secondary minerals produced by the alkaline alteration of bentonite.

Laboratory experiments in batch reactors were performed with bentonite and alkaline NaOH solutions at $Ca(OH)_2$ saturation (1:3 solid:liquid reactant mixture). Different geochemical conditions were used (NaOH concentrations of 0.1, 0.25 and 0.5 M, temperatures of 25, 75, 125 and 200 ºC, and reaction times of 1, 6, 12 and 18 months).

Analcime is observed to precipitate with changing morphology and composition as a function of the experimental conditions. Only minor precipitation of analcime is observed at 75 ºC with the highest NaOH concentration (0.5 M), but massive precipitation (20–35 % wt. in bulk reacted mixture) at higher temperatures (125 and 200 ºC), even with the NaOH 0.1 M solutions.

In general, Na is the dominant cation in the structural formula of the analcime formed, but also Ca becomes relevant in the composition at long time (12 and 18 months) with the lower concentrations of NaOH solutions (0.1 and 0.25 M) and could be related with the isostructural zeolite, wairakite. K and Mg are present but always remain in low concentration.

The Si/Al ratio in analcime is mainly controlled by the hydroxide concentration in solution. The decrease in pH observed in the reaction as a function of time produces a change in solubility of aluminosilicates, increasing thereby the Si/Al ratio.

The Si/Al ratio is related with the morphology of analcime observed by SEM (Scanning Electron Microscope). Hemihedral symmetry is observed in analcimes with lower Si/Al ratio and holohedral symmetry in analcimes with higher Si/Al ratio, being all values comprehended within a wide range (1.8–3.2).

In order to evaluate the chemical stability of the formed analcimes with different compositions and relate it with the potential geochemical conditions that will occur in a radioactive waste repository, a thermodynamic study has been applied, making use of the available thermodynamic data in literature (see [1]). The results of this study can be compared with the formation of other zeolites in similar experiments [2].

ZeoBase, a database for more than 5,000 standardized and corrected zeolite entries

Baur, W.H.[1] & Fischer, R.X.[2*]
[1]Dept. of Chemistry, Northwestern University, Evanston, USA
[2]Fachbereich Geowissenschaften, Universität Bremen, Germany
([*]rfischer@uni-bremen.de)

ZeoBase is a database for crystal structure data of zeolite-type compounds and minerals. Currently, it contains more than 5,000 entries with space groups, lattice parameters, atomic coordinates, chemical compositions and full references. Its unique characteristics are the standardized setting of all crystal structures and the individual examination of every data set for correctness, and internal and external consistency. The standardization procedure introduced in [1-3] allows the easy comparison of structural parameters and the unambiguous assignment of framework atoms to their sub- and supergroup counterparts, without being limited by space-group symmetry or settings. Thus, this set of crystal structure data provides information uniquely useful for the correlation of a host of structural and physico-chemical relationships. More than 40% of the data sets have been corrected or amended by additional information. Most of the entries contain additional information on synthesis and chemical composition.

The retrieval system of ZeoBase currently offers the following search options: zeolite name, framework type code, authors, year of publication, framework density, crystal system, T-O distances and their standard deviations, and chemical elements present in the zeolites as well as original and standardized space groups, unit-cell volumes, and lattice parameters. The possibility to select entries by their estimated standard deviations allows to list entries by the quality and accuracy of the structure determination. In addition, a number of keywords concerning method of sample preparation and treatment, and data collection is searchable.

The results can be displayed as tables, plots, or histograms. Data can be exported as cif files or they can be directly passed to the structure drawing program STRUPLO and the Rietveld program BRASS, where powder-diffraction diagrams can be calculated.

Since the names and labels of all individual atoms in each of the topologically identical crystal structures are standardized, one can follow particular bond lengths or bond angles in their symmetry-related changes from zeolite to zeolite. This can be visualized by plots that display various properties, such as framework density, mean bond lengths or angles, individual bond lengths or angles or chemical composition [4]. This is useful for studying the flexibility of zeolites as a function of their geometry, their topology or their chemistry. In addition one can see which zeolites can accommodate which cations within their frameworks or which frameworks can tolerate which exchangeable cations within their pores [4].

Synthesis of zeolite X from fly ash at 25°C by using seawater. The role of cations in crystallization

Belviso, C.[1*], Cavalcante, F.[1], Huertas, J.[2] & Fiore, S.[1]
[1]IMAA – CNR, Tito Scalo, Potenza, Italy
[2]CSIC, Granada, Spain

In this study an Italian coal fly ash was converted into zeolite in laboratory experiments with crystallization temperatures of 25°C. Distilled water and natural seawaters with different salinity (W1 and W2) were used during the hydrothermal synthesis (Table 1).

Table 1: Artificial and natural seawater composition (Values in g/L – salinity g/kg)

	Salinity	Cl^-	Na^+	SO_4^{2-}	Mg^{2+}	Ca^{2+}	K^+	B^{3-}	Sr^{2+}
Artificial seawater	35.000	19.353	10.764	2.701	1.297	0.406	0.387	0.066	0.014
Seawater - W1	26.300	14.542	8.486	2.000	1.034	0.374	0.333	0.046	0.013
Seawater - W2	38.000	24.560	12.621	3.129	1.473	0.518	0.487	0.062	0.018

The results indicate that X-type and A-type zeolite crystallization takes place by using seawater with higher salinity (W2), whereas no new mineral forms in distilled water (Fig. 1).

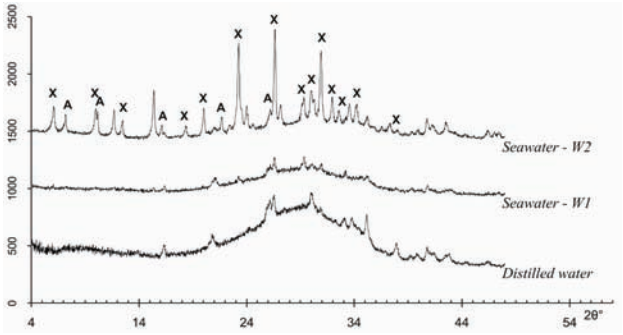

Fig. 1: XRD patterns of fly ashes incubated with: distilled water; W1 and W2 - seawater. X = zeolite X.

To minimize the biological effects and determine the role of different ions during the synthesis with seawater, experiments using artificial seawater and solutions with a salts concentration comparable with that of the single salts present in artificial seawater were carried out. In particular the effect of Na^+, Mg^{2+}, Ca^{2+} and Cl^- was studied and it was found that their availability in the solution accelerates the zeolite formation at a very low temperature (25°C) (Fig. 2)

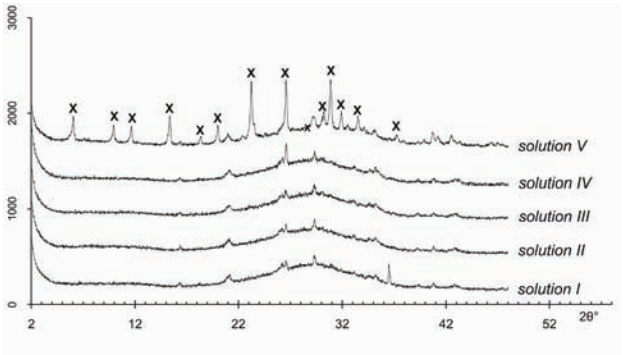

Fig. 2: XRD patterns by using different solutions corresponding to the total amount of NaCl (Solution I); MgCl (Solution II); CaCl (Solution III); C^- (Solution IV); NaCl plus MgCl (Solution V).

Mg^{2+} combined with Na^+ controls the process of synthesis. The dissolution process of alluminosilicate glass at higher incubation temperatures significantly reduces the effect of cations present in salt solution.

Melanophlogite: the only known natural molecule-containing SiO_2 clathrate

Geiger, C.A.* & Dachs, E.
Fachbereich Materialforschung und Physik, Universität Salzburg, Austria (*chg@min.uni-kiel.de)

Melanophlogite is the only known naturally occurring SiO_2 clathrate. It can occlude quasi-free N_2, CO_2, CH_4 and H_2S molecules but not H_2O in its micropores [1]. It has been reported from a number of localities worldwide in different low-temperature geologic environments. Melanophlogite's thermodynamic stability is not known. Low-temperature hydrothermal synthesis experiments indicate that structure-directing agents are needed for crystallization. The formation of silica-rich colloids/gels and crystal growth can be observed in glass-ampoule synthesis experiments. Other clathrasils/porosils have been synthesized in the laboratory but not found in nature.

In order to address the question of the thermodynamic stability of melanophlogite, the heat capacity of two different natural samples of approximate composition $46SiO_2 \cdot 1.80CH_4 \cdot 3.54N_2 \cdot 1.02CO_2$ from Mt. Hamilton, CA and $46SiO_2 \cdot 3.59CH_4 \cdot 3.10N_2 \cdot 1.31CO_2$ from Racalmuto, Sicily, along with a heated (molecule-free) sample of composition SiO_2, were studied between 5 and 300 K using relaxation microcalorimetry. The molecule-free sample was obtained by heating crystals from Racalmuto at 1173 K for 24 hr.

The standard third-law entropy of the molecule-free sample is S° = 2216.3 J/(mol·K) for 46 SiO_2 and the natural Mt. Hamilton and Racalmuto samples give S° = 2805.7 J/(mol·K) and S° = 2956.8 J/(mol·K), respectively. The entropy and the Gibbs free energy for molecule-free melanophlogite relative to quartz at 298 K are ΔS_{trans} = 6.7 J/(mol·K) and ΔG_{trans} = 7.5 kJ/mol, respectively. Thus, it does not have a thermodynamic field of stability in the SiO_2 system. The difference in C_p values between molecule-containing and molecule-free melanophlogite is characterized by an increase in C_p from 0 K to approximately 70 K and then reaches a roughly constant value at 70 K < T < 250 K. The ΔS_{rxn} at 298 K for $46SiO_2$(melan.) + xCH_4(gas) + yCO_2(gas) + zN_2(gas) = $46SiO_2 \cdot (xCH_4)_{12} \cdot (yCO_2,\ zN_2)_{14}$ is estimated to be about -642 J/(mol·K) and -802 J/(mol·K) for the Mt. Hamilton and Racalmuto samples, respectively.

The thermodynamic data, as well as published results on the occurrence of natural samples and associated phases such as cristobalite and chalcedony, suggest that melanophlogite can crystallize metastabily and possibly from a gel. The occurrence of melanophlogite and the lack of other SiO_2 clathrates/porosils in nature are probably due to the essential role of molecular structure-directing agents. For melanophlogite they can be CO_2, N_2 and CH_4, whereas the crystallization of other clathrate/porosils requires more chemically and structurally complex molecules that are not naturally abundant. Thus, many porosils that have been synthesized in the laboratory are not expected to be found in nature. Dodecasil 3C is an exception and an effort should be made to find natural specimens.

New structural data on cation-exchanged forms of hilairite

Grigoryeva, A.A.*, Zubkova, N.V., Pekov, I.V., Turchkova, A.G. & Pushcharovsky, D.Yu.
Geology Dept., Moscow State University, Moscow, Russia (*arina1984@bk.ru)

Hilairite, $Na_2Zr[Si_3O_9] \cdot 3H_2O$, is a natural microporous zeolite-like zirconosilicate with the structure based on the heteropolyhedral framework. The framework consists of isolated $[ZrO_6]$ octahedra and infinite helical chains $[Si_3O_9]_\infty$. Zeolitic cavities of the framework are occupied by Na cations and H_2O molecules [1]. Among natural zirconosilicates hilairite and the representatives of hilairite group are characterized by the widest pores. This fact provoked the study of the cation-exchange properties of hilairite under different conditions and the study of crystal chemistry of the received forms [2,3, this work]. For the cation-exchange experiments we used hilairite from the Hilairitovoye pegmatite, Kirovskii apatite mine, Mt Kukisvumchorr, Khibiny alkaline complex, Kola Peninsula, Russia. Crystal structure investigation of the hilairite from Khibiny [4] (sp. gr. *R*3, *a* = 10.5530(5), *c* = 7.9541(4) Å; R_{hkl} = 0.0280) indicated the formula $Na_{1.64}H_{0.36}ZrSi_3O_9 \cdot 3H_2O$ (small amount of H^+ here and in cation-exchanged forms were assumed to charge-balance the formulae and can be considered as the result of the first stage of cation-exchange experiments or possibly as a part of H_3O^+ cations partially substituting H_2O). It should be noted that hilairite from Khibiny has identical symmetry and Zr,Si,O-framework with previously studied hilairite from Lovozero massif [1] but differs from the latter by the localization of Na and H_2O in the cavities of the framework. This leads to the halved *c*-parameter of the studied sample in comparison with the hilairite from Lovozero.

Cation-exchange experiments were carried out in 1*M* aqueous solutions of $RbNO_3$ and $Pb(NO_3)_2$ at 90°C and in 1*M* aqueous solutions of KCl and $CsNO_3$ at 150ºC. Crystal structure study of the four cation-exchanged forms allowed revealing the following structural formulas: $Rb_{1.48}Na_{0.45}H_{0.07}ZrSi_3O_9 \cdot 0.53H_2O$ (sp. gr. *R*3, *a* = 10.4743(4), *c* = 15.5433(7) Å; R_{hkl} = 0.0413) and $Pb_{0.60}Na_{0.40}H_{0.40}ZrSi_3O_9 \cdot 3H_2O$ (sp.gr. *R*3, *a* = 10.4718(3), *c* = 7.9392(2) Å; R_{hkl} = 0.0387) for Rb- and Pb-exchanged hilairites; $K_{1.81}Na_{0.09}H_{0.10}ZrSi_3O_9$ (sp.gr. *R*3, *a* = 10.3804(2), *c* = 14.9541(6) Å; R_{hkl} = 0.0526) and $Na_{1.14}Cs_{0.55}H_{0.31}ZrSi_3O_9 \cdot 0.90H_2O$ (sp.gr. *R*32, *a* = 10.5472(4), *c* = 15.8797(7) Å; R_{hkl} = 0.0423) for K- and Cs-exchanged hilairites.

All studied structures as well as the objects of previous investigations of cation-exchanged forms of hilairite [2,3] retain heteropolyhedral framework consisting of $[ZrO_6]$ octahedra and $[Si_3O_9]_\infty$ chains. At the same time strong deformation of the framework leads to the doubling of the *c*-parameter and the symmetry decrease from *R*32 to *R*3 in the structures of K- and Rb-exchanged forms of hilairite. In the structure of Pb-exchanged hilairite a slight distortion of the framework leads to the sp. gr. *R*3 but the value of *c*-parameter is close to those found for the initial sample. The heteropolyhedral framework in the structure of Cs-exchanged hilairite is not distorted. The doubling of the *c*-parameter is caused by the positions of extra-framework cations and H_2O molecules.

Diagenetic zeolite formation / dissolution during burial diagenesis, and its influence on further cementation - examples from the Siri Canyon, Danish North Sea

Kazerouni, A.M.[1*], Weibel, R.[2], Friis, H.[1] & Svendsen, J.B.[3]
[1]Dept. of Earth Sciences, Aarhus University, Aarkus, Denmark
([*]afsoon.moatari@geo.au.dk)
[2]Geological Survey of Denmark and Greenland, Copenhagen, Denmark
[3]DONG Energy, Exploration and Production, Denmark

The Siri Canyon is a submarine canyon system eroded into the uppermost Chalk deposits and filled in with Palaeogene hemipelagic and turbiditic marls and mudstones interbedded with sandstones deposited from sandy mass-flows and turbidites. Core samples from 7 wells were studied. The reservoir sands in these wells all contain authigenic silica/quartz of various morphologies identified with a combination of traditional optical microscopy and scanning electron microscopy.

Late Paleocene–early Eocene volcanic ash layers are recognized throughout most of the North Sea and also recorded from the Siri Canyon wells. Volcanic lithoclasts are strongly altered and associated with diagenetic opal/ microquartz coatings and zeolite. Zeolite crystals formed simultaneously with opal and prior to microquartz but dissolved with increased burial depth. The dissolution of zeolite followed two steps; the core of the zeolite crystals appears to have been more unstable than the rim and dissolved first. Later the entire crystal dissolved and left an impression of the euhedral zeolite crystal in the microquartz coating. Such openings in the microquartz coating are nucleation points for macroquartz. Thus, the precipitation of zeolite may later facilitate further quartz cementation, which might otherwise be retarded by the presence of disordered microquartz.

The silica activity of pore fluids can influence zeolite precipitation. Although zeolite formation is clearly related to volcanic ash, zeolite has also formed in samples where no volcanic ash is demonstrated; it seems that a rapid supply of dissolved silica from dissolution of siliceous fossils was the main reason for the early co-precipitation of opal and zeolite.

There are two important sources for Si: 1) Biogenic opal from diatoms or radiolarians, which are abundant in some of associated shales; and 2) volcanic ash.

The dissolution of biogenic silica may result in a rapid release of silica thereby promoting the formation of diagenetic opal/microquartz, but there may be a limited release of Al. A limited release of Al may result in precipitation of Si-rich clinoptilolite, or zeolite may not precipitate at all. The dissolution of volcanic lithoclasts may also release a high rate of Al, resulting in abundant formation of Al-rich clinoptilolite. If both sources interact, a compositional variation may occur with time. The compositional variation may result in variable solubility and give rise to dissolution of the internal core prior to its rim. This dissolution behavior may have impact on the further quartz cementation.

The formation of various quartz morphologies influences the continued cementation by macroquartz. This effect may be counteracted by precipitation/dissolution of zeolite.

Occurrence and chemistry of natrolite group zeolites from Bakony–Balaton Highland Volcanic Field (West Hungary)

Kónya, P.[1*] & Szakáll, S.[2]
[1]Geological Inst. of Hungary, Budapest, Hungary
([*]kope@mafi.hu)
[2]Dept. of Mineralogy and Petrology, University of Miskolc, Hungary

Cavities of alkaline basalt of the Bakony–Balaton Highland Volcanic Field (BBHVF) contain miarolitic minerals, zeolites (phillipsite, chabazite, garronite, gmelinite, gobbinsite gismondine, analcime, leucite and natrolite group zeolites), carbonates (calcite and aragonite) and smectite (saponite and nontronite). Natrolite group minerals (natrolite, mesolite, scolecite, gonnardite, paranatrolite and thomsonite) of zeolites were investigated in detail. This assemblage was characterized by X-ray, DTA and WDS methods.

Natrolite usually occurs as colourless, translucent or transparent prismatic crystals up to 5 mm. It is frequently epitaxially intergrown with mesolite, scolecite and paranatrolite in radial aggregates. Gonnardite is a common zeolite mineral at BBHVF. It often occurs as epitaxial overgrowths with glassy, prismatic natrolite and thomsonite. It frequently appears as white centres (up to 1.5 cm in diameter) within hemispherical natrolite or thomsonite aggregates, but can also be observed as homogenous aggregates. Thomsonite commonly appears as white radial aggregates or epitaxially overgrown with gonnardite.

The natrolite has a significant CaO content, similar to a general character in many natrolites worldwide. Its R is between 0.59 and 0.61 Na/(Na+Ca) ratio of 0.94-0.99 close to the theoretical value (1.00). Chemical analyses show that gonnardites have a wide variation in CaO content (1.20 to 7.26). Si/Al ratio is between 1.21 and 1.45, the value of R ranges from 0.55 to 0.59. The Na/(Na+Ca) ratio (0.65-0.96) is also variable, reflecting, that all gonnardites are Na end-members. Scolecite has a significant Na_2O content, its Na/(Na+Ca) ratio is 0.28-0.34. Mesolite has a little higher concentration of Na than the ideal mesolite. The value of R is 0.58 to 0.59. It has a Na/(Na+Ca) ratio of 0.54-0.56. Si/Al ratio is 1.40. Paranatrolite has a higher CaO content than natrolite. Its lower Na/(Na+Ca) ratio (0.92) reflects more intensive $Ca \leftrightarrow Na_2$ substitution than in natrolite. Based on the WDS analysis the Na/(Na+Ca) ratio of thomsonite is 0.41-0.46, showing that it is a Ca end-member (Fig. 1).

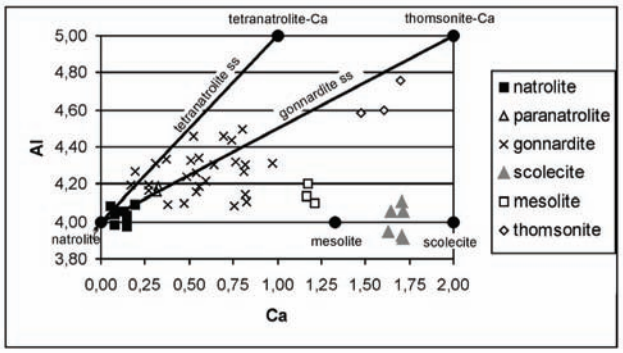

Fig. 1: Ca and Al contents per 20 framework O atoms per formula unit of samples (after Neuhoff et al. [1])

Raman spectroscopic study of zeolite group minerals

Hong, H.T.[1], Huang, E.[2], Liu, T.C.[1*] & Iizuka, Y.[3]
[1]Dept. of Earth Science, National Taiwan Normal University, Taipei, Taiwan ([*]liutc@ntnu.edu.tw)
[2]Center for General Education, ChungChou Institute of Technology, Chang-Hwa, Taiwan
[3]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan

Twenty-one natural zeolite and ten synthetic zeolite samples were studied by Raman spectroscopy and analyzed by electron microprobe. The results showed that the zeolites with the same secondary building units have similar Raman spectroscopic pattern. However, the fine structure of the Raman spectrum varies with their chemical compositions. The most distinguished Raman peaks show up between 390 cm^{-1} and 530 cm^{-1} in zeolites. These peaks represent the vibration of T-O-T (T=Si, Al) in tetrahedron, the low frequency M-O vibration mode (M are cations: Ca, Na, K etc.), and the high frequency T-O vibration mode.

The main frame in the structure of zeolites is the interconnection of SiO_4 and AlO_4. The Raman spectrum may shift with the replacement of Si by Al. With the increase of Al content, the Raman peaks at 440 cm^{-1} and 530 cm^{-1} shift slightly to higher wavenumber. This may be attributed to the smaller angle in T-O-T as Si is replaced by Al. The most obvious Raman vibration modes in the single 4-ring chains and double 4-ring chains are at 400 cm^{-1}, 480 cm^{-1}, and 490 cm^{-1}, respectively. They shift toward lower wavenumber with an increase of Al content. In zeolite, the most predominant Raman vibration modes are at 495 cm^{-1}, 480 cm^{-1}, and 491 cm^{-1}. However, these vibraton modes do not change with the variation of Al content. The T-O-T Raman vibration modes of heulandite are at 405 cm^{-1} and 482 cm^{-1}; whereas, the T-O-T Raman vibration modes of stilbite are at 410 cm^{-1} and 497 cm^{-1}.

The role played by boron in ANA type structure: potential trap for radioactive waste

Montagna, G.[1], Arletti, R.[1,2], Vezzalini, G.[1*] & Di Renzo, F.[3]
[1]Dept. of Earth Sciences, University of Modena and Reggio Emilia, Italy ([*]mariagiovanna.vezzalini@unimore.it)
[2]Dept. of Earth Sciences, University of Ferrara, Italy
[3]Inst. Charles Gerhardt Montpellier, Ecole Nationale Supérieure de Chimie de Montpellier, France

Zeolites show a highly accessible micropore system, an asset for cation removal from radioactive waste solutions but a drawback for long-term stockage. The structure of pollucite $CsAlSi_2O_6$ [1] is such that, once Cs^+ cations have been encapsulated in the aluminosilicate network, their loss is negligible. Hence the direct formation of pollucite in a waste solution can represent a promising method to immobilize cesium cations [2].

Boro-aluminosilicates were synthesized to verify the effect of boron content on cesium incorporation and retention in ANA structure. It is important to find a correct B amount that can promote sintering process without increasing the leaching rate [3].

Cs-bearing B-Analcime samples were hydrothermally synthesized using B/(B+Al) and Cs/(Cs+Na) in different ratios. Chemical and crystallographic data indicate that: i) the yield of incorporation of B is lower than that of aluminum in the intermediate terms of the solid solution; ii) a lower incorporation of B is observed in the Na-bearing samples; iii) the presence of B in the framework favors the Cs incorporation; iv) the presence of B and Na in the synthesis batch favors the complete crystallization of the product.

All the samples crystallize in the cubic system, space group $Ia\bar{3}d$. This result is in agreement with a disordered Si, Al and B distribution in the tetrahedra. The framework atom positions of all samples are strictly comparable to those of the natural analcime. The variability of lattice parameters depends on B content.

N-doped mesoporous TiO_2 as photocatalyst in textile wastewater treatment. The effect of the synthesis procedure

Păstrăvanu, C.[1,2*], Seftel, E.M.[1], Alexa, I.F.[1], Creţescu, I.[2] & Popovici, E.[1]
[1]Dept. of Materials Chemistry, "Al. I. Cuza" University of Iaşi, Iaşi, Romania ([*]cristinapastravanu@yahoo.com)
[2]Dept. of Chemical Engineering and Environmental Protection, "Gh. Asachi" University of Iaşi, Iaşi, Romania

Titania is the most effective photocatalyst and widely applied in air and water purification, deodorization, antibacterial and self-cleaning coating and other environmental applications. However, as a photocatalyst, titania can only be activated by UV light [1] because of its large bandgap value. Nitrogen doped into substitutional sites of TiO_2 has shown a narrowed bandgap as well as photocatalytic activity in the visible light [2].

We synthesized N-doped and non-doped mesoporous titania via hydrothermal and ultrasound methods using blockcopolymers (Pluronic P123 and F127) as surfactants and organic sources of Ti. Different types of N-doped and non-doped mesoporous titania were synthetised by varying the composition of the surfactant and nitrogen precursor. Characteristics of the prepared photocatalysts were investigated using UV absorbtion spectroscopy and N_2 adsorbtion-desorbtion technique.

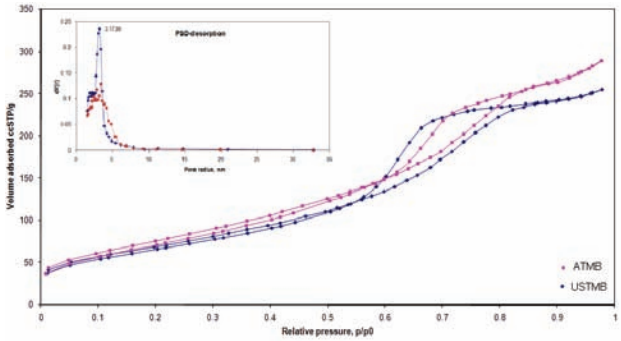

Fig. 1: Adsorbtion/desorbtion isotherms of the mesoporous titania (ATMB – via hydrothermal method; USTMB – via ultrasound method).

Mesoporous titania (N-doped and non-doped) were used as heterogeneous catalysts for the treatment of textile wastewater containing dyes. From the experimental results it was concluded that the N-doped mesoporous titania obtained by ultrasound method has higher photocatalytic activity as compared to N doped mesoporous titania prepared by hydrothermal method. Also, as expected, N-doped titania has proven to have higher photocatalytic activity than the undoped mesoporous TiO_2.

Mineralogy and properties of analcime-bearing rocks (Timan Region, Komi Republic, Russia)

Shushkov, D.
Inst. of Geology, Komi Scientific Center, Uralian Branch, Russian Academy of Sciences, Syktyvkar, Komi Republic, Russia (dashushkov@rambler.ru)

Analcime-bearing rocks from Carboniferous and Permian sediments occupy a vast area in the Timan – about 150,000 km^2. The Timan zeolite-bearing province dominated by analcime was discovered in the second half of the 20th century.

Analcime-bearing rocks are represented by siltstones and mudstones. Oligomictic and polymictic siltstones are characterized by spotty or irregularly bedded structures related to alternation of layers and nests of psammitic, silty, and pelitic material. The fine-grained material alternates with the coarse-grained material without any noticeable regularity in grain size. Silt-sized detrital particles are poorly rounded and sorted. Fragments of quartz, feldspar, volcanics and flakes of muscovite are cemented by the clayey and clayey–carbonate material. The cement has a spotty appearance owing to the presence of inclusions of reworked brown organic material of different tints. The cement has a basal and contact-basal pattern. Authigenic minerals are represented by sericite, chlorite, and pyrite.

Mudstones also have a spotty and irregularly bedded structure owing to the irregular development of ferrugination and different thicknesses of layers of inequigranular (psammitic and silty) material. Coarse-grained particles are represented by quartz, feldspars, carbonates, and volcanics. Pyrite and iron hydroxides are also present.

The analcime-bearing rocks have the following mineral composition (%): clay minerals (50–70), quartz (10–30), analcime (1–30), feldspars (2–10), carbonates (2–5), and pyroclastic material. The clay minerals are represented by disordered, mainly swelling, mixed-layer phases (illite-smectite, illite-chlorite), while kaolinite and chlorite are insignificant.

Analcime is found as isometric crystals, microoolite concretions, microgeode aggregates or cryptocrystallic cement. Analcime aggregates encrust roundish and oval cavities and also fill microfractures in rocks. Thin sections clearly reveal different stages of cavity filling by analcime – from insignificant encrustation to completely filling. Generally analcime aggregate has a different structure. Both thin-crystalline (size less than 0.01 mm) and medium-crystalline (crystal size of about 0.5 m) are observed. Intensively altered argillaceous-silica material is practically always present.

The mechanical, gravitational, magnetic, sorption and ion-exchange properties of analcime-bearing rocks have been studied. They are characterized by a high index of grindability and a low index of breakability and crush resistance, low values of the benzol-based pore volume and toluene-based specific surface area, and a medium porosity value.

Analcime-bearing rocks of the Timan region are characterized by low beneficiation potential. Preliminary ultrasonic treatment of the analcime-bearing rocks is efficient for the destruction of intergrowths along their boundaries and production of free analcime aggregates. The proposed beneficiation procedure yields 95 % analcime concentrate.

In the Komi Republic, analcime-bearing rocks are utilized in agriculture. They are also used for domestic needs (e.g. as biotoilets for domestic animals) and the solution of ecological problems (regeneration of soil polluted by oil). We have completed experiments on the purification of potable and industrial water using analcime-bearing rock subjected to thermal treatment. The experiments demonstrated that it was possible to decrease water coloration, turbidity, permanganate oxidation and total iron content.

Cation exchange properties of delhayelite (systems with Rb, Cs and Ba)

Turchkova, A.G.*, Pekov, I.V. & Yapaskurt, V.O.
Faculty of Geology, Moscow State University, Moscow, Russia
(*annaturchkova@rambler.ru)

The base of the crystal structure of delhayelite, ideally $K_4Na_2Ca_2[AlSi_7O_{19}]F_2Cl$ (Z=2), is a quasi-framework formed by two-layer tetrahedral blocks $[(Al,Si)_4Si_{12}O_{38}]$ and columns of CaO_5F octahedra linking them. K^+ and Cl^- ions are located in zeolite-like channels inside the tetrahedral block whereas Na^+ and F^- are between the blocks. Delhayelite is the only natural silicate with so strict ordering of both large cations and halogen anions. The mineral was formed in K-rich and H_2O-deficient, high-temperature peralkaline rocks. Under hydrothermal conditons, it alters to fivegite, $K_4Ca_2[AlSi_7O_{17}(O_{2-x}OH_x)][(H_2O)_{2-x}OH_x]Cl$ (x=0-2), and further to hydrodelhayelite, $KCa_2[AlSi_7O_{17}(OH)_2]\cdot(6-x)H_2O$, preserving the stable CaAlSiO fragment of the structure [1,2]. It caused our assumption that delhayelite can have ion-exchange properties.

Grains (0.5–3 mm) of delhayelite from the Khibiny alkaline complex (Kola Peninsula, Russia) were placed in 1N aqueous solutions of Na_2SO_4, K_2SO_4, $RbNO_3$, $CsNO_3$, $SrCl_2$, $BaCl_2$ and $CuSO_4$ for 3 hours at 80-90ºC and 1 atm and after that examined on polish sections using scanning electron microscopy and electron microprobe. In solutions of Na, K, Sr and Cu salts, the mineral shows no changes in its chemical composition while with cations Rb, Cs and Ba it demonstrates exchange. The distribution of cation-substituted areas in delhayelite crystals is very uneven: they are mainly concentrated around inner cracks and mineral inclusions. Ratios of Si, Al and Ca, forming the quasi-framework, remained without changes in these areas whereas contents of Rb_2O, Cs_2O and BaO increased from 0.0 wt.% in the initial delhayelite to 8.5–11.9, 10.1–27.0 and 8.5–11.3, respectively. In the Rb-exchanged form, content of Na_2O decreased from 6.4–6.7 wt.% to 1.2–2.5, K_2O from 19.2–19.8 to 3.5–7.2, F from 4.3–4.6 to 1.0–2.5, Cl from 3.8–4.1 to 1.0–1.8. In the Cs-exchanged form, their contents (wt.%) became: Na_2O 0.0–2.0, K_2O 0.9–8.8, F 0.0, Cl 0.0–1.8; in Ba-exchanged form: Na_2O 0.5–1.7, K_2O 3.3–9.8, F 0.0–2.4, Cl 0.6–1.8. Delhayelite shows the strongest affinity to Cs^+, and its most Cs-enriched form has the empirical formula: $Cs_{1.67}K_{0.16}Ca_{1.85}Al_{1.06}Si_{6.94}O_{17.47}(OH)_{1.53}(H_2O)_n$. It is most probable that large cations of Rb, Cs and Ba substitute K whereas Na and F are leached and the latter is partially replaced by H_2O.

Stepwise dehydration of goosecreekite: a structural study

Wadoski, E.*, Armbruster, T., Lazic, B. & Fisch, M.
Mineralogical Crystallography, Inst. of Geological Sciences, University of Bern, Switzerland (*eva.wadoski@krist.unibe.ch)

Goosecreekite $CaAl_2Si_6O_{16}\cdot5H_2O$, monoclinic space group $P2_1$, is a rare natural zeolite that was first described by [1] and has been further characterized by crystal structure determination [2]. The framework consists of completely ordered Si and Al tetrahedra that form eight-membered rings which are highly deformed. These create channels that are parallel to the **a**-axis. The channels are intersected by two additional eight-membered ring-channels parallel to the **b**-axis and the **c***-axis. Ca is located at the intersection of the channels and is bound to two framework O and five H_2O molecules [2]. Samples were from the type locality in Loudon County, Virginia, USA and Jalgaon Quarries, Maharastra, India. Unit cell parameters measured under ambient conditions are a 7.2993(3), b 17.4164(7), c 7.4421(3) Å, β 105.584(2)°, V 911.32 Å^3 (Loudon sample). In contrast to the Loudon sample, crystals from Jalgaon were mostly twinned [001,010,100]. The structures of goosecreekite from both localities show identical frameworks and corresponding channel occupants. Methods for stepwise (Δ = 25°C) dehydration were temperature dependent single-crystal and powder XRD as well as TG/DTA analysis.

According to single-crystal structure refinement goosecreekite looses $1H_2O$ pfu below 100°C leaving the framework unaltered. The Ca coordination decreases from seven-fold to six-fold. TG/DTA indicates further loss of ca. 8 wt.% H_2O between 150 and 310°C accompanied by a strong endothermic DTA signal. Single-crystal X-ray data indicate collapse of the tetrahedral framework at 175°C with a doubling of the c-axis (quenched to -100°C: space group $P2_1$, a 7.2197(16), b 16.392(4), c 14.292(3) Å,β 101.716(4)°, V 1656.14 Å^3). In addition, the new structure exhibits complex twinning. Upon partial dehydration two T-O-T bonds break creating two structural varieties that occur in a 1:1 ratio. Variety I has the original framework connectivity. Variety II displays an interrupted framework with two tetrahedra "flipped" into the channels to bond with Ca. The flipped tetrahedra must be hydroxylated. A single crystal heated up to 230°C and left at ambient conditions for one month rehydrated, recovering the original cell parameters when re-measured. After one month a powdered sample previously heated to 325°C also rehydrated to its original structure. Up to ca. 600°C, the X-ray powder pattern characteristic of the collapsed structure persists. Upon further heating the pattern becomes increasingly X-ray amorphous until complete destruction at ca. 675°C.

An additional dehydration step occurring between 310° and 600°C which is associated with further loss of ca. one H_2O was identified by TG/DTA data. Variety II of the collapsed structure is predicted to become more prevalent relatively to variety I with increased heating.

Based on stepwise dehydration data of goosecreekite, it can be seen that if extraframework Ca has less than six ligands (two framework O and four H_2O), topologic structural changes occur, such as breaking of T-O-T bonds. These changes are reversible until the structure becomes amorphous. Similar "flipped" tetrahedra, which become hydroxylated in the new interrupted framework, have been described upon dehydration of stellerite, $CaAl_2Si_7O_{18}\cdot7.25H_2O$, B [3].

Mineral reactions, development of porosity and their implications for CCS

Stanjek, H.
Clay and Interface Mineralogy, RWTH Aachen University, Aachen, Germany (helge.stanjek@cim.rwth-aachen.de)

Injection of CO_2 into (saline) reservoirs disturbs the thermodynamic equilibrium conditions because apart from temperature and pressure changes, the chemistry of the pore fluid changes, too. The induced reactions of the reservoir minerals towards new mineral assemblages will be associated with volume changes, which, in turn, will affect the long-term management and safety of reservoirs because of the development of porosity.

In a case study we investigated the possibility of combining CO_2 injection with the extraction of geothermal energy from deep saline reservoirs, which frequently contain anhydrite [1]. For modelling the redistribution of anhydrite and its potential conversion into calcite, near-equilibrium dissolution rates of anhydrite were measured and found to deviate significantly from transition-state-theory rates.

A safety-related aspect is the formation of porosity and permeability in cap rocks.

In laboratory experiments we could show that under certain hydrodynamic conditions the dissolution of Fe-bearing calcite led to the formation of preferential pathways, along which acid could percolate through long columns of calcite powder because of the formation of iron hydroxide coatings. These coatings shield the calcite from protonation.

In a current study, the impact of CO_2 on clay minerals is investigated. Apart from mineral transformations (e.g., dissolution of feldspars), it seems that supercritical CO_2 affects the amount of interlayer water in smectites. Changes of the interlayer composition, however, can lead to substantial volume changes, which in turn, will affect the porosity and permeability of cap rocks. There are also indications that clay minerals (especially smectites) can store some CO_2.

CO_2/H_2O/clay system from molecular simulation

Botan, A.[1,2*], Rotenberg, B.[1], Marry, V.[1], Turq, P.[1] & Noetinger, B.[2]
[1]PECSA, Université Pierre & Marie Curie and CNRS, Paris, France ([*]alexandru.botan@upmc.fr)
[2]Inst. Français du Pétrole, Rueil Malmaison, France

The development and use of technologies to capture and subsequently store of carbon dioxide (CO_2) in deep geological formations offers significant opportunities to reduce greenhouse emissions. In this context, understanding the migration of stored CO_2 through the porous host formation and the clay-rich cap rock is of great importance. Up to now the main focus in the literature is placed on the two-phase flow in porous media on the macroscopic scale and as result there is a lack of studies on the molecular level. However, a microscopic description is necessary to study some processes (swelling, cation exchange) inaccessible to macroscopic scale methods. One such process is the possible clay dehydration due to the presence of CO_2 which can lead to a significant shrinkage of clay particles and affect the clay permeability. Furthermore, a molecular point of view can be also useful in study of two-phase flow in clay. The surface wettability, densities, viscosities obtained from molecular simulation can be basis for subsequent studies of transport properties by continuous methods. In this study, we first investigated the thermodynamical properties related to swelling and the structure of CO_2 in hydrated Na-montmorillonite for micropores using the grand canonical Monte Carlo method. The system is in equilibrium with a reservoir, which sets the chemical potentials of CO_2 and H_2O. We then used molecular dynamics to determine the diffusion coefficients for equilibrated configurations. Some important findings are: the presence of CO_2 leads to a slight increase in equilibrium interlayer distances and a considerable decrease in diffusion coefficients for all species; CO_2 adopts a nearly parallel arrangement to the clay surface.

We also considered large (interpaticle) pores. Similarly to the bulk reservoir, two states with different density and composition are generally observed for given experimental conditions (see Fig. 1). In this example, the system in "water-rich" phase (a) is characterized by the liquid density and a small number of CO_2, whereas in case (b) the "CO_2-rich" phase is heterogeneous with water remaining close to the clay surface and gas CO_2 in the middle. We then use nonequilibrium molecular dynamics to determine the viscosity of the confined fluids. This was achieved by applying a uniform force on the fluid and fitting the resulting velocity profile to a Poiseuille flow [1].

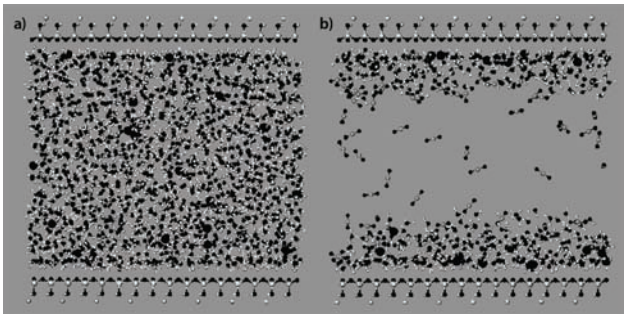

Fig. 1: Snapshots of phase transition of CO_2 in hydrated Na-montmorillonite: a)" H_2O-rich" phase, b)" CO_2 -rich" phase. The interlayer distance is 4.3 nm and the chemical potentials corresponds T=348.15 K and P = 25 bar in the bulk reservoir.

A high-pressure X-ray environmental chamber suitable for solid-liquid-gas studies

Guggenheim, S.* & Koster van Groos, A.F.
Dept. of Earth & Environmental Sciences, University of Illinois at Chicago, USA (*xtal@uic.edu)

An X-ray, high-pressure environmental chamber (HPEC) is described that is capable of pressures to 1000 bars and temperatures of -20 to 200°C. An integral, internal electromagnetic pump system was designed so that solid phases are maintained in suspension, thus allowing the sample to move freely in the aqueous liquid while being illuminated by the X-ray beam. In addition, the pump system allows the liquid to be readily saturated with gas (e.g., CH_4, CO_2, N_2). An external pump system is used to apply pressure, either using gas or liquid (e.g., CO_2 above the critical point). If gas is employed, this system controls the fugacity of the gas components by mixing with inert gases.

The HPEC is equipped with cooling jackets so that temperatures are varied by applying a cooling/heating fluid to the outside of the unit (using glycol or silicon liquid). This design readily accommodates experiments from -20 to 200°C. Window-to-window distances can be fixed from near 0.0 to ~4 mm, although a 2-mm spacing appears optimal. Most of our preliminary experiments have used this design. The unit uses 1-mm thick disks of vapour-deposited diamond as windows with O-ring seals, and employs a type-K thermocouple located at ~1 mm from the sample to measure temperature. The HPEC is mounted on an in-house, transmission-mode (Bruker) diffractometer equipped with Mo radiation, monochromator, MonoCap collimation, and area detector, although the design is compatible with transmission-mode diffractometers at the Advanced Photon Source (Argonne). The sample volume is ~10 mL, and catastrophic failure (of the O-rings) does not pose a significant hazard to either personnel or equipment.

Resultant diffraction frames consist of Debye rings from the solids and background effects (e.g., dispersion from the aqueous liquid, "hot" pixel effects). All background effects can be digitally removed by subtracting a diffraction frame from an experiment without solids present to produce a residual frame of Debye rings. A more traditional one-dimension pattern is obtained by integrating appropriately over chi to obtain a pattern that can be used as input into search-match or other data processing programs.

The chamber is well suited for experimental work that involves solids, liquids, and gases under high pressure over a wide range of temperatures.

Smectite–CO_2 interactions to 400 bars and 65°C

Giesting, P.[1*], Guggenheim, S.[1], Koster van Groos, A.F.[1] & Bertier, P.[2]
[1]Dept. of Earth & Environmental Sciences, University of Illinois at Chicago, USA (*giesting@alumni.nd.edu)
[2]Clay & Interface Mineralogy, RWTH Aachen University, Aachen, Germany

X-ray diffraction experiments were conducted on smectite in the presence of either CO_2 or He at high pressures and elevated temperatures using an environmental chamber. A Mg-exchanged smectite of approx. composition of $Mg_{0.17}(Al_{1.34}Fe_{0.44}Mg_{0.29})\ (Si_{3.75}\ Al_{0.25})\ O_{10}(OH)_2 \cdot nH_2O$ was dried for 42 hours at ~200°C and stored over desiccant until used. Experiments at 25°C and various CO_2 pressures (40, 80, 130, 200, 300, and 400 bars) show a 10-Å peak with a significant low-angle tail and, with increasing CO_2 pressure, this tail increases in height as the 10-Å peak diminishes in size. Experiments at 65°C and at CO_2 pressures of 1, 5, 10, 20, 40, 80, and 200 bars show similar X-ray patterns, except that the peak at 10 Å moved to 10.4 Å, and the peak did not diminish in height with increasing pressure. These results suggest that the 10.4-Å spacing is slightly more prevalent in the experiments at 65°C than at 25°C.

A series of experiments at 65°C with He (1, 40, and 130 bars) show similar behavior for the 10-Å peak as in the CO_2 experiments at 25°C. These results suggest that the change in peak and tail intensity is related to a partial dehydration and redistribution of H_2O within the interlayer of the smectite, rather than that a gas (e.g., He or CO_2) enters the interlayer of the clay. A near-second order, non-integral diffraction effect is observed at the 4.4-Å peak. This peak shows an intense tail at higher angles. Both effects indicate that two or more (001) spacings occur, further corroborating that the sample has undergone only partial dehydration. The similarity in patterns for both the CO_2 and He runs suggests that there is no evidence that CO_2 enters the interlayer of a nearly anhydrous clay at the conditions of these experiments. Additional experiments are being conducted to determine how changing the interlayer-cation population affects the interaction between smectite and CO_2.

Two sets of experiments were made under starting conditions of ambient humidity and with the clay suspended over a reservoir of H_2O. Under ambient humidity (~35 % RH) starting conditions, the environmental chamber was sealed and heated to 55°C. CO_2 was added and pressures were examined at 40, 80, 130, and 200 bars. A prominent peak occurs at 13.7 Å for all pressures and intensifies slightly as pressure is increased. Experiments with clay suspended over a reservoir of H_2O (at pressures of 1, 40, 80, 200, and 300 bars at 65°C) showed a peak at 16.3 Å, which intensified as pressure was increased. Additional experiments with He are underway.

Fluid-rock interaction with impure CO_2 by combining geochemical and geomechanical investigations: first results from the COORAL project

Marbler, H.*, Lempp, Ch., Pöllmann, H., Erickson, K. & Schmidt, M.
Geo-sciences, Martin Luther University Halle Wittenberg, Halle/Saale, Germany (*herwig.marbler@geo.uni-halle.de)

The storage of CO_2 with inherent impurities, such as SO_X, NO_X, O_2, CO, etc., affects fluid-rock interactions in deep geological formations. These include alterations and mineralogical transformations within the reservoir formation. The injection pressure may decrease fracture strength of the reservoir rocks, which would impair the formation stability within a short time period.

To understand this interaction of CO_2 with the host rocks, laboratory experiments are carried out with samples of possible reservoir rocks and brine (formation waters). Geomechanical test series are conducted in triaxial cells under lithostatic pressure conditions with supercritical (sc)CO_2 acting as pore fluid. For mineralogical and geochemical investigations the experiments are executed in autoclave systems under simulated in-situ temperature conditions. In the autoclave system a set of rock samples of different silicate and carbonate bearing sandstones are allowed to react with fluids and well-defined compositions of impure scCO_2 to optimize the real-time alteration scenarios.

Geochemical modelling of CO_2/mineral interaction record various mineralogical and geochemical effects in the system i.e. changes of the major element and trace element composition as well as the initial formation of hydrocarbonate minerals. Laboratory experiments with scCO_2 in interaction with reservoir rocks will be carried out to verify such geochemical alterations and mineralogical transformations. Geomechanical tests show that increasing pore fluid pressure with scCO_2 as well as with water has strong effects on the rock strength. CO_2 in the supercritical state, acting as pore fluid, is able to displace formation water (brine) or dissolve into these waters as well as infiltrate smaller pore spaces in the reservoir rock in comparison to brines. This so called capillary trapping plays an important role for long term storage of CO_2 in deep geological formations. However, scCO_2 induces fine fractures in sandstones especially in inhomogeneities within the rocks which may result in decreasing fracture strength of the reservoir rocks, especially with enhanced injection pressure. Therefore, the evolution of the pore space and the formation of cracks and fractures as well as additional alteration effects by scCO_2 may influence the storage capacity and long-term safety of the storage formation. The knowledge of these dynamic processes both in geochemical/mineralogical and geomechanical terms is of great importance to allow for long-term safety predictions over timescales of up to thousands of years.

Modelling of mineral alteration in a natural CO_2 reservoir

Montegrossi, G.[1], Ruggieri, G.[1], Bicocchi, G.[2], Vaselli, O.[1,2], Burgassi, P.[3], Tassi, F.[1,2], Jordi, B.[4] & Del Villar, L.P.[5]

[4]Passeig de García i Faria, 49-51, Barcelona, Spain
[5]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT), Madrid, Spain

The investigation of natural reservoirs as analogue of Carbon Capture and Sequestration (CCS) site has a considerable impact in the reaction path modeling. It is indeed the main information able to predict the mineral evolution during and after CO_2 injection in feasible CCS site.

In the 80's, during oil exploration in central Italy, a high pressure CO_2 reservoir was found while drilling the PSS1 well, located in the San Cassiano basin, Tuscany, Central Italy [1]. The CO_2 reservoir has pressure higher than 600 bar and a temperature of about 115°C. The reservoir rocks at depth of about 3,700 m consist of altered volcanic rocks. According to ENI report (1983) the original rocks had an andesitic composition.

The aim of this work is to assess a reaction path able to predict the reservoir rocks evolution from the pristine mineralogical composition to the present one. The mineralogical and mineral chemistry investigation was carried out on 6 drill core samples from the CO_2 reservoirs horizons. The examined samples are made of volcanic rocks almost completely replaced by hydrothermal minerals. The alteration mineralogical assemblage is mainly composed by silicates (quartz, albite, illite and chlorite) and carbonates (calcite and ankerite) and minor amount of Fe-oxides/hydroxides and Fe-Ti-oxides. The reaction path model here presented is performed by using the geochemical computer program PHREEQC (Version 2.15). The database is corrected to take into account the pressure by means of SUPCRT92.

The general idea is that a nearly iso-chemical evolution of the mineralogical assemblage has occurred, as a consequence of inflow of CO_2-rich aqueous fluid with a progressive dry-out of the reservoir fluid. Thus, the geochemical model strategy proceeds through a fully kinetic approach, because the carbonation is not expected to have reached the equilibrium. It seems reasonable to assume that CO_2 input has left a gross overpressure of about 230 bars. During such event the fluid present in the formation was displaced by CO_2, progressively drying the reservoir out. In this setting the chemical evolution of the system may have proceeded with a progressively lowering of the water/rock ratio.

Mineral traps for CO_2 in mine tailings

Wilson, S.A.[1,4*], Dipple, G.M.[1], Power, I.M.[2], Barker, S.L.L.[1], Fallon, S.J.[3], Raudsepp, M.[1] & Southam, G.[2]
[1]Mineral Deposit Research Unit, The University of British Columbia, Vancouver, BC, Canada ([*]siowilso@indiana.edu)
[2]Dept. of Earth Sciences, University of Western Ontario, London, ON, Canada
[3]Research School of Earth Sciences, Australian National University, Canberra, Australia
[4]Current address: Dept. of Geological Sciences, Indiana University, Bloomington, IN, U.S.A.

At some ultramafic-hosted mines, accelerated weathering of Mg-rich mineral waste (tailings) can produce significant amounts of hydrated Mg-carbonate minerals. In mine tailings, trapping and storage of atmospheric CO_2 within these minerals can occur on a kilotonne to megatonne scale and, in some instances, may represent a significant offsetting of a mine's greenhouse gas emissions [1,2].

We have investigated CO_2 mineralization within Mg-carbonate minerals (typically hydromagnesite, dypingite, nesquehonite, and lansfordite) in the tailings from four mine sites in Western Australia and Canada [1-3]. Among these ultramafic-hosted mines, the extent and rate of CO_2 trapping and the identities of the mineral hosts to CO_2 vary. Isotopic investigations suggest that the rate of carbon cycling between geological, industrial, and atmospheric reservoirs within ultramafic mine tailings is largely controlled by climate and tailings management practices.

Kinetic exchange of C isotopes, during fast precipitation of carbonate minerals in mine tailings, complicates interpretation of stable isotopic data. Therefore, we have used radiogenic ^{14}C to assess the extent to which modern, atmospheric CO_2 has been captured within hydrated Mg-carbonate minerals.

Quantitative mineralogical procedures that use X-ray powder diffraction data, including a combination of Rietveld refinement and reference intensity ratios, allow quantification of the mineral hosts to CO_2 from trace to readily detectable abundances. Quantitative mineralogical results can be used with ^{14}C data to assess the amount of CO_2 trapping within hydrated Mg-carbonate minerals. Furthermore, Rietveld refinement results can assist in determining which gangue minerals are the primary sources for Mg in these minerals.

Our results indicate that some large, ultramafic-hosted mining operations, like the Mount Keith Nickel Mine in Western Australia, are able to offset >15% of their annual greenhouse gas emissions by passive uptake of atmospheric CO_2 into carbonate minerals. Reaction of ~10% of the annual production of serpentine-rich tailings at Mount Keith has the potential to completely offset the mine's greenhouse gas emissions. Preliminary results suggest that this acceleration might be achievable through a combination of redesign for tailings storage facilities and microbially mediated processing of mineral waste [3-5].

Long-term CO_2 storage in weathered peridotite due to replacement of low-T altered olivine (deweylite) by calcite

Beinlich, A.[1,2*], Plümper, O.[1], Hövelmann, J.[1] & Austrheim, H.[1,2]
[1]Physics of Geological Processes, University of Oslo, Norway (*andreas.beinlich@fys.uio.no)
[2]Dept. of Earth Sciences, University of Oslo, Norway

In contact with CO_2, peridotite is known to be reactive and eventually transforms into ophicarbonate and listwaenite. Here we present observations from serpentinized peridotite clasts from the Devonian Solund Basin, SW Norway. These clasts show evidence for a stepwise reaction history starting with initial serpentinization and resulting in the formation of carbonates and quartz. Thus, the clasts represent a natural analogue for CO_2 sequestration in ultramafic rocks, a strategy proposed by the Inter-Governmental Panel on Climate Change [1] for long-term CO_2 storage. In several layers of the basin, the carbonatized ultramafic clasts are important constituents and account for up to 20 vol.% of the basin infill.

The investigated clasts show a concentric build-up with green to grey olivine- and serpentine bearing cores surrounded by mm to 10 cm thick, carbonate-quartz-talc-zones of red to black shades. Textural observations indicate the following alteration sequence: An early stage is represented by ocean-floor serpentinization of peridotite resulting in a typical mesh texture, with veins of serpentine and Ni-rich hematite surrounding compartments of relict olivine (Fo_{90}). During subsequent low-T alteration under near-surface conditions, relict olivine breaks down to form an extremely fine grained alteration product. In the more advanced ophicarbonate stage, interaction with a Ca-bearing fluid within the basin caused calcite formation in cells surrounded by serpentine. The textural evolution is accompanied by a decrease in whole-rock MgO from 40 to 2 wt.% and a CaO increase from 1 to 35 wt.%. All clasts are characterized by high trace-element concentrations of Cr and Ni revealing their ultramafic origin.

Scanning transmission electron microscopy (STEM) enabling high-angle annular dark field (HAADF) imaging reveals that olivine breaks down to a fine grained intergrowth of amorphous serpentine and poorly crystalline talc (deweylite) and that subsequent carbonatization proceeds as dissolution of deweylite coupled with direct precipitation of calcite.

Hydrothermal batch experiments (130-160 bar PCO_2; 200°C; 1-3 weeks reaction time) show that the cells filled with deweylite are the favourable site of reaction presumably due to its large reactive surface area and high degree of disorder. In contrast, relict olivine and surrounding serpentine remain almost inert during the carbonatization stage.

Although the clasts are characterized by high initial Mg concentrations, calcite represents the dominant carbonate phase indicating that magnesite formation is thermodynamically not favoured as soon as Ca is introduced to the system which is further corroborated by geochemical modelling (PHREEQC). Mg removed from the clasts during alteration is partly consumed by replacement reactions in the vicinity of the clasts where Fe-minerals (almandine) are replaced by Mg-minerals (talc). For basins containing abundant peridotite clasts, the outlined process will influence the CO_2 and MgO budget.

Molecular species in microporous cordierite

Geiger, C.A.[1*], Rahmoun, N.S.[2] & Heide, K.[2]
[1]Fachbereich Materialforschung und Physik, Universität Salzburg, Austria (*chg@min.uni-kiel.de)
[2]Institut für Geowissenschaften, Universität Kiel, Germany

Cordierite, $(Mg,Fe)_2Al_4Si_5O_{18}\cdot x(H_2O,CO_2)$, is a microporous silicate having about 20 volume % void space. It is typically found in metamorphic and in certain igneous rocks. It can occlude a number of different molecular and atomic species that reflect the nature of the fluid phase during crystallization and/or equilibration.

We undertook a mass spectrometric study to investigate all occluded volatile species in a systematic manner for a series of cordierite samples. The method, DEGAS, requires only small milligram quantities of material, which are heated continuously at a controlled rate from 25°C to 1400°C. The mass-to-charge ratios of the degassed molecules and their related species are measured by a quadrupole mass spectrometer. Twenty cordierite samples from a wide range of petrologic environments and having different compositions were investigated.

The cordierites show H_2O and CO_2 as the most abundant primary occluded molecules. Their degassing temperatures lie between 750 and 1000°C and 750 and 1200°C, respectively. There is reasonable agreement in CO_2 and H_2O concentrations determined by the DEGAS method and those determined by the Karl Fischer titration method. H_2O contents range from approximately 0.0 wt% to 2.34 wt % and CO_2 from 0.0 wt% to 1.97 wt%. Ratios of X_{CO_2}/X_{H_2O} for samples containing measurable amounts of both molecules range from about 0.2 to 5.6 and there exists an inverse relationship between CO_2 and H_2O contents. Cordierites from pegmatites and medium-grade metamorphic rocks are relatively rich in H_2O and poor in CO_2, whereas cordierites from the granulite facies have more CO_2 than H_2O. Different isotopic compositions for both CO_2 and H_2O are observed. A number of other occluded molecular or atomic species were identified at minor and/or trace concentration levels. They include $^{40/36}Ar$, He, SO_2, N_2, H_2S, H_2 and Na and possibly CH_4 and HCl. The presence of primary CO could not be ascertained. The relative concentrations of primary occluded atoms and molecules in natural cordierite vary approximately as: $H_2O \sim CO_2 >> N_2 > Ar \sim H_2S > He > SO_2$ with possibly very minor H_2, CH_4 and HCl.

The types of molecules and atoms that are incorporated in cordierite and their concentrations depend on three factors: i) the temperature and pressure during crystal growth, ii) crystal-chemical and molecular properties and iii) the composition of the fluid under which the cordierite crystal crystallized or equilibrated.

The DEGAS profiles also sometimes show degassing peaks for Ar, H_2S, SO_2 and possibly a CH_3 species, for example, at low temperatures around 150°C. They are likely related to adsorbed surface species, whose exact physical and chemical state is not clear. Strong degassing "events" are also observed for some species at temperatures between about 300°C and 700°C and they are possibly related to very minute solid-phase inclusions such as those associated with pinite.

The DEGAS results give, for the first time, a broad picture of the various types of molecules and their relative concentrations in cordierites occurring over a wide range of geologic environments.

Changes in structure and cage occupancy of methane- and CO_2-hydrate under high pressure

Hirai, H.[1*], Machida, S.[1], Tanaka, T.[1], Honda, M.[1], Kawamura, T.[2], Yamamoto, Y.[2] & Yagi, T.[3]
[1]Geodynamics Research Center, Ehime University, Matsuyama, Japan ([*]hirai@sci.ehime-u.ac.jp)
[2]National Inst. of Advanced Industrial Science and Technology, Tsukuba, Japan
[3]Inst. for Solid State Physics, Tokyo University, Kashiwa, Japan

Gas hydrates are clathrate compounds composed of hydrogen-bonded water molecules forming cages and guest gas molecules contained in the cages. Methane hydrate, called fiery ice, is expected as a clean and fruitful energy resource, while methane is a greenhouse gas even more potent than carbon dioxide at causing global warming. In the solar system, methane hydrate is thought to be an important constituent of outer giant planets and their satellites, such as Uranus, Neptune, and Titan. CO_2-reduction in the Earth's atmosphere is one of the most urgent subjects of mankind. Some technical developments to seclude excess CO_2 at ocean floor as CO_2 hydrate or CO_2 fluid have been proceeded. In the solar system, a possible existence of CO_2 hydrate in and beneath Martian permafrost has been predicted from spacecraft probes and theoretical studies. Therefore, knowledge of the structural changes of both hydrates under wide pressure-temperature conditions is required from various standpoints for overcoming mankind's urgent problems of dwindling energy resources and global warming, as well as for answering fundamental questions about the internal structure of the neighbour planet and icy bodies.

High pressure experiments with methane hydrate and CO_2 hydrate were performed using diamond anvil cells. For the former one the pressure range was 0.2 GPa to 86 GPa at room temperature and for the latter one the pressure ranges was 0.2 to 3.0 GPa and temperature range was 300 K to 80 K using a helium-refrigeration cryostat system. Although, both hydrates have same structure, sI, at low pressure, they showed completely different behaviour under high pressure region.

X-ray diffractometry and Raman spectroscopy revealed phase changes of both hydrates as follows. For methane hydrate, sI transformed a hexagonal structure, sH, at about 1 GPa and further transformed to a filled ice Ih structure at 2 GPa, and it survived at least up to 86 GPa [1-3]. At about 15GPa, the guest methane molecules exhibited orientational ordering in the structure, although they rotated freely below the pressures. And, at about 40 GPa the host water molecules showed symmetrization of hydrogen bond. These properties might lead the outstanding stability under high pressure. For CO_2 hydrate, the phase boundary between the hydrate and CO_2 + water turned from positive slope to negative one at a inflection point (294 K, 328 MPa), thus CO_2 hydrate can survive only low temperature region at the higher pressures. The characteristic may come from some interaction between host water molecules and guest CO_2 ones, which is possibly induced by that CO_2 molecule has hydrophilic oxygen atoms at both sides.

Experimental study of CO_2 capture and storage possibility on drilling core samples from Hungary

Király, Cs.[1*], Berta, M.[1], Falus, Gy.[2], Székely, E.[3] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Dept. of Petrology and Geochemistry, Eötvös University, Budapest, Hungary ([*]csilla.kiraly.hu@gmail.com)
[2]Eötvös Loránd Geophysical Institue (ELGI), Budapest, Hungary
[3]Budapest University of Technology and Economics (BME), Budapest, Hungary

The concentration of CO_2 in the atmosphere has increased significantly since the industrial revolution. To reduce the CO_2 level, a new area of research has been created, which has a clear goal to find geological formations below the surface where a long-term and safe storage of CO_2 can be guaranteed [1]. These reservoirs are found in salt domes, depleted hydrocarbon fields, non-economical coal beds, deep saline aquifers and mafic or ultramafic rocks [2].

The sedimentary system in the Pannonian Basin contains several sub-basins, which are potential storage places, namely porous sandstone bodies with regional coverage by low permeability pelitic rocks [3]. Our main aim is to carry out an experimental series on pairs of potential reservoir and cap rock from cores drilled for hydrocarbon exploration.

As the first step, rock samples have been selected from the Jászság Basin by using databases from hydrocarbon exploration because several deep wells had been drilled in the Pannonian Basin. Hence, we could choose the most promising area by evaluation of the well-logs~~,~~ containing the borehole-geophysical results, the carbonate~~-~~content and the petrologic description of the formations of the stratigraphic section.

In the studied area there are 4 major formations (2 storage and 2 cap rock formations) that are potentially available for future CO_2 storage. To decide what core sample to use in the experiments, we need to take into consideration all the~~se~~ data collected from the well-logs.

The second step of the presented work relates to preliminary petrophysical tests and geochemical analyses. These were made from thin section description for the original mineral composition and scanning electron microscope images taken from the natural surfaces of the rock to study directly the pores and surface morphology. Semi-quantitative analysis on mineral constituents in sandstone samples were also carried out. We were able to identify minerals such as plagioclase, orthoclase, albite, carbonate, clay minerals, micas, and pyrite.

As a third step we treated the samples with supercritical CO_2 at similar pressures and temperatures at the possible reservoir conditions to model the expected chemical processes.

In this way, we can make some restrictions about which geological formations would be reasonable for storage and which would be reasonable for the cap rock.

Mineralogy and geochemistry of methane-bearing sediments of the Gulf of Cádiz (Atlantic Moroccan Margin)

Mata, M.P.[1*], Falagán, C.[2], Martos R.[2], González-López, N.[3], Casas, D.[1], Sánchez-Bellón, A.[2], Martínez, J.[2], López-Aguayo, F.[2], Narjisse, A.M.[4,2] & Somoza, L.[1]
[1]Instituto Geológico y Minero de España, Tres Cantos, Madrid, Spain ([*]p.mata@igme.es)
[2]Depto. Ciencias de la Tierra, Facultad de Ciencias del Mar y Ambientales, Universidad de Cádiz, Cádiz, Spain
[3]Instituto Español de Oceanografía, Fuengirola, Málaga, Spain
[4]Dept. Géologie et Océanologie, Faculté des Sciences et Techniques, Université Abdelmalek Essaâdi, Tétouan, Morocco

The Gulf of Cádiz has been extensively surveyed in recent years and several gas-related fluid escape seafloor structures have been identified as mud volcanoes, pockmarks and carbonate crusts. Methane-gas hydrates have been sampled at least from five mud volcanoes in the area. Sediments of mud volcanoes, named mud breccia, are made of mud and clasts and are carried up from deeper areas associated with the fluids. Diagenetic minerals, mainly carbonates and sulphides, resulting from the anaerobic oxidation of methane by microbial processes are frequent in the discharge areas

Gravity cores collected during the MVSEIS08 cruise on the Atlantic Moroccan Margin have been studied. The cores were taken on the summit and slopes of Moroccan mud volcanoes from 400 up to 1400 m depth. A detailed mineralogical analysis by XRD, chemical composition including XRF core-scanner ICP, and organic matter content (OM), C/N ratios, of 4 different mud volcanoes have been performed in order to determine whether there is a characteristic mineralogy in the gas-related sediments. A detailed clay mineralogy study is being carried out, as they can provide important information about the nature and depth of the fluids and the reactions of gas with clays, as smectite may interact at reticular scale with hydrates [1].

The results show that mud breccia of mud volcanoes show an enrichment in clay minerals compared with the adjacent sediments of the continental margin, being illite, smectite and minor chlorite and kaolinite the main clays present at the mud breccia. Anomalous contents of smectite have been detected in some mud breccia units. This enrichment has been previously reported in the Pacific, Mediterranean or the Iberian continental margin of the Gulf of Cádiz. Chemical composition as determined by XRF core-scanner and ICP, show a characteristic chemical composition for the mud breccia showing an increase in Al, Si, K, Ti, Fe and other clay-related elements. Low OM and carbonate contents have been observed in the mud breccia compared with the sediments of the area. C/N ratios show lower values for mud breccia than for the rest of the units.

The mineralogical and chemical analysis of the cores reflects different origins and diagenetic processes for each unit: hemipelagic sediments of the slope are carbonate-rich, and mineralogy reflects the terrigenous input and processes of the continental margin, while gas-related units have abundant clays and authigenic and diagenetic minerals. As a natural analogue of gas storage, this mineralogy reflects the origin, capture and storage of methane in the marine environment. Clays are related to the origin and transport of the fluids and sediments and the final storage of gas is made by bacterial carbonates. The clayey nature of the mud breccia, leads to considerations regarding new diagenetic processes in methane-seeping areas and also to the abundances and distribution of clay minerals on continental margins.

Development of pressure cells for laboratory powder diffractometers

Whitfield, P.S.[1*], Mitchell, L.D.[1], Ross, J.[1] & Parise, J.B.[2]
[1]National Research Council Canada, Ottawa, Canada ([*]pamela.whitfield@nrc.gc.ca)
[2]Dept. of Geosciences, SUNY Stony Brook University, Stony Brook, NY, USA

Development of pressure cells for lab powder diffractometers at NRC began in 2006. The first cell (rated 125 bar, -40 to 200ºC) was based on the work of [1], but changes were made to make the design ASME pressure-code compliant. The cell was used successfully to collect in-situ MoKα XRD data on polymer crystallization under high pressure CO_2. On termination of the polymer project it was determined that such instrumentation could be useful for fundamental studies related to CO_2 sequestration. Given the sluggish nature of many sequestration-related reactions, long-term lab-based experiments can be more useful than the limited beamtime available at synchrotrons. Limited proof-of-concept studies were successfully undertaken on the carbonation of calcium silicate hydrate and wollastonite [2]. Unfortunately the design and materials (304SS) of the first generation stage were not capable of attaining and retaining the conditions required for serious sequestration studies.

A second generation stage has been designed for the physical and chemical conditions required for down-hole studies, including deep brine aquifers. Made from C-22 nickel superalloy for corrosion-resistance, it is designed for 300 bar and 300ºC (electrically heated) with concentrated chloride solutions at pH3. Use in lab systems requires the use of AgKα radiation with 0.635cm thick Ta-coated Be windows. The design allows use in both reflection and transmission geometry so is also suitable for synchrotron applications without modification. The design is undergoing pressure vessel certification in Ontario and a mock-up was constructed from C-22 (Fig. 1) to verify the FEA thermal modelling portion of the stress analysis.

Once commissioned, studies will be conducted under down-hole conditions on pure materials and core samples. The aim is to provide experimental kinetic data to improve geochemical models for long-term CO_2 storage. A second stage will be used at the NSLS for studies on more rapid reactions.

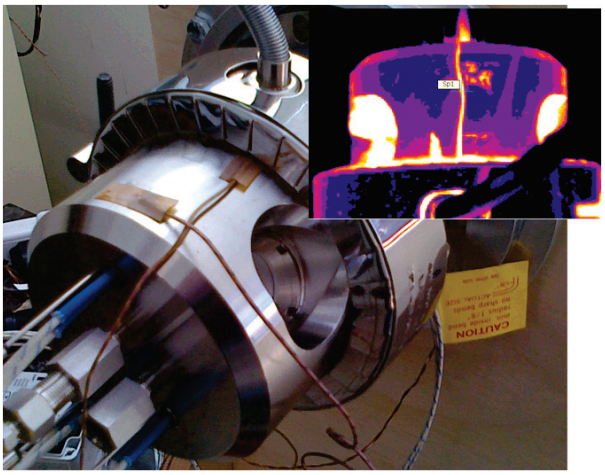

Fig. 1: Picture of 2nd generation stage mock-up instrumented for thermal tests. Inset is an infra-red image taken from above while holding at an internal temperature of 300ºC.

Implications of sand-bentonite mixtures used for radioactive waste disposal

Rueedi, J.*, Marschall, P. & Schwyn, B.
National Cooperative for the Disposal of Radioactive Waste (Nagra), Wettingen, Switzerland (*joerg.rueedi@nagra.ch)

In the Swiss low- and intermediate level waste (L/ILW) disposal concept a design option (engineered gas transport system - EGTS) was studied in the past years aiming at increasing the gas transport capacity of the backfilled underground structures without compromising the radionuclide retention capacity of the engineered barrier system. It involves specially designed backfill and sealing materials such as high porosity mortars as backfill materials for the emplacement caverns and sand/bentonite (S/B) mixtures for backfilling other underground structures and for the repository seal.

Preliminary experimental studies confirmed the high gas transport capacity of the S/B mixtures. These experiments have shown the ability to design S/B mixtures with specific target permeabilities for water and gas flow. First experiences were gained through the Gas Migration Test (GMT) at Grimsel Test Site (GTS) for which a comprehensive laboratory programme on combined gas/water transport in S/B mixtures has been performed.

Numerical simulations were conducted which demonstrate the effective functioning of the EGTS concept for a range of repository configurations and parameter variants. The model calculations show clearly that the gas produced in emplacement caverns can be released efficiently along the engineered gas transport system to the backfilled access tunnel where it accumulates and eventually escapes into the adjacent rock formations. The model calculations show as well that both the length and the average gas/water permeability of the repository plugs and the seal are important design parameters to avoid excess gas pressures in the repository.

Two major scientific questions were raised in the previous studies. On the one hand, up-scaling of S/B material properties (e.g. water and gas permeability) gained from small scale laboratory samples to the behaviour of a repository plug or seal is seen as an important research topic. The impact of material heterogeneities induced during construction is important for the long-term prediction of gas pressure evolution in a repository. On the other hand, past research work has indicated that long-term interaction of cementitious materials with S/B mixtures may impair the gas transport capacity of S/B plugs and seals potentially leading to increased pressures in the system.

Building on experiences so far, a broad experimental program has started in 2009 as part of the EU 7th FP project FORGE. This laboratory program includes both small scale experiments to investigate in detail the material properties and small-scale gas and water transport behaviour and a larger scale demonstration (mock-up) experiment of the repository seal. An in-situ experiment at realistic scale is currently in the planning stage. This systematic approach will provide important insights into the up-scaling of S/B material properties and its potential impact on the overall system performance.

Parallel experiments are performed to investigate in detail the evolution of cement-S/B interfaces and their impact on the S/B material properties in general, and on gas permeability in particular. Recent developments in the analysis and visualisation of porous materials are applied and further developed to obtain detailed information on structural and hydrochemical changes at and near these material interfaces.

Crystallization of secondary sulfate and phosphate phases in cementitious conglomerates exposed to polluted environments

Secco, M.[1*], Maritan, L.[1], Lampronti, G.I.[2], Mazzoli, C.[1] & Artioli, G.[1]
[1]Dept. of Geosciences, University of Padova, Italy (*michele.secco@unipd.it)
[2]Dept. of Chemical Science "G. Ciamician", University of Bologna, Italy

A case study presenting considerable degradation of a reinforced concrete industrial building, constructed at Porto Marghera (Venice, North-Eastern Italy) in 1969, is described. The Porto Marghera area suffered from severe atmospheric pollution, with noteworthy industrial emissions of sulfate and nitrate pollutants. Moreover, the site was affected by intense phosphate soil pollution, related to the production of superphosphate-based fertilizers in the industrial plant.

The concrete of the structure is highly incoherent with intense superficial exfoliation, up to several centimetres thick. Superficial black crusts are uniformly distributed, whereas in the lower portions of the structure in close contact with the soil the cement matrix below the cortical layer shows an anomalous yellowish colour. Here the conglomerate is highly incoherent and the binder tends to pulverize.

A selection of altered concrete samples was analyzed through a profile multi-analytical approach consisting of a combination of optical microscopy, X-ray powder diffraction, and scanning electron microscopy coupled with EDS analysis, with the aim of characterizing the secondary phases formed and modelling the alteration processes. Furthermore, sequence of reactions, environmental conditions (ions concentration, temperature, pH, pe), and stability of secondary mineral phases were thermodynamically modelled using PHREEQC2 software.

The results of this combined approach suggest severe decalcification of the cement matrix and formation of secondary sulfates and phosphates according to a marked mineralogical and textural zoning: a) Gypsum in the superficial efflorescence; b) Gypsum-brushite solid solution in the superficial black crusts; c) Apatite in the inner altered portions.

The heterogeneous microstructural development of secondary phases was interpreted taking into account the different source of sulfate and phosphate pollutants, from atmospheric aerosols and through capillarity transport from the soil, respectively. Moreover, the presence of brushite – phosphate phase more stable at low pH – at the surface suggests that these portions were exposed to higher acidity conditions, related to sulfuric acid formation in the pore water after reaction with atmospheric sulfates (Fig. 1).

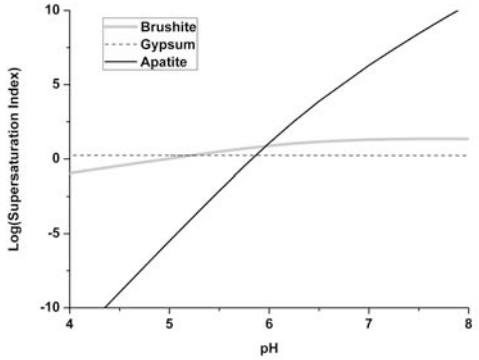

Fig. 1: Supersaturation index ($\log(a/a_{eq})$) of secondary phases as a function of pH: apatite and brushite precipitation and dissolution strongly depend on pH.

Reactive transport modeling of grout-rock interaction

Soler, J.M.[1*], Hautojärvi, A.[2] & Vuorio, M.[2]
[1]IDAEA-CSIC, Barcelona, Spain ([*]josep.soler@idaea.csic.es)
[2]POSIVA OY, Eurajoki, Finland

Grouting of water-conducting fractures with low-alkali cement is foreseen by Posiva (Finnish nuclear waste management agency) for the potential future repository for high-level nuclear waste in Finland. A possible consequence of the interaction between groundwater and grout is the formation of high-pH solutions which will be able to react with the host rock (gneisses) and alter its mineralogy and porosity.

A reactive transport modeling study of this possible alteration has been started following the recommendations from Posiva. First, the hydration of the low-alkali cement has been modeled, using results from the literature [1,2] as guide. The hydrated cement is characterized by the absence of portlandite and the presence of a C-S-H gel with a Ca/Si ratio about 0.8 after tens of years (Ca/Si is about 1.7 in Ordinary Portland Cement). Afterwards, a one-dimensional system simulating the contact between a grouted section of a fracture and the gneiss has been studied. The results from the simulations show a very fast (days to weeks) sealing of porosity at the rock-grout interface. The precipitation of C-S-H (tobermorite), and also ettringite in some cases, is responsible for this fast sealing of porosity. The mixing by diffusion of a Ca-rich solution from the grout and a Si-rich solution from the rock causes this precipitation.

New calculations have finally been started simulating the interaction between flowing water and grout and the alteration of the host rock as this water (high-pH plume) flows beyond the grouted section of a fracture.

C-S-H gel dissolution kinetics

Trapote, A., Cama, J.[*] & Soler, J.M.
Dept. of Geosciences, Institute of Environmental Assessment and Water Research, IDAEA, CSIC, Barcelona, Spain
([*]jordi.cama@idaea.csic.es)

C-S-H gel, which constitutes at least 60% of the fully hydrated Portland cement paste, is the main responsible of the durability and barrier properties of cement. Although C-S-H solubility has been studied by many authors, the dissolution kinetics is not known. In this communication we present kinetic data based on the results obtained from flow-through experiments.

The C-S-H gel used in the experiments was obtained by hydration of synthesized C_3S ($3CaO \cdot SiO_2$), which results in the formation of C-S-H and portlandite. C-S-H was ground to a size fraction of ~ 10 μm and the solid Ca/Si stoichiometric ratio was about 1.65 (electron microprobe analysis). The flow-through experiments were carried out at room temperature (22 ± 2°C) and under CO_2-free N_2 atmosphere to avoid carbonation. Ca and Si concentrations and pH were monitored during the experiments. The flow rate was kept constant either at 0.05 or 0.13 mL min^{-1}.

The evolution of pH and Ca and Si concentrations showed three distinct stages during the experiments: (1) Ca concentration was much larger than Si at the start of the experiments, indicating preferential dissolution of portlandite ($Ca(OH)_2$) and slow close-to-equilibrium dissolution of C-S-H. (2) As the portlandite content diminished a gradual decrease in Ca and increase in Si was observed, indicating an increase in C-S-H gel dissolution. The aqueous Ca/Si ratio decreased to values below 10. pH also decreased. (3) Concentrations of Ca and Si and pH (9.7 – 11.4) reached steady state. At this stage the aqueous Ca/Si ratio remained constant at about 0.9 indicating that (i) the C-S-H gel was the main dissolving phase and (ii) the dissolution reaction was stoichiometric with respect to a phase with a Ca/Si ratio similar to that of tobermorite. Steady-state dissolution rates of the C-S-H gel normalized to the final BET specific surface area ranged from 10^{-11} to 10^{-10} mol m^{-2} s^{-1}.

Based on these results two main conclusions can be drawn:

1) The dissolution of the C-S-H gel is initially incongruent (preferential release of Ca) and evolves to the congruent dissolution of a phase with tobermorite stoichiometry (Ca/Si = 0.83), which is consistent with the solubility model presented by Kulik and Kersten [1].

2) The dissolution rate of this end-member is not especially fast, similar for instance to that of feldspars. These values highlight the necessity of considering C-S-H dissolution kinetics in cases where water flows by advection through mortar or concrete (fast transport; dissolution rate is the limiting factor in C-S-H dissolution).

Time- and space-resolved investigations of cementitious materials by X-Ray diffraction methods

Schlegel, M.*, Mueller, U., Panne, U. & Emmerling, F.
Federal Institute of Materials Research and Testing, Berlin, Germany (*moritz-caspar.schlegel@bam.de)

Cementitious building materials are present in our every day life almost everywhere. Due to the nature of the cementitious binder those materials can be described as multi component nano composite materials. However, analyzing their microstructure and the phase composition of the hydration products is a difficult task due to their nano size and poor crystallization. Furthermore, to study degradation mechanisms spatial data are needed linked to the microstructure of the cementitious paste. In recent years new possibilities have arisen in order to investigate these difficult materials by means of analysis with synchrotron radiation.

The objectives of this work are therefore the observation of the time resolved hydration of cement-phases and the analysis of spatial resolved phase assemblage of chemical attacked mortar and concrete including synchrotron methods.

The hydration processes were examined by diffraction with synchrotron radiation in transmission geometry with a wavelength of 1.0656 Å at the μ-spot beamline at BESSY II, Berlin. An ultrasonic trap provided the contact free analysis of a sample and ensures a constant water cement ratio. This is a tremendous improvement since former studies using capillaries coupled with water injection system could not guarantee a homogeneous dispersion of water within the cement suspension. The integration time for a single diffraction pattern was about 30 sec due to the high photon flux of the synchrotron facility and allowed a detailed view into the dynamics of the hydration processes at early stages. The results were completed by long-time studies over 28 days using the X-ray diffractometer D5000 from Bruker with $Cu_{K\alpha}$-X-Ray source and Bragg-Brentano geometry.

The space-resolved phase compositions were determined on sulphate and chloride attacked mortal and concrete. The reaction fronts were localised through micro XRF by determining the S and Cl concentrations at the interface of the sulphate and chloride solution and the bulk material. The synchrotron radiation source was used to identify the phase composition in-situ. The primary focussing optics allowed a spatial resolution down to 10 µm for samples with thicknesses of about 2 mm. This led to a comprehensive analysis of the reaction fronts induced by chemical attacks. In comparison to former investigations an in-situ characterisation of the phase composition within the dense microstructure of the cementitious materials was carried out. Additionally, it is not necessary to destroy the microstructure by e.g. grinding or milling as with common preparation techniques for standard powder diffraction methods.

Investigation of the decomposition mechanism of larnite (β-Ca_2SiO_4)

Apostolaki, Ch.*, Markopoulos, Th. & Perdikatsis, V.
Dept. of Mineral Resources Engineering, Technical University of Crete, Chania, Greece (*xapostol@mred.tuc.gr)

Natural Hydraulic Limes (NHL), produced by firing marly limestone, contain mainly portlandite $Ca(OH)_2$ and larnite (β-Ca_2SiO_4, e.g. β-C_2S). Mixing NHL with aggregates, a mortar is formed, appropriate for restoration and conservation purposes of monuments and historical buildings. Portlandite is transformed to calcite, while larnite in Ca-Si–Hydrates, such as $(CaO)_{2-n}SiO_2(H_2O)_{m-n}$ [1] or C_2SH [2].

Previous results of NHL samples, curred in an open atmosphere with a relative humidity of 50 to 65 % for six months, showed that the content of calcite was higher than of that expected due to the carbonation of portlandite, whereas the larnite content was reduced. The above observation indicates that the decomposition of larnite could also lead to the formation of calcite [3]. In order to study the decomposition of larnite by avoiding the presence and the carbonation of portlandite, experiments using pure synthetic larnite were carried out. The pure synthetic larnite was synthesised by mixing CaO and SiO_2, in 2:1 molar ratio and firing the mixture at 900°C for 12 hours. The produced larnite sample was pure and contains small amounts of SiO_2 less than 1%. Two different experiments have been done. In the first experiment 1 gr of larnite powder was exposed in continuous humidified airflow of 90% RH. In the second experiment 1gr of larnite powder was placed in distilled water. The water was boiled additionally in order to remove possible dissolved CO_2.

Mineralogical analysis was carried out by X-ray powder diffraction analysis (XRD) on a Bruker D8 Advance Diffractometer, using Ni-filtered Cu Kα radiation with a Lynx Eye strip silicon detector. Data were collected from 3° to 70° 2θ with a step size of 0.02° and a count time of 0.5 sec per strip step. The crystalline phases were identified using the Diffrac plus Software (Brucker AXS) and the PDF database. Corundum or silicon powder has been added as an internal standard for the quantification of the amorphous content. The quantitative analysis was performed by the Rietveld method using the TOPAS (BRUKER) software program. Using the Rietveld refinement Rwp and Rp were 9.15% and 6.87 % respectively while the relative error for the quantitative analysis was ~ 3%.

The XRD analyses of larnite in humidified airflow of 90% RH, after a curring period of three months, shows a content of 58.6 % larnite, 24.2 % calcite, 1% quartz and 16.2 % amorpous. In contrary, the XRD analysis of larnite in pure water, shows mainly portlandite and some weak reflexions, which could not be interpreted. Therefore the main quantity of portlandite has been removed from the sample. After removing, a small amount of portlandite was observed and the Ca-Si- Hydrates, Jennite $Ca_9H_2Si_6O_{18}(OH)_8.6H_2O$ and Oyelite $(CaO)_xSiO_2.zH_2O$ were identified proceedings.

In the first experiment portlandite is absent due to its conversion to calcite, while in the second one, calcite, was not detected due to the absence of CO_2. According to the above results the decomposition of larnite took place following the reactions:

$$Ca_2SiO_4 + 2H_2O \rightarrow 2Ca(OH)_2 + SiO_{2\ amorph} \quad (1)$$
$$Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O \quad (2)$$
$$Ca(OH)_2 + SiO_{2\ amorph} \rightarrow \text{Ca-Si-Hydrates} \quad (3)$$

These results are in full accordance with previous research results on Natural Hydraulic Limes (NHL) [3].

Supercritically carbonation of calcium aluminate cements and silica fume. Application to a high level nuclear waste repository

Rozalén, M.[1], Hidalgo, A.[2] & Huertas, F.J.[1*]
[1]Instituto Andaluz Ciencias Tierra, CSIC-UGR, Granada, Spain (*javier.huertas@eez.csic.es)
[2]Estación Biológica de Doñana, CSIC, Isla de la Cartuja, Sevilla, Spain

Bentonite and concrete are essential components in building of a geological repository. Bentonite is used as an engineering barrier, due to its physico-chemical and mechanical properties, and cementitious materials are used for lining of tunnels for rock support, fix sealing cracks and many other purposes. In underground HLNW repositories, leachate of concrete elements will produce an alkaline plume. The alkaline solutions can react with the bentonite in the proximity of concrete, inducing dissolution and precipitation of a number of phases.

A strategy to reduce the potential damage of the alkaline plume over the bentonite barrier includes work with low pH concretes. The use of calcium aluminate cement (CAC) pastes, as an alternative for Portland cements, is tested in this work evaluating physical and chemical properties and the enhancement of these properties using supercritical carbonation methods.

High-pressure carbonation experiments were carried out using mixtures of CAC and silica fume (80%CAC+20%SF) in a high pressure apparatus with continuous CO_2 flow [1]. Additionally, cement pastes, raw and carbonated, were reacted with bentonite from Cabo de Gata (SE Spain) in natural granite solutions at 80°C until solution pH reached a stable value (approximately 9). The solutions were renewed periodically and analyzed for pH, Si, Al, Fe, Mg, Ca, Na and K. Solids were also analyzed by XRD, SEM and FTIR.

The results show that carbonation modifies the pH up to values below 8.5 in carbonated zones, which reduces the propagation of an alkaline plume towards other components of the barrier. Moreover, it causes changes in mineralogy reducing water permeability as a consequence and decreasing the chance of transport of aggressive fluids through pores.

Mineralogy obtained from bentonite/cement mixture experiments indicates partial dissolution of calcite and portlandite, as well as complete dissolution of hydrated and anhydrous Ca-Al-Si phases. No significance changes are observed in montmorillonite, whose exchange complex is saturated with calcium.

Partial dissolution of different phases yields pH decrease in non-treated cements. This effect is stronger in supercritically carbonated cements improving the durability of the system.

In conclusion, bentonite is able to buffer the alkalinity plume derived from concrete in the repository through dissolution of bentonite and precipitation of secondary products, as trioctahedral smectite (saponite like), zeolites and presumably Mg hydroxides and amorphous gels. The formation of these products contributes to maintain the properties of the barrier, preserving swelling and cationic exchange properties.

Characterization of the concrete alkali reactivity of granitoid and dolomitic aggregates

Sabino, N.[1,2], Santos Silva, A.[1], Menezes, P.[1], Moita, P.[2], Candeias, A.E.[3] & Mirao, J.[2*]
[1]Materials Dept., National Laboratory of Civil Engineering, Lisbon, Portugal
[2]HERCULES Laboratory and Geophysics Center of Evora, University of Évora, Portugal ([*]jmirao@uevora.pt)
[3]HERCULES Laboratory and Chemistry Center of Evora, University of Évora, Portugal

The general designation of "internal expansive reactions" includes the alkali-silica reaction (ASR) and the internal sulfate attack by delayed ettringite formation (DEF). These reactions are characterized by the formation of expansive compounds in hardened concrete and consequent cracking of the structure. In Portugal, the number of structures, mainly dams and bridges, affected by ASR is very significant and in some cases require considerable investment in rehabilitation interventions.

Moreover, previous research [1] has shown that the use of some aggregates, initially regarded as inert, can cause problems, proving the need for further insight on the role of aggregates and prevent the occurrence of ASR in constructions.

The economic value of various types of structures (e.g. dams, bridges, airfields) and the high costs related to structural degradation including losses of functionality and the permanent or temporary unavailability (for repair and rehabilitation) could be an important overthrow. Thus thorough understanding of the earth materials requirements for concrete manufacture are of vital economic importance in view of the prevention of deterioration and aging of structures whose longevity and functionality must be guaranteed. It is imperative to provide the concrete producers with the necessary knowledge in order to avoid this type of concrete degradation. Particularly important is the recently approved Lisbon-Madrid High Speed Train railway construction. This expensive operation will require large quantities of aggregates for the construction of bridges and other concrete infrastructures.

Three main sources of raw materials will be considered for the study: St. Eulalia, Montemor and Cano. These quarries are already major exploitation sites separated by 50 km and not far from the future High Speed Train railway. Two of them are granitoid rocks but the raw material from St. Eulalia is richer in quartz and poorer in ferromagnesian minerals than the Montemor aggregates (fig. 1 left). The enrichment in calcium of feldspar goes together with the iron and the magnesium. The Cano aggregates (fig. 1 right) are very different materials. The main lithology is a dolomite rock with local microscopic enrichments in phyllosilicates and very deformed quartz.

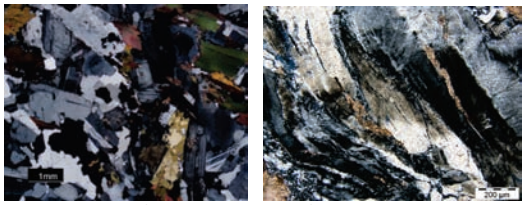

Fig. 1: Aggregates from Montemor (left) and Cano (right) quarries.

Mineralogical and textural characterization of the aggregates was done by optical microscopy. The crystallinity of quartz was also evaluated by XRD and FTIR. The aggregates were also studied by accelerated expansion mortar-bar and concrete-prism tests to evaluate their potentially alkali-reactivity. The relationship between aggregates characteristics and their behaviour in what concerns to alkali reactivity will be discussed.

Ettringite mapping by X-Ray diffraction computed micro-tomography and quantitative image analysis

Valentini, L.[1*], Dalconi, M.C.[1], Parisatto, M.[1], Cruciani, G.[2] & Artioli, G.[1]
[1]Dept. of Geosciences, University of Padua, Italy ([*]luca.valentini@nuigalway.ie)
[2]Dept. of Earth Sciences, University of Ferrara, Italy

The formation of ettringite plays a critical role in the process of hydration of cement pastes. During the early stages of hydration, reaction of the aluminate phase (C_3A) with calcium-sulfate, yielding ettringite, prevents the occurrence of the undesirable effect known as "flash-set". On the other hand, formation of ettringite during late stages of hydration, which commonly occurs in heat-cured pastes, induces the build-up of dilative stresses that may ultimately lead to severe cracking within the matrix and at the interface with aggregates. Therefore, investigating the rates and modes of ettringite formation, and its spatial location and local abundance within the paste, is crucial to understanding both early-stage kinetics and processes related to deterioration.

In this study, a 3D non-invasive technique based on computed micro-tomography, coupled with X-ray diffraction (XRD-CT) is developed with the aim of mapping the distribution of ettringite within a cement paste. The main advantage of this technique is that the spatial distribution of ettringite (or other phases) can be studied on a three-dimensional basis, and without perturbing the microstructure of the sample. The output of the tomographic reconstruction consists of a series of 2D slices in which the relative amount of ettringite is encoded as a grey intensity value. A strategy was devised in order to convert the grey intensity values into volume fractions of ettringite, by calibration with the overall weight fractions relative to the various phases, obtained by Rietveld refinement of the diffraction patterns acquired by XRD-CT. Moreover, analysis of the images by a multifractal technique provided a tool for quantitative comparison of the ettringite distribution patterns in different samples, e.g. collected at different hydration times, or in OPC pastes with and without admixtures. The results of the multifractal analysis may also provide information about the modes of ettringite growth and aggregation during hydration.

Quantification of surface topography alteration by converged roughness parameters

Fischer, C[1,2*] & Lüttge, A.[2]
[1]Georg-August-University, Göttingen, Germany
([*]cornelius@rice.edu)
[2]Rice University, Houston, TX, USA

Dissolution or corrosion at mineral or material surfaces results in rough surface topographies with amplitudes at the micron to submicron range. The quantification of the evolution of surface topography during dissolution or corrosion reactions is a prerequisite to understand surface reactivity and spatial reactivity anisotropies.

Characterization and quantification of spatial and amplitude variations of material surfaces by surface roughness parameters is limited by both the spatial frequency bandwidth of the sensor as well as the field of view. Superposition of several surface building blocks of a given surface leads to complex surface-roughness parameter results of surfaces modified by dissolution or corrosion processes.

Here we present an analytical approach to deconvolve results of roughness parameter measurements. We apply *converged* surface roughness parameters for the detection and quantification of surface building blocks responsible for the respective amount of roughness parameters as a function of the field-of-view of the dataset [1]. Subsections of varying size of a given surface topography dataset were analyzed. Surface data were collected using vertical scanning interferometry (VSI), a surface-sensitive method with sufficient lateral and remarkable high vertical resolution.

As an example, we apply root-mean-square (rms) roughness (*Rq*) to quantify amplitude variations and the interfacial area ratio (*F*) to quantify the evolution of the total surface area of reacted surfaces. This approach is helpful for several mineralogical and technical applications. As an example, the evolution of iron oxide encrustation topographies was investigated. Surface sections with a specific micron to submicron rms-roughness show preferred colloidal particle adsorption [2]. This example underlines the potential of the approach discussed here to understand environmental processes as well as to develop technical applications.

Iridescent surface layers on altered bottle glass: from the Outback into the nanoscale lab

Milke, R.[1*], Hammerschmidt, K.[1], Wirth, R.[2] & Ganzel, J.[3]
[1]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany ([*]milke@zedat.fu-berlin.de)
[2]Helmholtz-Zentrum Potsdam Deutsches GeoForschungszentrum GFZ, Potsdam, Germany
[3]Berlin-Zehlendorf, Germany

Iridescent glass is a familiar finding from archeological sites, when glass objects were buried in soil or sunk in the sea for several 100s or 1000s of years. The change in surface structure leading to this optical effect has been related to thin chipping-off alteration layers. Modern methods like FIB-FEG-SEM (focused ion beam – field-emission gun scanning electron microscopy) that provide high resolution in imaging as well as chemical and structural analysis allow new views on this phenomenologically long known type of glass corrosion.

We investigate surface layers on glass bottles dug up in Australian opal fields where they were thrown away by miners not longer than a few decades ago. According to the local people these colory bottles indicate recent opal precipitation. This is not confirmed by our analytical work. The surface layers are rich in SiO_2, and strongly depleted in Na_2O, K_2O and CaO compared to fresh bottle glass, but also Al_2O_3 is largely retained. From a bulk chemical point of view the glass surface alteration is similar to siallitic weathering of (sub)tropical soils.

Isotope analyses of fresh bottle glass *vs.* alteration layers indicate shifts both in the Sm-Nd and the Rb-Sr radiogenic systems that can only be explained by chemical exchange between a fluid and the glass surfaces. The surface layers contain about 1 wt% Cl that is absent in the fresh glass, thus indicating that the corrosion layers formed by interaction with salinar soil fluids.

Electron-transparent foils were produced and investigated by STEM and TEM methods. The surface layers are not comprised of regular spheres like precious opal, but of loosely connected and easily chipping-off regular layers. Their thickness is remarkably uniform in the 200–500 nm range, being in most cases constant for a specific sample over stacks of 20 or 30 alteration layers.

This constancy in layer thickness signals a close relation to either a material-specific or a site-specific quality of the altered glass that leads into a chemical-mechanical feedback. The most obvious driving force for this periodic effect is volume change (increase by hydration *vs.* decrease by leaching of alkali elements and others); nevertheless structural changes (devitrification) might also be important.

The iridescence at first place attracts notice because it produces bright colors in the narrow spectrum visible to the human eye; the significance of the corrosion processes behind this optical effect might be of much wider significance.

Impact of lichens on granite weathering in the High Tatra Mountains (South Poland)

Michalik, M.[1*], Maciejowska, A.[1] & Wilczyńska-Michalik, W.[2]
[1]Inst. of Geological Sciences, Jagiellonian University, Kraków, Poland ([*]marek.michalik@uj.edu.pl)
[2]Inst. of Geography, Pedagogical University, Kraków, Poland

Increase of weathering rate of aluminosilicate rocks caused by lichen encrustation is often suggested; however, a protective role of lichen is also postulated.

The aim of the study was to determine the transformation of the granite rock-forming minerals under lichen crust (*Rhizocarpon geographicum* and *R. alpicola*). Samples were collected in the northern part of the Tatra granite (from 1500 to 1860 m asl). Studied rocks are metaluminous to peraluminous, composed of quartz and plagioclase with lower amount of K-feldspar and biotite. Muscovite (both, primary and secondary) occurs as minor component. Granodiorite and tonalite dominate in the study area; granite is present mainly in pegmatite zones relatively rich in K-feldspar. Rocks are medium- to coarse-grained. Granites are hydrothermally altered (chloritization of biotite, albitization of feldspars, and development of epidote).

A yellowish, rusty or bleached zone (up to few mm thick) is present in the rock beneath lichen crusts. The outer layer of the rock is cracked, and the density of cracks is variable. Cracks are often filled by lichen hyphae but empty ones occur as well. Rock fragments are often detached and incorporated into the lichen crust. Fragmentation of the rock can be caused by mechanical action of lichen (swelling and contraction of hyphae inside rock related to changes of ambient humidity or freeze-thaw processes).

Contact between quartz and feldspar grains is usually sharp. Contact between lichen and biotite is complex especially in case of biotite crystals with cleavage plains oriented perpendicularly to the rock surface. In such case hyphae penetrate deeply into biotite (up to 1-2 mm). Deep penetration results in splitting of biotite fragments and formation of small lenses of biotite remains surrounded by hyphae.

Interaction between lichen and minerals results in chemical transformation of minerals. Feldspars in the vicinity of lichen hyphae exhibit lowering of alkali and increase of Al contents. Altered biotite exhibits relatively low content of K (often below 0.5 atom pfu based on 11 oxygen atoms) and high content of Al (and concentration of Ca in numerous spot analyses). This trend of chemical transformation can be connected with the formation of biotite/vermiculite interstratified minerals. However, biotite/vermiculite was not determined by using X-ray diffraction techniques. In the vicinity of altered biotite, accumulation of Fe (or Fe and Ti) is common.

The presence of Al, Si, K, Ca, Fe, S, Cl and P in the outer part of lichen encrustation suggests that these elements originate from decomposed minerals but probably partly also from adsorption of atmospheric pollution components.

Results indicate that biomechanical and biochemical processes are active during lichen-rock interaction. Chemical decomposition of feldspars is common; decomposition of biotite is often usually significantly advanced but depth of alterations is limited. Accumulation of different elements in the reaction zone was previously determined but newly formed minerals have not been recorded yet.

Improvement of engineering parameters of soil filling materials and their effect on the corrosion of steel

Ismail, A.I.M.[1*], Ghany, N.A.A.[2] & Ryden, N.[3]
[1]Geological Science Dept., National Research Centre, Dokki, Cairo, Egypt ([*]ali_ismail_2000@yahoo.com)
[2]Electrochemistry and Corrosion Lab, Dept. of Physical Chemistry, National Research Centre, Dokki, Cairo, Egypt
[3]Dept. of Engineering Geology, Lund Institute of Technology, Lund, Sweden

Structures such as natural gas, crude oil pipelines and water mains are only some of the many structures reported to have been affected by soil corrosion around the world. The fundamental cause of the deterioration of steel pipelines buried underground is soil corrosion. Before such a structure is put in place the risk of corrosion and the need for corrosion protection measures should be estimated. The position of the buried structure in relation to the groundwater table is of major importance for corrosion. Even in the soil above the groundwater table, there is water held by capillaries and pores. The finer the soil particles (e.g. clay) and pore size the more water is held.

In this study the effect of filling materials, comprising granular sand and gravel fill, on the corrosion rate was studied. The effects of curing time of soil blends were also investigated. Engineering properties including soil plasticity, compaction test, unconfined compression strength (UCS), swelling and shrinkage were measured using British Standards (BS) methods. The corrosion rates of steel in soil blends were determined by weight loss method and electrochemical technique. The soil blends were characterized using Scanning Electron Microscopy (SEM), X-ray Diffraction (XRD) and Energy Dispersive Spectroscopy (EDX). The results showed that addition of portland, iron and anti-sulphate cements as stabilizers reduces the corrosion rate of steel structures and increases the resistivity of soil blends.

Corrosion rates determined by Vertical Scanning Interferometry

Luttge, A.[1,2*], Salas E.C.[1] & Arvidson, R.S.[1]
[1]Dept. of Earth Science, Rice University, Houston, TX, USA
[2]Dept. of Chemistry, Rice University, Houston, TX, USA
([*]aluttge@rice.edu)

Corrosion is one of the critical challenges modern industrial societies are facing. Conservative estimates place an annual 276 billion dollar price tag on corrosion in the United States alone – and the tendency is quickly increasing. Challenges for our fight on corrosion include not only the repair of structures but a combination of assessment, prevention and process control. These tasks entail an interdisciplinary approach to the study of kinetics and corrosion mechanisms at the molecular level. As the repository of sophisticated analytical and experimental techniques, modern mineralogy is well suited to play a critical role in this interdisciplinary approach and our fight against corrosion.

We study surfaces of reflective materials such as crystalline materials, cements, glasses, metals, and living organisms, and their precipitation, dissolution, corrosion, and growth kinetics with Vertical Scanning Interferometry (VSI). Through coupling of experimental and modeling techniques (Fig. 1) and the complementary use of both Atomic Force Microscopy (AFM) and VSI we are able to directly observe the surface and its dynamic changes over a wide range of length and time scales. Although these methods do not typically permit the direct observation of molecular-scale sites, such as kink sites and their distribution, this information can be provided by parameterized kinetic Monte Carlo (MC) simulations and associated modeling techniques such as Molecular Dynamics calculations (MD).

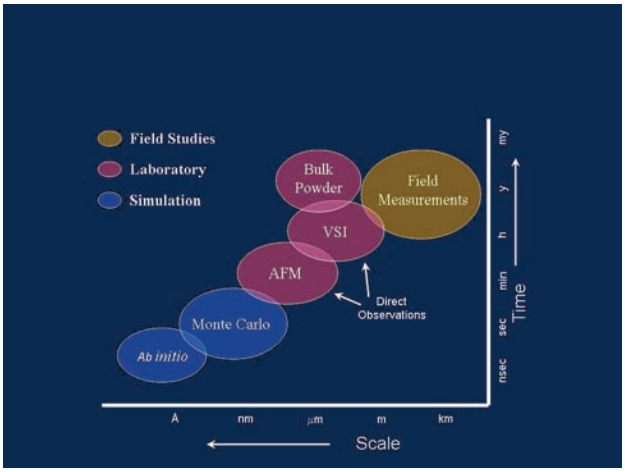

Fig. 1: Length and time scales relevant to corrosion processes.

The active surface of clays for healthy environments: dynamic of pesticides

Cornejo, J.
Instituto de Recursos Naturales y Agrobiología de Sevilla, CSIC, Seville, Spain (cornejo@irnase.csic.es)

Clays and "anionic clays" are layered natural and synthetic compounds, respectively, with very special surface properties. They are wonderful materials!

Clay minerals are composed by aluminosilicate layers negatively charged balanced with cations in the interlayer space. Smectites are a clay mineral group having swelling or expandable structure that makes the interlamellar structure accessible to cationic or polar organic molecules. On the contrary the "anionic clays" are layered double hydroxides (LDH) positively charged that is balanced by hydrated anions between the layers. Moreover, LDH has a very special property: when heated at 500ºC a mixed oxide is obtained and when put it in water rehydrates, recovering the original LDH structure. The sorption of anions from aqueous solutions by reconstruction of LDH structure is based on so-called "memory effect", which provides them with recycling possibilities. Several examples of interactions of these materials and organic molecules are shown.

The main characteristic of these materials is the high adsorption capacity and how easy they can be modified by changing the original surface properties into new ones almost "a la carte". The layer charge and the origin of the charge is a key parameter affecting sorption and chemical and phothochemical degradation reactions.

Clay minerals and LDHs are important sorbents when chemicals are ionic, ionizable or polar because their hydrophilic character. Replacement of inorganic interlayer exchangeable ions by organic ones has been shown to change the nature of the surface from hydrophilic to hydrophobic increasing mineral affinity for hydrophobic organic compounds. The selective modification of clay minerals with organic cations containing appropriate functional groups is a novel technique to maximize the affinity of the adsorbent for a given chemical.

These organoclays can be widely used as sorbents for diverse target molecules. These materials are of special interest for decontamination or contamination prevention purposes in soil and water environments e.g: in clay-pesticide formulations. Factors influencing the release rate and extent of pesticides from clays and organoclays are still issues which need to be addressed. The characteristics of the clay mineral, the amount and nature of exchangeable cations, the clay-pesticide ratio, and the procedure followed to prepare the formulation all affect the interaction of the pesticide with the sorbent and in turn its release from the formulation. Interactions mechanisms of original and modified clays with organic molecules are discussed.

Organoclays and organoLDHs based on large and small organic cations/anions are proposed not only as carriers in pesticide formulations to retard pesticide leaching after soil application and slow release of bioactive chemicals and photostabilizers but also as filters or barriers for water decontamination.

Uptake of uranium(VI) by clay minerals

Bachmaf, S.* & Merkel, B.J.
Dept. of Hydrogeology, Technische Universität Bergakademie Freiberg, Germany (*samerbachmaf@yahoo.de)

The transport of U(VI) in columns packed with different clay minerals was investigated. The major aim was to verify if the phenomena reported in previous batch experiments are true as well with flow through conditions.

Although smectites have higher cation exchange capacity than kaolinites, both kaolinite minerals (KGa-1b and KGa-2) showed much greater uranium sorption than smectites; requiring hundreds of pore volumes to achieve breakthrough. This can be considering as obvious evidence that surface complexation was the dominant mechanism for uranium retardation in all columns. The high uranium sorption capability for kaolinite is because it contains more exposed aluminol surface site which have greater binding affinity with respect to uranium than silanol sites.

The irreversible sorption of U(VI) observed in smectites packed columns can be attributed to the high content of iron oxide in the bentonite structure (e.g, 4.3% for SWy-2) comparing to that in the kaolinite structure (e.g., 0.2% for KGa-1b), which has a pronounced sorption affinity to uranium. In addition, the presence of the basal plane in (2:1) clay minerals can obviously delay the U(VI) desorption. Therefore, a slow diffusion of uranium from the surface into the interlayer forming stable surface complexes is delaying uranium extraction. The mineral composition and the degree of crystallinity plays an important role for sorption and desorption of U(VI).

Quantitative U(VI) recovery rates were obtained from the calculation of mass balance in all columns. U(VI) was totally recovered from kaolinite (although slowly), whereas 53 µg and 93µg of U(VI) remains in STx-1b and SWy-2 at the end of the experiments, which is an clear indication for irreversible adsorption (Table 1).

On the contrary, it is noticeable that the amount of U(VI) desorbed from IBECO was significantly higher than sorbed before. This can be attributed to an amount of uranium released from bentonite structure.

Table 1: Mass balance for sorbed and desorbed uranium

	Total U in µg/L	
Columns packed with	**sorbed**	**desorbed**
IBECO	474	542.1
STx-1b	566	513
SWy-2	724	631
KGa1b	877	877
KGa-2	939	928

A fast method to determine the cation exchange capacity of clays with guanidinium

Minder, P.* & Plötze, M.
Institute for Geotechnical Engineering, ClayLab, ETH Zurich, Switzerland (*pascal.minder@igt.baug.ethz.ch)

The common procedures of determining the cation exchange capacity (CEC) of clays with ammonium ions are often time-consuming and laborious [1]. Fast methods have been developed for a wide range of clay minerals using transition metal ions as exchanging index cations, e.g. copper triethylenetetramine $[Cu(trien)_3]^{2+}$ [2]. However, this method suffers from a significant underestimation of the CEC of vermiculite-bearing soils. The values depend from sample preparation. Excessive mechanical and chemical pretreatment and a longer exchange reaction time are needed to measure vermiculite CEC values effectively [3].

A new method was developed to measure the CEC of vermiculites in a simple way by exchanging the cations in one step by the highly adsorbing organic cation guainidinium $C(NH_2)_3^+$. Guanidinium (Gdn) concentrations were measured by fluorescence spectroscopy following a method proposed by Conn and Davis [4].

In our approach only some simple mechanical sample preparation is required before the exchange reaction. The sample material needs to be grinded down to a grain size less than 63 µm. Dispersion in water is achieved by ultrasonic treatment prior to the addition of the index ions. The exchange reaction then takes place within 4 hours in an aqueous solution of guanidine hydrochloride. Table 1 gives a comparison of the CEC obtained by different methods for a bentonite and a vermiculite.

Table 1: CEC (meq/100 g) from different methods

	(1)	(2)	(3)
Bentonite Calcigel	65	65	64
Vermiculite <63 µm	159	25	150

(1) Ammonium method [1], (2) Cu(II)trien method [2]. (3) Gdn method

First results show good agreement of the CEC measured with guanidinium and those measured with ammonium. Currently an experimental program is running, to apply the method to a larger range of clay minerals and to determine and improve the accuracy and the precision of the method.

Investigation of adsorption properties of a kaolinite and nontronite containing clay from Dikozu region (Eskisehir-Turkey)

Orhun, O.*, Dikmen, Z. & Dikmen, S.
Dept. of Physics, Anadolu University, Eskisehir, Turkey
(*oorhun@anadolu.edu.tr)

Instrumental characterization of a clay sample from Dikozu region (Eskisehir-Turkey) was performed by various techniques such as XRD, XRF, TGA/DTA, SEM. XRD analysis was realized by XRD apparatus (Rigaku, Rint 2200). Weight percentages of the sample were calculated from XRD pattern via the method developed by Moore and Reynolds [1] (Table 1). Besides, IR spectrum of the sample was obtained from FTIR spectrometer (Bruker, IFS 66v/S). Chemical analyses of the sample were taken by means of an WDXRF apparatus (Rigaku, ZSX Primus) (Table 1). TGA/DTA analysis of the sample was obtained from Thermal Analysis System (Setaram Setys Evolution 1750) and SEM images were taken by SEM system (Zeiss, EVO 50 EP). The results of instrumental analyses were compared with each other and they show consistency [2,3].

Table 1: XRD and XRF results of the sample from Dikozu region (Eskisehir-Turkey)

Components of the clay sample: nontronite (20.1%), dolomite (35.1%), kaolinite (44.8%)
Chemical analysis of the clay sample: SiO_2(49.183%), Al_2O_3(29.35%), Fe_2O_3 (2.654%), K_2O(0.043%), MgO(8,571%), TiO_2(0.08%), other (0.814%), ignition loss (23.516%)

The clay sample, 90 µm in size, was prepared by grinding and sieving processes. After the preparation of the sample, the investigation of adsorption properties was realized by high speed volumetric sorption analyser (Quantachrome, Nova 2200). Before analysis of the adsorption properties, the sample was activated thermally in 110°C during 3 hours. Specific surface area and density of the sample were determined in the medium of liquid nitrogen (77K) by using B.E.T. method. Adsorption isotherms were consistent with B.E.T. model. After obtaining the B.E.T.isotherms, the values of the specific surface area and density of the sample were 53.043 m^2/g and 2.2 g/cc respectively.

Investigation of water vapour adsorption properties of the sample was realized by volumetric adsorption system (Quantachrome, Autosorp 1). Water vapour adsorption-desorption isotherms were consistent with B.E.T. model. Specific adsorbed water vapour, specific surface area and specific retention capacity of the sample were 30 cc/g 147.2 m^2/g and 32.630 cc/g respectively. The specific surface areas of the sample determined by using different adsorbates were found different. This difference comes from the molecular structures of nitrogen and water.

Stability and forms of Fe in natural and modified clays: connection to sorption properties

Dousova, B.[1*], Kolousek, D.[1], Grygar, T.[2], Herzogova, L.[1], Lhotka, M.[1], Machovic, V.[1], Krejcova, S.[1] & Jakubikova, B.[1]
[1]Institute of Chemical Technology in Prague, Prague, Czech Republic ([*]Barbora.Dousova@vscht.cz)
[2]Institute of Inorganic Chemistry ASCR, Rez, Czech Republic

The stability and forms of structural Fe in natural aluminosilicates have been usually based on the redox potential, predominantly in aqueous environment. The oxidation-reduction processes of Fe particles in soils and sediments strongly influenced not only physical chemical properties, but also surface properties of aluminosilicates (specific surface area, surface charge) [1], closely related to the adsorption behaviour of solid phase.

Recently Fe-modified aluminosilicates have opened new possibilities in adsorption technologies due to the change of surface charge (pH_{ZPC}) and thus a strong affinity to anionic contaminants. Four natural and two modified clays with a high content of Fe (Table 1) were investigated in term of Fe forms, their changes during adsorption processes and the stability under balanced and/or disturbed conditions in solid-aqueous system (redox potential, ionic strength, pH, microbial activity, competitive ions, etc.) [2,3].

Table 1: Relative content of Fe in natural and modified clays (% wt.)

	locality	characteristic	Fe (%wt)
Kaolinite	Király Hill, Hungary	natural	3.0
Illite clay	Illite pit in Tokai, Hungary	natural	1.7
Smectite clay	Lignite pit, Visonta, Hungary	natural	to 6.9
Calcined kaolin	West Bohemia, CR (pit)	modified Fe^{2+}/Fe^{3+}	4.1/27.2
Bentonite	West Bohemia, CR (pit)	natural	14.6
		modified Fe^{2+}/Fe^{3+}	17.8/28.6
Kaolinite clay	West Bohemia, CR (clay deposit)	natural	8.9

The detailed characterization of Fe chemistry in different types of aluminosilicates anabled to predict the stability and detention time of surface fixed particles forming complexes and/or covalent bonds via Fe ions. These properties particularly affected the adsorption quality of clay sorbent both in natural systems and in technological processes. The adsorption/ desorption of dissolved ions including toxic contaminants strongly depended on their initial concentration, and also on surface Fe phases (their amount and chemical forms). However, the stability of saturated sorbent also related to the type and purity of clay matrix, binding character, physical chemical properties and ageing time.

Synthesis and investigation of physicochemical properties of Zr,Al-pillared montmorillonites

Timofeeva, M.N.[1*], Panchenko, V.N.[1], Chesalov, Yu.A.[1], Tsybulya, S.V.[1] & Bolormaa, O.[2]
[1]Boreskov Institute of Catalysis, Novosibirsk, Russia ([*]timofeeva@catalysis.ru)
[2]Faculty of Chemistry, National University of Mongolia, Ulan Bator, Mongolia

Nowadays for direct elimination the pollutions considerable attention has been given to the development of new functionally active sorbents based on clay minerals due to their unique structural and physicochemical properties. Multicomponent systems containing two mixed ions, such as Al/Ga-, Al/Fe-, and etc., are of particular interest due to their unique textural and physicochemical properties.

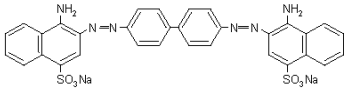
A Na-containing naturally occurring montmorillonite was intercalated with solutions containing Al-, Zr-, and mixed Zr,Al-cations, with various Zr/Al ratios [1]. The Zr,Al-PILCs were obtained by calcination of the intercalated precursors at 450°C. Characterization studies were performed by use of XRD, FTIR, DR-UV-vis and N_2-adsorption/desorption analysis.

Effect of Zr/Al ratio of Zr,Al-containing pillaring solution on structural and physicochemical properties of Zr,Al-PILCs was examined. As can be seen from Table 1 all Zr,Al-PILCs showed ordered, layered structures with basal spacing between 18.3 -16.4 Å (14.7 Å for Na-clay). The increase in Zr content in Zr,Al-PILCs favours the increase in interlay distance (d001), although the specific surface area slightly changes.

Table 1: Textural data of Zr,Al-PILCs

	Al % wt	Zr % wt	S_{BET} $m^2 \cdot g^{-1}$	d_{001} Å
Al-CAC	8.80	0	216	18.3
Zr,Al-CAC(70/10)	8.76	1.89	271	17.6
Zr,Al-CAC(70/20)	8.72	3.58	240	17.0
Zr,Al-CAC(70/30)	8.15	3.00	205	16.4
Zr-CAC	5.55	11.6	206	10.7

The increase in Zr content makes alterations in nature and strength surface functional groups that were confirmed by IR spectra of adsorbed CO and $CDCl_3$. The increase in Zr content leads to the change in surface acidity. The Zr,Al-PILC in the aqueous suspensions became coloured after the adsorption of Congo red (CR). The following stainings were obtained, on Zr,Al-PILC(10/70) - red, on Zr,Al-PILC(20/70) - violet-red and on Zr-PILC - dark violet (Fig. 1). It appears that CR can serve as an indicator of the surface acidity of montmorillonite.



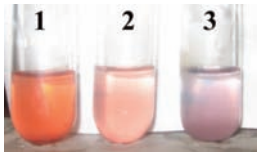


Fig. 1: Adsorption of Kongo red (0.035 $mg \cdot ml^{-1}$) on Zr,Al-PILC(10/70) (1), Zr,Al-PILC(20/70) (2) and Zr-PILC (3) at 25°C.

The effects of surface acidity of Zr,Al-PILCs, initial pH value of the Congo red dye solution and temperature on adsorption capacities of samples for CR dye have been investigated.

Electric-field induced alignment of modified Na-fluorohectorite clay particles

Rozynek, Z.*, Wang, B. & Fossum, J.O.
Dept. of Physics, NTNU, Trondheim, Norway
(*zbigniew.rozynek@ntnu.no)

The electric field induced alignment of organically modified sodium-fluorohectorite (Na-Fh) clay particles suspended in silicone oil was studied by means of synchrotron wide angle X-ray scattering (WAXS).

This report focuses on the comparison between the anisotropic arrangement of organically modified clay particles and their previously studied non-modified counterparts [1].

Na-Fh particles suspended in oil undergo a fast and extended structuring when subjected to an electric field [2]. As a coarse approximation, the Na-Fh clay platelets forming the chain can be represented as disk-shaped aggregates, whose orientation is defined by a unit normal vector. Thus, the anisotropic arrangement of the system can be described by an orientation distribution that is a function of the normal vectors for all aggregates [3]. The classical Maier-Saupe function was used for the orientation distribution, since it was found to be suited to our data, as discussed previously by Méheust, et al. [4]

In fig. 1 the experimental set-up is presented whereas fig. 2 shows two-dimensional diffractograms.

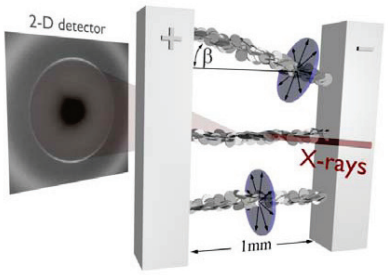

Fig. 1: Experimental geometry for the WAXS measurements. Particles are forming chains along the E-field.

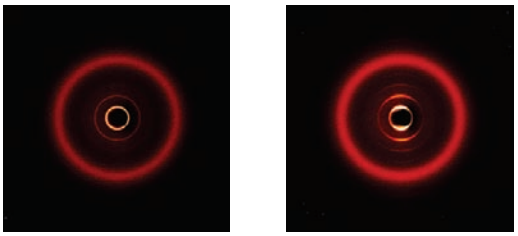

Fig. 2: WAXS patterns of modified clay particles without (left) and with (right) E-field applied (0.35 kV/mm).

The WAXS data showed that the degree of anisotropy was higher for the system with organically modified Na-Fh particles (S=0.71) than for unmodified clay particles (S=0.63). This can be explained by fact that the modified clay particles do not form large aggregates as it is the case with unmodified particles, leading to a better organization of the constituents of this electrorheological fluid.

Dissolution of the surfactants modified montmorillonite in HCl

Pálková, H.[1*], Jankovič, Ľ.[1], Zimowska, M.[2] & Madejová J.[1]
[1]Institute of Inorganic Chemistry SAS, Bratislava, Slovakia
(*helena.palkova@savba.sk)
[2]Institute of Catalysis and Surface Chemistry PAS, Krakow, Poland

Various concepts have been applied to modify the properties of clay minerals in order to widen their possible applications. For example, cationic organic surfactants are often used to change their surface properties. On the other hand, acid activation is an appropriate method for alteration of the clay minerals structure. In this work these two methods of modification are united and the stability of organo-modified montmorillonite in inorganic acid and the influence of the acid treatment on final textural and morphological properties of obtained products are examined.

Ca^{2+} cations in Ca-SAz-1 montmorillonite were exchanged with organic cations with different length of alkyl chains: tetramethylammonium (Me_4N^+), tetraethylammonium (Et_4N^+), tetrapropylammonium (Pr_4N^+), and tetrabutylammonium (Bu_4N^+). The results of the chemical analysis revealed very low Mg and/or Al content present in the solid reaction product after 8 hrs dissolution of Ca-SAz-1 in 6 M HCl, indicating almost completely decomposed sample. Me_4N-SAz sample was dissolved in similar extent. However, with increasing size of the organic cation higher resistance to acid attack in order Ca ≤ Me_4N^+ < Et_4N^+< Pr_4N^+< Bu_4N^+ was observed. About one half of the initial aluminium content still remained in the solid reaction product for Bu_4N-SAz dissolved even for 8 hrs. SEM analysis showed that destruction of the original layer composition upon acid treatment became evident also from the overall morphology of the particles, their size and aggregation. The exposed planes of large plate-like montmorillonite aggregates were disintegrated and smaller fine grains were created. Formation of protonated silica as a product of acid leaching led to the sharp increase in BET surface area of Ca-SAz-1 from 70 m^2/g to 467 m^2/g, after 4 hrs of treatment. The only sample reaching the similar maximal BET value was the 4 hrs treated Me_4N-SAz. The course of the BET values for all samples is given in Fig. 1. The gradual increase in the BET surface area was also observed for Bu_4N-SAz, but it did not reach the values found for other studied samples (Fig. 1), which confirmed only partial decomposition of this montmorillonite. Bulky organic cations cover larger surface area of montmorillonite, what decreases the accessibility of the interlayers to proton attack causing the increase in the resistance of the clay layers to the acid.

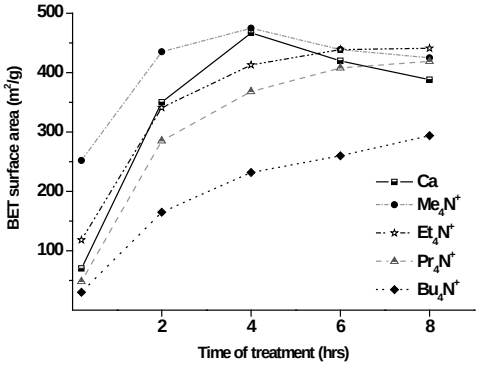

Fig. 1: BET surface areas of untreated samples and samples dissolved in 6M HCl at 80°C for various times.

Influence of clay's cation exchange capacities (CEC) on organoclay structure and locations on the loaded surfactants

He Hongping*, Ma Yuehong, Qing Yanhong, Zhu Jianxi & Yuan, Peng
Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China (*hehp@gig.ac.cn)

During the last two decades, organoclays have attracted great interest due to their wide applications such as adsorbents for organic pollutants and clay-based nanocomposites [1]. However, some important aspects still have not received enough attentions, such as the influence of the characteristics of the used clays and configuration of the used surfactants on the microstructure and property of the resultant organoclays, the microstructural evolution of organoclays when heated. These are of high importance for the applications of organoclays.

In this study, three montmorillonites with different cation exchange capacities (CECs) and surfactants with different alkyl chain length and chain number were used to prepare organoclays at different surfactant concentrations. A combination of various characterization techniques was applied to investigate the microstructure of the obtained organoclays and their microstructural evolution when heated. The present study shows that the basal spacing of the organoclays increased with surfactant loading [2,3], while the maximum basal spacing increased as the alkyl chain length of the surfactant increased [2]. For the same surfactant, the maximum basal spacing of the organoclays was little influenced by the CEC of the montmorillonite component [4]. The level of surfactant loading required to reach the maximum basal spacing, however, strongly depended on the CEC. For a given surfactant, the maximum basal spacing increases with the increase of chain number.

When heating the organoclays, there is a slight increase of basal spacing before 340°C and after this temperature, there is an obvious decrease of the basal spacing, indicating the degradation the intercalated surfactants. The XRD patterns at different temperatures and TG curves of the organoclays indicate that there are two basic different locations of the loaded surfactants: 1) adsorbed on the clay external surfaces, including in the pores available between clay particles with a "house of cards" structure [5], 2) intercalated into clay interlayer spaces via two different ways, i.e., surfactant cations replacing the interlayer exchangeable metals and surfactant molecules being adsorbed into interlayer spaces [6,7].

Effect of clay amendments on wettability of peat-based growing media – relation between capillary water uptake and EDX data on surface composition

Below, M.*, Walsch, J. & Dultz, S.
Institute of Soil Science, Leibniz University of Hannover, Germany (*m-below@web.de)

In Europe 200.000 tones of clays are used for growing-media annually. Peat, an important substrate component gets highly hydrophobic if it is getting dry. The addition of clay to peat induces a coated surface with hydrophylic properties on the organic matter which improves rewettability and reduces the risk of erroneous irrigation. At present there is only empirical knowledge about the amount of clay needed and the optimum mineral parameters for different horticultural purposes.

For the organic substrate component a blend of different sphagnum peats with a moderate degree of decomposition, obtained from Klasmann Deilmann GmbH (Geeste-Groß Hesepe, Germany) was used. Seven clay samples highly different in their mineral parameters from the Mesozoic-Tertiary weathering mantle, Rhenish Massif were obtained from Stephan Schmidt KG (Langendernbach, Germany). A saprolitic clay, two bentonites, and two translocated clays as well as two blends were included. Mixtures of 10, 20, and 30 kg clay with 1 m³ peat were prepared.

For the evaluation of the water uptake characteristics a capillary-rise method, developed for inhomogeneous, fibrous and swelling materials (Dutch RHP-foundation) was used. The coverage degree of the peat surfaces with clay minerals was described by the C/Si ratio determined by energy dispersive X-ray spectroscopy (Quanta 200, Fei) for sections of 6 mm².

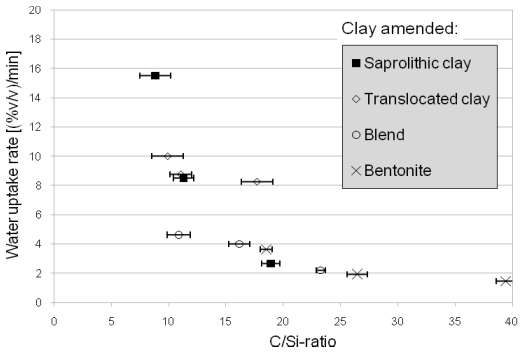

Fig. 1: Effect of four different clays amended in amounts of 10, 20, and 30 kg/m³ peat on the water uptake rate. The C/Si ratio (n=5) indicates the coverage degree of peats surfaces with clay.

At low C/Si ratios, where the surfaces of peat are most complete coated with clay minerals, all clay-peat systems show the highest water uptake rate (Fig. 1). Highest variability is observed for a saprolitic clay rich in illite and kaolinite, where the water uptake rate ranges from 2,6 to 15,5 %v/v/min. For the translocated clay and bentonite, the absolute amount of amended clay showed minor effects, but water uptake rate is quite higher than that of original peat (1,3 %v/v/min). Water uptake rate is not only affected by clay mineralogy where clays rich in illite and kaolinite show quite stronger effects than bentonites, but also by parameters such as particle size, content of secondary oxides and sorption capacity for dissolved organic matter.

Future work focuses on the stability of peat and clay aggregation during a vegetation period, which is determined at present in tests on flocculation considering electrolyte effects of fertilizers.

Spectral properties of Rhodamine 6G in smectite dispersions: effect of the monovalent cations

Czímerová, A.*, Bujdák, J. & Jankovič, Ľ.
Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovak Republic (*uachczim@savba.sk)

Montmorillonite monoionic forms with alkali metal and NH_4^+-cations were prepared by ion exchange. The hydration properties and binding of the ions to montmorillonite surface and the swelling properties of the mineral specimens were analyzed. Whereas Na^+- and Li^+-ions were fully hydrated over a large range of conditions, large size K^+, NH_4^+, and mainly Rb^+ and Cs^+ ions were apt to bind directly to the oxygen atoms on the mineral surface. The forms with large ions exhibited reduced hydration and swelling and the absence of macroscopic swelling of the respective aqueous colloids. The interaction of laser dye rhodamine 6G (R6G) in montmorillonite colloids was investigated by absorption and steady-state fluorescence spectroscopies. Significant effects of the properties of both the inorganic ions and swelling properties of colloidal dispersions on R6G molecular aggregation were observed. Large amounts of the molecular aggregates were formed in the colloids of Na^+- and Li^+-montmorillonites. The aggregates absorbed light at significantly lower wavelengths (~460 nm) with respect to the light absorption by non-aggregated dye (535 nm). Fluorescence spectroscopy provided a key evidence for the assignement of the type of the aggregates: The emission of the aggregates at relatively low energies proved these assemblies are rather a mixed *H*-/*J*-type than ideal *H*-aggregates. The presence of parent inorganic cations of larger size led to a significant lowering of the amount of the R6G aggregates in favor of the monomers. Investigations of the evolution of the dye aggregation with time indicated basic features of dye aggregation reaction: The size of parent inorganic ions did not affect the reaction mechanism, but rather limited the extent of the reaction. Probably the forms with large inorganic ions, such as Rb^+ and Cs^+, did not provide sufficient surface for the formation of the large size assemblies of the dye. This property can be explained in terms of strong association of the large alkali metal ions to clay mineral surface, as well as to reduced swelling in the colloidal systems of respective forms.

Characterization of Turkish kaolinite and its electrokinetic behavior in some aqueous solutions

Dikmen, S.*, Dikmen, Z. & Orhun, O.
Physiscs Dept., Science Faculty, Anadolu University, Eskisehir, Turkey (*sdikmen@anadolu.edu.tr)

The interaction of kaolinite [$Al_2Si_2O_5(OH)_4$] particles is of particular importance in widespread applications, e.g., in ceramics, in the manufacture of paper (as a coating, pigment, and filler), in inks and paints (as an extender), and as an additive in the production of rubber and polymers [1]. The behavior of kaolinite particles in suspensions, pastes, and composite materials is controlled by surface chemistry properties. Investigation of the electrokinetic behavior, characterization of the particle sizes, shapes and surface properties of the particles that compose the clay is essential [2].

In the first part of study, to determine some characterization of kaolinite sample obtained from Eskişehir (Mihalıççık) region various analysis techniques such as X-Ray Diffraction (XRD), X-Ray Flouresence (XRF), Fourier Transform Infrared- (FT-IR), Scanning Electron Microscope (SEM), specific surface area (BET), Thermal Analysis (DTA-TG), PSD (Particle Size Distribution) have been used. In the second part of the study, zeta potential (ZP) of the powdered kaolinite was investigated behavior in the presence of chloride-based metal salts (NaCl, $CaCl_2$ and $AlCl_3$) at a constant pH and also at different pHs, without metal salts.

Based on the result of semi-quantitative XRD analyses by Moore and Reynold's method [3], content of Ahirozu kaolinite is 92.2% kaolinite and 4.7% quartz and 1.1% calcite.

Investigating the variation of zeta potential of kaolinite, according to pH, it was found that it has point of zero charge (pzc) on about pH 3.5 and its zeta potential is negative above the pzc and positive under the pzc. Because of its pzc' value on about pH 2 and increasing the concentration of H^+ ions through the aqueous medium, electrical double layer is pressed and then the value of zeta potential increases to 3 mV.

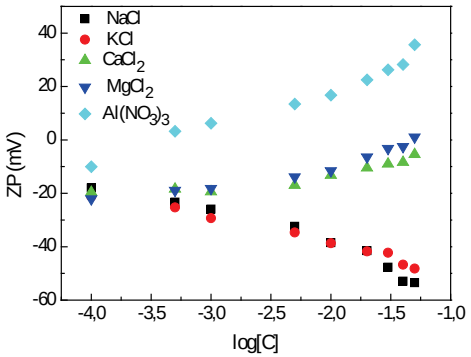

Fig. 1: Effect of the metal salts on the zeta potential of Turkish kaolinite.

Complexation and interfacial behavior of possible environmental contaminants

Fazekas, P.[1], Fenyvesi, É.[2], Lovas, G.[3] & Csempesz, F.[1*]
[1]Inst. of Chemistry, Laboratory of Colloid and Supramolecular Systems, Eötvös University, Budapest, Hungary
(*csf@chem.elte.hu)
[2]Cyclolab Cyclodextrin Research & Development Laboratory Ltd., Budapest, Hungary
[3]Dept. of Mineralogy, Eötvös University, Budapest, Hungary

The removal of damaging chemicals has been a fundamental point in environmental research and technology, and in many related fields. For this reason, increasing attention has recently been directed to studies concerning the interfacial properties of possible environmental contaminants since they may underlie efficient technologies in treatments of soils and/or surface waters. supramolecular substances offer potential in controlling interfacial processes and represent unique models for the study of their non-covalent interactions with several chemicals.

In this paper, the relevance of inclusion complexation in improving the aqueous solubility of possible soil and water contaminants and also, the interfacial behavior of the formed supramolecular complexes are outlined. To this end, solubilization of a sparingly soluble polycyclic aromatic hydrocarbon (phenantrene, which may accumulate in soils) and a better soluble drug (carbamazepine, which may contaminate surface and ground waters) with native cyclodextrins (α-, β- and γ-cd), and with randomly methylated β-cd (rameb) or hydroxy-propyl β-cd (hpbcd), respectively, was studied in aqueous solutions. In addition, the surface properties of these chemicals and inclusion complexes at air/solution interfaces, and their adsorption from aqueous suspensions onto particles of a fractionated clay mineral (activated bentonite, particle size < 1 μm) were investigated.

The aqueous solubility of both the phenantrene and the carbamazepine could be considerably increased in solutions of suitable cyclodextrins. RAMEB and HPBCD proved to be the most efficient solubilizers for these substances. These results suggest that dissolved cyclodextrins may form inclusion complexes with each chemical. Association constants ($K_{1:1}$) for the complexes of 1:1 molar ratio have been; therefore, calculated from the experimentally determined solubility isotherms.

Certain supramolecular complexes exhibited surface activity. The complexes of both chemicals formed with the RAMEB of individually amphiphilic character and also, with the HPBCD resulted in definite reduction in the surface tension of their aqueous media.

In individual adsorption from aqueous media only slight amounts of each chemical accumulated on the Na-bentonite particles. However, the dissolved inclusion complexes adsorbed much better onto this mineral than either the individual host or the quest molecules. Especially, the carbamazepine-RAMEB and the carbamazepine-HPBCD complexes exhibited high affinity for the particle surfaces. Correlation was found between the extent of adsorption of the different inclusion complexes and their surface activity.

Preparation of modified sorbents from rehydrated clay materials

Lhotka, M.*, Machovič, V., Doušová, B. & Koloušek, D.
Institute of Chemical Technology in Prague, Prague, Czech Republic (*miloslav.lhotka@vscht.cz)

The use of clay materials as selective sorbents of different contaminants belongs to very efficient methods [1]. A natural kaolin was calcined to metakaolin and than rehydrated at different temperatures to a highly porous sorbent. The kinetics of this process was measured, with subsequent XRD and IR characterization of arised phases [2]. The specific surface and pore distribution of new phases were also assigned. In addition, the obtained kaolin was also pre-treated with Fe^{3+} ions to improve its sorption affinity to anionic particles. Fe-modified kaolin was then used for the adsorption of As/Se oxyanions, and the adsorption efficiency in dependence on the physical chemical properties (pH, As/Se concentration) of initial solution and the surface properties of sorbent (specific surface, modification method) were investigated. The adsorption properties of newly prepared sorbents were finally compared with calcined kaolins in both raw and modified forms. The theoretical and maximum adsorption capacities of rehydrated kaolins are summarized in Table 1.

Table 1: As(V)/Se(IV) adsorption on raw and Fe-modified rehydrated kaolin under the various rehydration time

Sorbent	S(BET) (m2/g)	As(V) sorption		
		$Q_{theor.}$ (mg/g)	q(max) (mg/g)	ε(max) (%)
1 day	31,75	0,49	0,35	0,5
4 days	98,57	**0,98**	**0,65**	**5,9**
7 days	103,1	0,04	0,27	1,1
1 day-Fe	27,06	6,12	6,43	96,2
4 days-Fe	**40,66**	**6,93**	**7,33**	**96,8**
7 days-Fe	38,71	6,30	6,45	96,8

Sorbent	Se(IV) sorption		
	$Q_{theor.}$ (mg/g)	q(max) (mg/g)	ε(max) (%)
1 day	1,92	1,36	8,5
4 days			
7 days			
1 day-Fe	-	5,64	59,4
4 days-Fe	-	**7,52**	**70,7**
7 days-Fe	-	6,36	62,1

As(V) adsorption on Fe-modified kaolin ran almost quantitatively by high sorption capacities, and the procedure according to Langmuir model should be considered. Se(IV) adsorption proved a different mechanism and lower sorption capacity probably resulted from the surface and binding properties of adsorbed anion. The 4-days rehydrated kaolin demonstrated the highest specific surface and the best adsorption properties for both As(V) and Se(IV) oxyanions.

Quantification of particle retention at natural rough black slate surfaces

Michler, A.[1*], Darbha, G.K.[1], Schäfer, T.[2], Lüttge, A.[3] & Fischer, C.[1,3]
[1]Georg-August-Universität, Göttingen, Germany (*amichle@gwdg.de)
[2]Inst. fur Nukleare Entsorgung, KIT, Karlsruhe, Germany
[3]Rice University, Houston, TX, USA

Adsorption of colloids at rock surfaces is an important environmental process. Quantitative predictions about immobilization of colloids are critical for colloid-aided contaminant transport. In the field of acid mine drainage (AMD) the retention of colloids is of particular interest because of their high potential to sorb and transport heavy metals, trace elements or radionuclides, often released during oxidative and acid rock weathering conditions [1]. Our recent studies showed that under unfavourable electrostatic conditions, the importance of surface roughness for deposition of colloids is increased [2].

Here we present a quantitative and experimental approach to investigate the relationship between micrometer to submicrometer roughness of black slates and the retention of polystyrene latex particles. Rock surface topography as well as particle retention were quantified using three-dimensional data, collected by vertical scanning interferometry (VSI). Roughness parameters (root mean square roughness, *Rq* and interfacial area ratio, *F*) were calculated based on previous studies about roughness quantification at irregular surfaces [3]. The adsorption experiments were performed as flow-through (fluid cell) and dipping experiments at pH = 6.5, where the rock surface is negatively charged according to streaming potential measurements. In a first experimental approach we used spherical particles with a diameter of 2 µm. They were negatively charged to assure conditions of electrostatic repulsion.

First results showed that micrometer-sized slopes at edges of clay mineral or organic matter aggregates are the preferred sites of adsorption of black slates (Fig. 1). Typical *Rq* and *F* values for these inclined planes of high particle density were around 0.3 µm respectively 2.8.

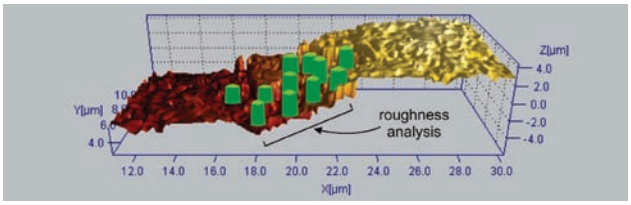

Fig. 1: High density of adsorbed particles (cylinders) at micrometer-sized slope.

Further experiments will be accomplished with smaller polystyrene particles of colloidal size. Additionally, iron and phosphate colloids will be used to resemble more AMD conditions.

Layer charge characterization of acid treated clay minerals by their interaction with methylene blue cations

Pentrák, M.*, Czímerová, A., Madejová, J. & Komadel, P.
Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia (*martin.pentrak@savba.sk)

Changes in layer charge of various clay minerals upon acid treatment were studied using their interactions with methylene blue (MB) cations. This fast method is frequently used for qualitative estimation of the layer charge of smectites; however, its utilization for other clay minerals is rare. Less than 2 μm fractions of bentonites SAz-1 (Cheto, Az, USA), SWy-2 (Wy, USA) and JP (Jelšový Potok, Slovakia) containing dominantly montmorillonite were studied together with illite/smectite DVS (Dolná Ves, Slovakia), IL (Ca-illite #36, Morris, Il, USA) and kaolinite GF (Gold Field, Pugu Hills, Tanzania). Dissolution in HCl was performed at 95°C for periods of 1–36 hours.

Dye cation agglomeration at the mineral surface depends on layer charge density and results in creation of different forms of MB absorbing visible light at different wavelengths. The spectrum of MB adsorbed on SAz-1 shows a single band at 568 nm attributed to H-aggregates which are preferentially formed on the high charge surface. Two bands of similar intensities at 568 nm and 668 nm assigned to H-aggregates and monomers, respectively, prove medium layer charge density in JP. Mainly monomers absorbing at 668 nm are detected on SWy-2 confirming the lowest charge of this montmorillonite. Absorption bands of both H-aggregates and monomers appear in the spectra with DVS and IL. The intensities of the 568 and 667 nm bands indicate medium layer charge density for IL and slightly higher for DVS. The spectrum of MB on GF kaolinite shows only a band at 667 nm attributed to the monomers and proving very low charge of this sample.

The extent of structural modification of clay minerals upon acid treatment depends on the mineral type and its chemical composition. Chemical analyses of the liquid reaction products show that the dissolution rate of the montmorillonites decreases in order SAz-1>JP>SWy-2. Non-expandable interlayers in DVS and IL increase their stability in HCl as compared to montmorillonites. Kaolinite with none or minor substitution in the layers dissolves most slowly. The spectra of MB on the acid-treated samples show that the degradation of the mineral structure is closely connected with the layer charge reduction. The negative charge sites in these materials are too far each other and MB cations cannot form H-aggregates with neighbouring cations. Therefore the intensity of the H-aggregates band at 570 nm gradually decreases in favour of monomers.

The fastest decrease of the layer charge occurs for high charged montmorillonite SAz-1. The intense band of monomers at 668 nm in the MB spectrum of SAz-1 treated for 8 h confirms that the reaction product is a material of low charge density. To get similar MB spectra for middle charged JP and low charged SWy-2, at least 18 and 24 hours dissolution time, respectively, is needed. The presence of some expandable interlayers in DVS and IL allows the interaction of MB not only on the surfaces but also in the interlayer space of these minerals. The intensities of the H-aggregates and monomers bands show only small effect of HCl on the layer charge of DVS and IL upon treatments up to 12 h. On the other hand, the changes of the spectral properties are significant after 36 h, while the charge on kaolinite has not changed. The layer charge density controls the extent of MB agglomeration on natural and acid-treated clay minerals.

Thermal behaviour of ground and unground leached vermiculite

Perez-Rodriguez, J.L.[1*], Maqueda, C.[2], Subrt, J.[3] & Balek, V.[3]
[1]Instituto de Ciencia de Materiales de Sevilla CSIC, Sevilla, Spain (*jlperez@icmse.csic.es)
[2]Instituto de Recursos Naturales & Agrobiologia de Sevilla, Sevilla, Spain
[3]Institute of Inorganic Chemistry, Řež, Czech Republic

The preparation of porous materials from clay minerals including vermiculite by selective leaching with acid has been study by several authors. The presence of iron in vermiculite plays an important role in the specific surface area obtained after acid treatment. Grinding of clay minerals significantly influences their leaching behaviour [1,2].

Ground and unground vermiculite from Santa Olalla (Huelva, Spain) was used as starting material. Vermiculite samples (<80 μm) left untreated and ground for three minutes were leached with HCl solution 1.0 M at a solid/acid mass ratio of 1:20. The suspensions were maintained at 80 ºC and stirred for 24 h.

The ground vermiculite from Santa Olalla treated with 1M HCl produced a residue constituted by silica and iron oxides.The porosity studies showed that the high surface area of this residue may be attributed to the presence of iron coming from structural iron. Using HRTEM it was found that the HCl treated ground vermiculite sample consists of amorphous silica and β-FeOOH (akaganeite) microcrystals containing a small amount of Ti and Cl^- as impurities.

The DTA-TG study showed an endothermic effect at 70ºC attributed to water mass loss and a small exothermic at 280ºC.The XRD diagrams of the residue heated in a high temperature chamber from 30 to 1200ºC at 10º min^{-1} were registered every 50ºC. The starting ground 1 M HCl leached vermiculite was partially crystalline on account of presence of the crystalline β-FeOOH. This phase is present untill150 ºC. Whereas the sample heated between 150 and 800ºC was practically amorphous. This is in agreement with the observations that β-FeOOH decomposes to amorphous or poorly crystalline phase β-Fe_2O_3 transforming only slowly to crystalline α-Fe_2O_3. At 850 °C the sample showed the first signs of crystallinity fully developed at 1050 °C. At this temperature the sample was crystalline, consisting of quartz, cristobalite, α-Fe_2O_3 and ε-Fe_2O_3. The shifting of the crystallization temperature toward higher temperature and the consequent stabilization of the amorphous Fe_2O_3 nanophase is attributed to what is called the preventive role of the silica matrix. This effect results in fact that well crystalline iron oxide nanoparticles embedded into the silica matrix are formed usually at relative high temperatures in range 600-1000 °C in contrast to silica free material.

Influence of thermal pre-treatment conditions on the reactivity of kaolinite and illite/smectite clays in alkaline and alkaline earth solutions

Seiffarth, T.*, Hohmann, M., Posern, K. & Kaps, Ch.
Chair of Building Chemistry, Bauhaus-University Weimar, Weimar, Germany (*torsten.seiffarth@uni-weimar.de)

Metakaolins, or alumosiliceous fly ashes are commonly used as starting materials for the generation of geopolymeric binders. Geopolymers are made by the means of reactive materials containing a certain amount of silicate and aluminate phases which can be dissolved by an alkaline medium. As a result of this, stable polymeric networks of alumosilicates will be formed [1]. The search for alternative low cost or high available resources as geopolymer raw materials is a matter of economic interest. This study focuses on the potential of kaolinite and illite/smectite clays in this regard.

The influence of the thermal pre-treatment conditions on the reactivity of the clays in alkaline and alkaline earth solutions has been investigated. Kaolinite and illite/smectite based clays were thermally activated between 550 and 950°C in oxidizing and reducing atmosphere, respectively. Changes were characterized by different methods (thermal analysis, XRD, dissolution tests). Isothermal calorimetric measurements were carried out to characterize the reaction process in alkaline media. The reached activity was followed by the degree of dehydroxylation and the amorphous content.

The potential of a raw material for the geopolymer reaction by alkaline activation can be derived from the molar ratio of soluble Si/Al in alkaline solutions. Therefore, dissolution tests in 10% NaOH solution (150 mg solid, 150 ml solution, 60°C) were carried out. Time of dissolution was varied (1d, 3d, 7d). Additionally, the standard Chapelle test was executed to determine the pozzolanic reactivity.

More Si than Al is dissolved from all samples after any dissolution time. That was already found for raw kaoline [4]. But on the one hand, the molar ratio of soluble Si/Al decreases with increasing dissolution time. On the other hand, this ratio increases with increasing pre-treatment temperature. This behaviour was remarkably influenced by the atmosphere of the thermal pre-treatment. The reactivity of the clays calcined in reducing atmosphere was higher than those calcined in oxidizing atmosphere at the same temperature.

It could be found that the influence of the thermal pre-treatment conditions on the reactivity of clays becomes more dominant in case of illite/smectite clay. The presence of 2:1 clay minerals results in a Si/Al ratio higher than 2. The dissolution of these minerals is slower than the dissolution of metakaolin. That was also demonstrated in former studies [3]. In addition to the type of clay minerals, the miner components (like calcite and dolomite) affect the molar ratio of soluble Si/Al [2].

Special attention should be paid to the determination of the optimal pre-treatment conditions when illite/smectite based clays are utilized as geopolymer raw materials.

Computational simulations of interactions of aflatoxin B1 with smectite

Szczerba, M.[1*] & Deng, Y.[2]
[1]Inst. of Geological Sciences, Polish Academy of Sciences, Kraków, Poland (*ndszczer@cyf-kr.edu.pl)
[2]Dept. of Soil and Crop Sciences, Texas A&M University, College Station, TX, USA

Adsorption isotherms, animal feed and human diet trials have demonstrated the effectiveness of smectite-rich bentonites in reducing or alleviating the toxicity of aflatoxin B1 (AfB1). More and more spectroscopic and mineralogy data have been accumulated to elucidate the molecular mechanisms of reactions between the mycotoxin and the minerals. Unambiguous explanations, however, have been hindered by the complexity of the spectra and lack of definite assignments on the vibrational bands. The objective of this study was to verify and refine the theories about the bonding of AfB1 to smectite. We conducted computational simulations to find the theoretical band positions in the hypothesized models and compared the simulated patterns with the experimental data to find the best match. Geometry optimization and theoretical IR spectra for aflatoxin and aflatoxin-smectite complexes were performed with density functional theory (DFT) at PCM/B3LYP/DGDZVP level of theory.

It was found that in the humid environment AfB1 forms complexes with smectite through water bridges between AfB1 and exchange ions in smectite. On the other hand, at 0% humidity AfB1 carbonyl groups were connected to the ions through ion-dipole interactions. The experimental spectra were in excellent agreement with theoretical calculations. The calculation allowed accurate assignments of the bands of experimental spectra.

Organoclay-herbicide interaction mechanism as affecting the bioavailability of organoclay-based formulations of atrazine in soil

Trigo, C.[1], Koskinen, W.C.[2], Celis, R.[1], Hermosín, M.C.[1] & Cornejo, J.[1*]
[1]Instituto de Recursos Naturales y Agrobiología de Sevilla, CSIC, Sevilla, Spain ([*]cornejo@irnase.csic.es)
[2]USDA-ARS-University of Minnesota, Minnesota, USA

Organoclays have been proposed as pesticide supports to prolong the efficacy and reduce the large runoff and leaching losses that usually suffer pesticides when they are applied in an immediately available form [1]. The bioavailability of several organoclay-based formulations of atrazine for bacterial degradation in soil was studied. Two different organic cations, L-carnitine (CAR) and hexadecyltrimethylammonium (HDTMA), were incorporated into Na-rich Wyoming montmorillonite (SW) and Ca-rich Arizona montmorillonite (SA) as a strategy to enhance the affinity of the clay minerals for atrazine (Table 1), and then organoclay-based formulations of atrazine were prepared by supporting the herbicide on the organoclays.

Table 1: Some characteristic of the organoclays used

Organoclay	OCTS[1]	d_{001} (Å)[2]
SW-CAR	61	14
SW-HDTMA	100	18
SA-HDTMA	101	24

[1]Percentage of the CEC of the clay compensated by organic cations, [2] Basal spacing value (Å)

Solvent extraction methods were used to correlate atrazine residue bioavailability in soil to atrazine mineralization using an atrazine degrading bacterium. A soil from Minnesota (USA) was treated with the organoclay-based formulations of ^{14}C-atrazine and with free ^{14}C-atrazine, and then inoculated with *Pseudomona* sp. strain ADP, a microorganism capable of rapidly mineralizing atrazine. Evolved-$^{14}CO_2$ was determined during a two-week incubation period. The amounts of ^{14}C-atrazine residues distributed between the aqueous-extractable, metanol-extractable, and bound fractions in the soil were determined at t=0 and after the two-week mineralization period, for the different formulations assayed.

Results indicated that non-extractable atrazine residues in soil increased with aging and that the mineralization rate of atrazine adsorbed on SW-HDTMA and SA-HDTMA decreased with the affinity of the organoclay for the herbicide. However, the formulation based on SW-CAR displayed a distinct behavior. Despite the very high affinity of SW-CAR for atrazine, mineralization occurred at a similar rate compared to that found for the free herbicide. Desorption experiments demonstrated that atrazine is readily released from SW-CAR at high pH levels, such as that provided by the soil tested, making the herbicide immediately available for degradation.

Improving the wettability of peat based growing media by the amendment of clay

Walsch, J.[*] & Dultz, S.
Inst. of Soil Science, Leibniz Universität Hannover, Germany
([*]walsch@ifbk.uni-hannover.de)

Clays are widely used in horticulture for the amelioration of the chemical and physical properties of peat based growing media. A common problem of such substrates rich in organic matter arises from their poor wettability in the dry state. Up to now, less is known on how clay amendments differing in mineralogical composition and other mineral parameters affect the wettability behaviour of peat based growing media. In this study special emphasis was given on the adsorption of peat derived dissolved organic matter (DOM) onto the external surfaces of clay minerals in the substrate, as this process may render a clay surface from hydrophilic to hydrophobic.

Seven different clays varying in their mineral parameters (texture, mineralogical composition, cation exchange capacity (CEC), specific surface area (SSA) and oxalate and dithionite soluble Fe and Al) were used to investigate their effect on wettability and water uptake characteristics on a peat blend with a moderate degree of decomposition. The wettability was assessed in terms of contact angle (CA) measurements, calculation of surface free energies (SFE), and water uptake measurements using a capillary rise method (CRM). Differences in the affinity for peat derived DOM was determined in batch adsorption experiments and variations in the kind of adsorbed DOM fractions were traced by UV-Vis spectrometry before and after adsorption.

The wettability of peat based growing media was markedly influenced by the amount and kind of amended clay. Both, the substrate wettability as well as sorption of peat derived DOM onto clay surfaces showed strong relation to mineral parameters. Sorption of DOM increased with increasing CEC, SSA, Fe_d, and $\sum Fe_o+Al_o$ of the clays, while the substrate wettability was negatively correlated with the SSA ($r^2 = 0.66$), CEC ($r^2 = 0.69$), Fe_d ($r^2 = 0.68$) and $\sum Fe_o+Al_o$ ($r^2 = 0.61$). By considering the amount and kind of mineral bound DOM species, a non-linear regression explained 69% and 85% of the variations in substrate wettability. Overall, the results provide a useful basis for the selection of suitable clay amendments for improving the wettability of peat based growing media.

Nanocomposite clay minerals with fluorescence properties based on intercalation of kaolinite

Zacher, T.[1*] & Janek, M.[1,2]
[1]Dept. of Physical and Theoretical Chemistry, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
([*]zacher@fns.uniba.sk)
[2]Institute of Technology, Slovak Academy of Sciences, Bratislava, Slovakia

The topic of this contribution is preparation of new organomineral derivatives, because they combine the structural, physical and chemical properties of both the inorganic host material and the organic guest species at a nanometer scale [1]. Kaolinite, despite its wide abundance in nature [2] and interesting intercalation properties [1,3] has been less studied as a precursor mineral for new organomineral materials, when compared to the smectite clays for example [4], presumably due to the difficulty in expanding the interlayers of kaolinite compared to other expandable layered materials. Methods based on the modification of preexisting inorganic structures offer considerable flexibility in the design of new hybrid materials [5].

This study has shown that the new inorganic - organic layered hybrid materials with fluorescent properties based on kaolinite can be prepared by intercalation of laser dye Coumarine 4 using guest – displacement reaction with ethylene glycol according to [6]. Prepared material was characterized using X - ray diffraction (XRD) and Fourier transform infrared spectroscopy (FTIR).

New type of inorganic – organic nanocomposite based on intercalation of kaolinite with fluorescent dye could be used to prepare antiseptic systems (e.g. painting colours, textile fibres etc.) because these systems have potential to produce singlet oxygen which has antiseptic and disinfecting effects.

Thermal treatment of organoclays enhances their sorptive potential: a weakened water-organic sorbate competition on mildly heated sorbents?

Borisover, M.[1*], Yariv, S.[2], Bukhanovsky, N.[1] & Lapides, I.[2]
[1]Institute of Soil, Water and Environmental Sciences, The Volcani Center, ARO, Bet Dagan, Israel
([*]vwmichel@volcani.agri.gov.il)
[2]Institute of Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Recently, we have observed that thermal treatment of organoclays (formed by exchange reactions between organic cations and inorganic cations of a clay mineral) can improve their ability to sorb organic compounds from water [1,2].The aim of the presented work is to examine how this thermal treatment effect is related to the structure of organic sorbates and exchanged organic cations. The organoclay sorbents were prepared from Wyoming bentonite through replacing exchangeable Na+ by n-hexadecyltrimethylammonium (HDTMA), tetraethylammonium (TEA) and benzyltrimethylammonium (BTMA). Then, the organoclays (and Na-bentonite itself) were heated at 150, 250, 360 and 420oC for 2 hours in air and subjected to aqueous sorption of a series of probe organic compounds (phenanthrene, nitrobenzene, atrazine, phenol, m-nitrophenol) capable of different types of molecular interactions. We have demonstrated that a mild heating (at 150 0C) of organoclays can result in a distinct increase of a sorptive efficacy of sorbents. As follows from XRD, FTIR, elemental composition and TG data, this mild thermal treatment of organoclays is associated with fairly small changes (if any) in the sorbent structure.

Heating of organoclays at higher temperatures results in a loss of organic carbon and significant changes in the organoclay structure. Further improvement of a sorptive efficacy as compared with treatment at 150 0C, if occurs, is minor. This was in contrast to our earlier expectations of a significant contribution of charcoal and oxidized organic matter formed in the clay interlayer space to the organic sorbates-organoclay interactions. It is suggested that a mild thermal treatment of clay-based sorbents results in a partial loss of a sorbent ability to rehydrate in aqueous solutions thus weakening water-sorbate competition for sorption sites on a mildly heated sorbent, and therefore, increasing a potential of organoclays to sorb organic compounds from water. In particular, organic sorbates capable of specific interactions with siloxane surfaces may demonstrate the increase of sorption on a pre-heated organoclay. In organoclays with long-chain organic cations (e.g. HDTMA) capable of additional blocking the clay surface, the enhancing effect of thermal pre-treatment on sorption of organic compounds may be mitigated as compared with organoclays formed by smaller-size organic cations (e.g. TEA and BTMA).

A parallel is hypothesized between a mechanism suppressing a hydration of a sorbent after its mild thermal pre-treatment and a recognized fixation of certain inorganic cations occurring during clay heating at higher temperatures. Important implications associated with the observed phenomena include a possibility of activating organoclays for environmental applications and a better understanding of relative role of natural organic and clay components in retention of organic pollutants by environmentally important sorbents influenced by elevated temperatures (e.g. soils affected by fire).

Simultaneous sorption of lead and phenol by bentonite and organobentonite

Honfi, K.[1], Klumpp, E.[2], Kilár, F.[1], Dékány, I.[3] & Pernyeszi, T.[1*]
[1]Dept. of Analytical and Environmental Chemistry, Faculty of Science, University of Pécs, Pécs, Hungary
([*]ptimea@ttk.pte.hu)
[2]Research Centre Jülich GmbH, Institute of Chemistry and Dynamics of the Geosphere IV, Agrosphere, Jülich, Germany
[3]Dept. of Physical Chemistry and Material Science, Faculty of Science, University of Szeged, Szeged, Hungary

Clays or organoclays have been used as barrier to prevent the transport of hazardous contaminants in landfills. However, clays are known to effectively sorb mostly inorganic contaminants, while organoclays are mainly used for organic contaminants. Since the organoclays are basically clay particles modified with cationic surfactants, there might be an optimal coverage of cationic surfactant on the clay particles to sorb both inorganic and organic contaminants. In order to determine the optimal mass of cationic surfactants on the bentonite, bentonites were treated with various ratios of dodecyltrimethylammonium bromide (DDTMA) and benzyldodecyldimethylammonium bromide (BDDDMA). The role of the benzyl group of surfactant molecules was also studied in the sorption processes.

Phenol and lead were selected as representative contaminants. Sorption kinetics and isotherms of contaminants by both organobentonites were selectively studied in the function of surface coverage. When either phenol or lead exists as a single contaminant, phenol sorption increased with increasing DDTMA and BDDDMA to bentonite ratios, and lead sorption decreased with increasing DDTMA and BDDDMA to bentonite ratios. Sorption of phenol was a function of DDTMA and BDDDMA coverage on the bentonites, while lead sorption was much more influenced by the initial lead concentration than the mass of surfactants added to the bentonites.

Hydrotalcite – like compounds as adsorbents of phenols and their environmental applications

Butenko, E.[*] & Kapustin, A.
Azov Sea State Technical University, Mariupol, Ukraine
([*]butenkoeo@rambler.ru)

This work is devoted to studies of processes of sorption of phenols by synthetic clay minerals of different composition.

To prevent dangerous contamination of the environment, industrial wastewaters should be cleaned from pollutants such as phenols [1]. The problem of pollution of natural waters, the growth in the amounts of waste waters and the search for effective methods of cleaning them are realy urgent.

The purpose of this work is the search for new anionic sorbents. Their application would help to effectively remove phenols from wastewaters.

The most promising sorbents are those based on double hydroxides of metals with the structure of hydrotalcite. They are cheap, accessible and effective, universal sorbents, with a high absorption capacity, resistance to environmental stress and can serve as excellent carriers for fixing on the surface various compounds including their modification.

The 2:1 clay minerals capable of changing the interlayer distances are very effective. Water molecules, as well as the cations and anions can be adsorbed also in the interlayer space of these minerals. Therefore it is possible to place large ions between the layers and form columns to create a system of pores where various small molecules can be placed. The pores size resulting in the intercalation process is about several tenths of nanometers. The samples were synthesized with the following ratios of cations in the matrix (Table 1).

Table 1: Samples of LDHs

MgO, mol/mol	k, мol/l·s
0,52	833,3
0,72	1290,3
0,81	1666,7
0,86	1739,1

The specific surface of LDHs was determined by low-temperature nitrogen adsorption chromatographic method with subsequent processing of the results obtained by BET method.

The change of interlayer distance in LDHs after the adsorption of phenol, were investigated.

Nanotubular particles derived from kaolin group minerals - structural and textural examination

Matusik, J.[1*], Wisła-Walsh, E.[2], Gaweł, A.[1], Bielańska, E.[3] & Bahranowski, K.[1]
[1]Dept. of Mineralogy, Petrography and Geochemistry,
AGH University of Science and Technology, Krakow, Poland
([*]jakub_matusik@wp.pl)
[2]Dept. of Power Engineering and Environmental Protection,
AGH University of Science and Technology, Krakow, Poland
[3]Institute of Catalysis and Surface Chemistry,
Polish Academy of Sciences, Krakow, Poland

Modified intercalation/deintercalation method was used to increase the efficiency of nanotubes formation from kaolin group minerals differing in degree of structural order [1]. At variance with our earlier work [2], methanol was used instead of 1,3-butanediol for the grafting reactions. The intercalation of hexylamine was followed by intercalation of octadecylamine [3]. Materials obtained by different procedures were subjected to detailed physico-chemical characterization (nitrogen adsorption/desorption, XRD, FTIR, DSC and TEM). The use of methanol instead of 1,3-butanediol led to a significantly different result. The content of nanotubes was much higher in the case of "Maria III" kaolinite samples containing minerals of high structural order. Poorly ordered samples ("Jaroszów kaolinite and "Dunino" halloysite) yielded less nanotubes than in the case of grafting with 1,3-butanediol. Enhanced formation of nanotubes in "Maria III" kaolinite was tentatively attributed to higher reactivity of well ordered kaolin minerals toward methanol rather than 1,3-butanediol, resulting in a more efficient amine intercalation. The additional intercalation of longer chain octadecylamine significantly increased the content of formed tubes.

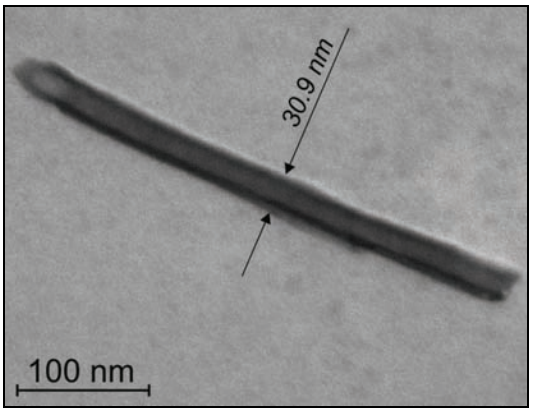

Fig. 1: TEM microphotograph of a kaolinite nanotube.

The diameters of rolled layers observed by TEM were ca. 30 nm (Fig. 1) and corresponded to diameters of newly formed group of pores detected by textural analysis. This confirmed that nanotubes contributed to a significant increase of surface area and total pore volume, observed for "Maria III" kaolinite. In the case of "Jaroszów" kaolinite and "Dunino" halloysite the changes of textural parameters were connected with the presence of macropores and mesopores with diameters different from these observed for nanotubes. These pores were assigned to interparticle and interaggregate spaces in stacks of platey particles and small amount of nanotubes.

[6]Saga Ceramics Research Laboratory, Arita-machi, Saga, Japan

In the present study TiO_2/clay nanocomposites were sythesized by dispersion of TiO_2 on the surfaces of two different natural clay minerals, palygorskite and halloysite, in order to increase the dispersion of TiO_2 and therefore its photocatalytic action. Deposition of TiO_2 on the clay minerals surfaces were conducted by using a sol-gel method with titatnium isopropoxide as a precursor under hydrothermal treatment at 180 ^oC. The phase composition, particle morphology and physical properties of the samples were characterized by several analytical techniques including XRD, SEM-EDS, TEM, ICP, ATR-FTIR, BET and porosimetry analysis. The synthetic procedure allows the homogeneous distribution of TiO_2 grains on the surfaces of the clay minerals leading to the improvement of the properties and potential uses of the nanocomposites. It was found that after treating with TiO_2, the halloysite and palygorskite samples showed mesopores of about 5.6 and 6.5 nm, respectively, while the macropores of halloysite (lumen) disappeared. The latter is attributed to the covering of the lumen of halloysite tubes by TiO_2 nanoparticles and for that reason the pore size of the TiO_2–treated halloysite was significantly smaller. The photocatalytic efficiency of clay-titania nanocomposites was measured in decomposing NOx, CO_2, and CH_3CHO gas. The supported catalysts showed higher activity in decomposing NO*x* gas and lower in CO_2 and CH_3CHO gas under visible-light irradiation (λ> 510 nm) and UV light irradiation (λ> 290 nm) compared to that of the standard commercial titania, P 25.

Effect of oligomerically modified montmorillonite on morphologies and properties of polycarbonate/montmorillonite nanocomposites

Huang Xiaoling, Wang Xiaoli, Su Haiquan[*] & Zhang Bingbing

School of Chemistry and Chemical Engineering, Inner Mongolia University, Hohhot, P.R. China
([*]haiquansu@yahoo.com)

Great efforts have been paid to polymer-clay nanocomposites in the past decades since those materials possess significantly improved physical [1] and other properties including thermal stability [2] and decreased flammability [3,4] over the virgin polymer.

In this work, two oligomeric surfactants (COPS-B and COPS-O) as shown in Fig. 1 were used to treat sodium montmorillonite via standard ion-exchange methods to give thermally stable oligomerically modified montmorillonites to prepare polycarbonate/montmorillonite nanocomposites (PC/MMT) by melt processing using a twin screw extruder.

Fig. 1: Structure of oligomeric surfactants used to treat sodium montmorillonite.

The results of TEM and XRD indicated that the PC/MMT nanocomposites had partially exfoliated and partially intercalated structures. Both clay loading and organic treatment structure of MMT influenced the morphologies and properties of the nanocomposites. The structure similarity, i.e., the strong interaction, between the polymer matrix and the organic treatments of the clay was a critical factor for controlling clay dispersion and exfoliation, and hence the mechanical and the heat insulation properties of the nanocomposites.

Analysis of all the composites indicated that once the clay mineral loading exceeded a critical value, it became a negative factor for forming high level dispersion to obtain better mechanical properties. Good mechanical properties of PC/MMT nanocomposites were obtained with a clay loading less than 2 wt%. A thermal-stable organic treatment was crucially important for an expected nanocomposite system with good thermal stability. It partly depended on the organic treatments of MMT used in the composites.

Great differences were observed between COPS-B and COPS-O composites. COPS-B showed visible advantage to COPS-O. Benzyl group of COPS-B in composites might play an important role in the process.

Bentazone and phenanthrene adsorption on external montmorillonite surface - Monte Carlo modelling

Tunega, D.[1,2*] & Meleshyn, A.[3]
[1]Inst. of Soil Research, University of Natural Resources and Applied Life Sciences, Vienna, Austria
[2]Inst. for Theoretical Chemistry, University of Vienna, Austria
([*]daniel.tunega@univie.ac.at)
[3]Center for Radiation Protection and Radioecology, Leibniz University Hannover, Germany

Bentazone and phenanthrene are pesticides with different fate in soil. Bentazone can be rapidly transported by infiltrating water into ground water due to its high solubility, minimal sorption to soil particles, and low degradability. On the contrary, phenanthrene is retained by sediments and soil materials. The mechanism of the retention of nonionic hydrophobic organic compounds in soil is still debated and has been attributed to their partitioning either to organic matter or to soil clay minerals. A recent study has reported on strong phenanthrene sorption capacities of smectites, which are comparable to those of soil clays containing a considerable amount of organic matter [1].

In order to address open questions, the structural and energetic characteristics of bentazone and phenanthrene interaction with external surface of montmorillonite were studied using Monte Carlo simulations at ambient conditions. In the first part of this work, the adsorption of the studied molecules at the montmorillonite-air and montmorillonite-water interface is simulated in a constant *NVT* ensemble using the Metropolis algorithm for sampling structural properties. The simulations predict the most favourable alignments of adsorbed molecules in dependence on the varying coverage and on the thickness of the adsorbed water film. In the second part, an expanded ensemble density of states method [2] based on the Wang-Landau algorithm [3] is applied to the equilibrated systems for sampling potential of mean force profiles between the adsorbed molecule and the montmorillonite surface. Reaction path coordinate is defined as the distance between the centre of mass of the molecule and the montmorillonite surface. The following possible reaction paths are explored: (1) above a free octahedral substitution, (2) above a ditrigonal cavity centre near a tetrahedral substitution paired with Na+ ion, and (3) above a tetrahedral Si site near the octahedral substitution chosen in (1). The simulations predict the most favourable reaction path between bentazone/phenanthrene and the montmorillonite surface. A discussion on the detailed molecular-scale data on the preferred adsorption positions of the studied pesticides at the montmorillonite-water and montmorillonite-air interface based on the calculated free energy profiles will be given.

Molecular dynamics simulation of TCDD adsorption on clay mineral

Zhu, R.[1,2], Parker, S.C.[2*] & Shapley, T.[2]
[1]Dept. of Environmental Science and Technology, Xiangtan University, Hunan, China
[2]Dept. of Chemistry, University of Bath, Bath, UK
([*]s.c.parker@bath.ac.uk)

Adsorption of organic toxicants on clay minerals is now receiving considerable attention, because contact with clays is thought to influence the transport, toxicity and bioavailability of the organic toxicants in the environment. Although experimental methods have been employed to investigate the adsorptive characteristics (e.g., batch equilibrium adsorption, spectroscopic characterization), molecular simulations represent a significant complementary approach because they can provide atomic-level insight into the adsorption process.

We report our recent research work about TCDD (2,3,7,8-Tetrachlorodibenzodioxin) adsorption on pyrophyllite and montmorillonite using molecular dynamics simulations. One of the central challenges is to develop and apply an effective force field between the pollutant and clay surfaces. We have considered a number of models. One of the most efficient is where the clay minerals were built using the ClayFF model from Cygan et al [1], and the CVFF force field was used to build TCDD and clay-TCDD potential.

Table 1 lists the adsorption energies of TCDD on the outer surface and interlayer of pyrophyllite and montmorillonite using these models within the NVT ensemble at 300K.

Table 1: Adsorption energy of TCDD on clay minerals (eV)

	Pyrophyllite	Montmorillonite
Surface	-0.44	-0.83
Interlayer	5.33	3.60
Interlayer[a]	-0.62	-1.51

The adsorption energy of TCDD on pyrophyllite was comparable with the results from DFT calculation [2], while on montmorillonite the adsorption energy was more negative. This indicates a stronger interaction between TCDD and montmorillonite. Examination of the structure shows that the interaction between K^+ and TCDD accounts for the larger adsorption energy at the montmorillonite surface.

The intercalation energies of TCDD for both pyrophyllite and montmorillonite are highly positive, because this contains the energy to separate the two layers and insert the TCDD molecule. This strong interaction between the layers of the clay minerals has also been shown by Heinz et al [3].

In another simulation, we inserted TCDD into the interlayer region but with the layers already separated. Thus, the energy for separating the layers is excluded. In this case, the adsorption energies were more negative than for the free surface (Table 1). This was because both the two layers could contribute to the adsorption of TCDD.

The above results show that although TCDD could interact strongly with clay minerals in the interlayer region, the large energy for separating the sheets could prevent the adsorption into the interlayer space of the clay minerals. However, once the layers were separated by other pillars (e.g., organic cations), the clay minerals are predicted to strongly adsorb the organic toxicants, and then influence their environmental behaviours.

The influence of heteropolyacids on the textural properties of Fe-montmorillonite

Badmaeva, S.V.* & Khankhasaeva, S.Ts.
Baikal Institute of Nature Management SB RAS, Ulan-Ude, Russia (*badma77@binm.bscnet.ru)

Intercalated clays present great interest as supports for synthesis of new catalysts [1]. For synthesis of composite metal-oxide materials with high disperse uniform distribution of metals it is perspective the use polyoxometallates, containing several metals atoms in the structure of their complex ions [2].

Materials have been synthesised using two methods: I - adsorption of heteropolyacids $H_4SiW_{12}O_{40}$, $H_3PMo_{12}O_{40}$ on Fe-montmorillonite (Fe-MM-500°C) calcinated at 500°C; II - simultaneous introduction of pillaring solution (1M $FeCl_3$ + 1M NaOH) and a solution containing the heteropolyacids into suspension of clay previously dispersed by ultrasound (22 kHz, 3 min). The preparation Fe-MM method was described in our early work [3]. All the samples were calcinated at 500°C for two hours.

The samples obtained belong to mesoporous materials (Fig. 1), but the samples obtained by method II contain also micropores which surface area is equal to 5.0-17.7 m^2/g (Table 1). At that the treatment by heteropolyacids in both cases leads to a decrease in specific surface area and pore volume in comparison with Fe-MM, that may be caused by adsorption of polyoxometallates in their mesopores.

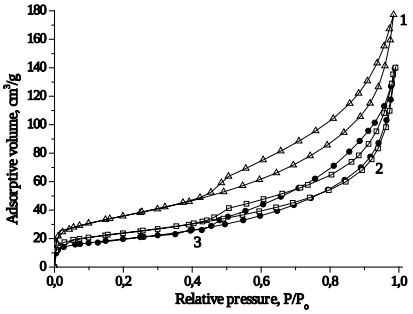

Fig. 1: N_2 adsorption/desorption of samples: 1- Fe-MM, 2- $SiMo_{12}$/Fe-MM (I) and 3- SiW_{12}/Fe-MM (I).

The Fe content in the samples is 4.0-4.6 wt.%. The quantity of introduced Mo and W depends on the method of synthesis of the material. The content of W in the samples SiW_{12}/Fe-MM obtained by method I and II is 1.82wt.% and 0.17 wt.% accordingly. The content of Mo in the samples $SiMo_{12}$/Fe-MM is 1.13wt.% (method I) and 0.53 wt.% (method II).

Table 1: Textural characteristics of composite materials

Materials (method)	Fe wt.%	W(Mo) wt.%	S_{BET} m^2/g	ΣV pore cm^3/g	D_{pore} Å	S_μ m^2/g	ΣV_μ cm^3/g
Fe-MM	4.6	0	128	0.274	85	-	-
SiW_{12}/Fe-MM (I)	4.5	1.82	84	0.217	103	-	<0.001
SiW_{12}/Fe-MM (II)	4.0	0.17	93	0.235	101	5.0	0.003
$SiMo_{12}$/Fe-MM (I)	4.4	1.13	70	0.216	123	-	<0.001
$SiMo_{12}$/Fe-MM (II)	4.6	0.53	92	0.183	80	17.7	0.009

S_{BET} – surface area, ΣV pore – total volume pore, D_{pore} – diameter pore, S_μ - surface area of micropore, ΣV_μ - volume pore of micropore.

The results of this work confirm the possibility of application of Fe-MM as supports for synthesis of catalysts.

Dispersion influence on activation energy of kaolinite dehydratation

Bortnikov, N.S., Piloyan, G.O.*, Novikov, V.M. & Soboleva, S.V.
Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry, Russian Academy of Science, Moscow, Russia (*piloyan@igem.ru)

Kinetics of kaolinite dehydratation has been studied for many decades revealing that, depending on the degree of structural perfection, concentration and extensive defects, the activation energy of dehydratation reaction changes within the range of 80-175 kJ/mol, significantly changing the reaction rate. According to the particle size, kaolinite belongs to so-called nanocrystalline materials, being characterized by size effects: dependence of material properties on its dispersivity**.** It was shown theoretically and experimentally in Piloyan & Bortnikov [1] that activation energy of reaction should decrease with dispersivity increasing. Using the approach developed in Piloyan & Bortnikov [1], in the present work the influence of dispersions on kaolinite activation energy has been investigated. As the object of study the alluvial kaolinite from Zhyravliny Log deposit (South Ural) has been chosen. The different technologically important kaolinite fractions (10-5, 5-1, 1-0.5, <0.5 μm) have been investigated by the method of transmission electron microscopy (including SAED and HRTM). Following the methodology of Piloyan & Bortnikov [1], the formula connecting the size of the coherent dispersion block with activation energy of dehydratation reaction and surface enthalpy has been received:

$$\ln(r) = A - \frac{E}{RT_m} + \frac{2H_F}{r\rho RT_m} - B\ln(I)$$

Where A and B are constants, r – the size of coherent dispersion block, E – energy of activation, R – gas constant, H_F–surface enthalpy, ρ – molar density of kaolinite, T_m – temperature of thermal effect peak on DTA curve, I – index of thermal effect form. Using experimental data the following regression equation was obtained

$$\ln(r) = 29.8887 - 21248.6 T_m^{-1} + 17.2323\, T_m^{-1} r^{-1} - 3.48522 \ln(I)$$

From this equation it has been found, that the activation energy of dehydratation reaction for kaolinite macrocrystals is 176,6 kJ/mole, that is characteristic for well crystallized kaolinites. Surface enthalpy is 0.73 J/m^2 coinciding (within the limits of experimental error) with the value of 0.62 J/m^2, obtained in Salles et al. [2]. The results obtained are shown in Table 1.

Table 1: Experimental data for the kaolinite studied

Fraction (μm)	Kaolinite content (%)	T_mK	I	r (нм)	E kJ/mole
10-5	86,4	823	1,56	27	171,3
5-1	89,3	833	1,85	23	170,4
1-5	89,24	848	2,4	17	168,2
<0,5	88,64	833	2,5	15	167,1

Role of clays in the preservation of organic matter

Drouin, S.[1], Boussafir, M.[1] & Robert, J.-L.[2*]
[1]ISTO, Orléans, France
[2]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France
([*]jean-louis.robert@impmc.upmc.fr)

It is commonly admitted that clay minerals can play a major role in the preservation of organic matter under aquatic environments and their transfer to sediments. The mechanisms of fixation of organic molecules by clays remain obscure. Series of *in vitro* and *in vivo* experiments have been performed, under marine and lacustrine environments, with synthetic saponites of variable charge and a natural low-charge montmorillonite.

This study shows the absence of intercalation of organic molecules in the interlayer space of clays. Only sorption on clay surfaces and edges occurs. *In vitro* experiments show that organo-clay interactions are mainly controlled by the type of organic molecules and particularly by the nature of their functional groups. *In vivo* experiments indicate that fresh organic matter is more easily adsorbed than diagenetically evolved one. The clay surface charge density also controls the nature and concentration of adsorbed organic species. Under lacustrine environments, a selective sorption of aromatic molecules is observed on low-charge clays.

Attempts to destabilize the obtained organo-clay compounds, by hard alkaline treatment, were unsuccessful and indicate the great stability of these associations, with strong and probably multiple bonds. Owing to this high stability of organo-clay assemblages, the organic matter becomes unavailable to benthic fauna and bacteria in natural environments.

Therefore, sorption on clays can be considered as one of the preservation mechanisms of organic matter and controls the incorporation of metabolisable molecules into sediments.

Ag- and Cu-vermiculite nanocomposites and their antibacterial effect

Hundáková, M.[1*], Valášková, M.[1] & Pazdziora, E.[2]
[1]Nanotechnology Centre, VŠB – Technical University of Ostrava, Czech Republic ([*]marianna.hundakova@vsb.cz)
[2]National Reference Laboratory, Institute of Public Health in Ostrava, Czech Republic

Clay minerals belong to the important materials which can serve as metal nanoparticles matrixes thanks to their structural properties. In this study, vermiculite from Brazil was used as starting material. Beside montmorillonite [1, 2], vermiculite is sometimes used as a matrix for silver and copper nanoparticles [3].

Vermiculite (V) was treated with different molar concentrations of aqueous solutions of $AgNO_3$ and $Cu(NO_3)_2$ and Ag-V, Cu-V, Ag,Cu-V materials were synthesized. Samples were evaluated for the effect of solutions concentrations on the quantity of Ag and Cu, structure changes of vermiculite and antibacterial activity.

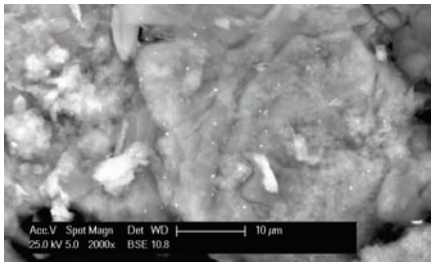

Fig. 1: The SEM micrograph of Ag-V (white dots represent Ag agglomerates on the vermiculite surface).

The morphology was studied using scanning electron microscopy (SEM). The SEM micrograph of Ag-V (Fig.1) showed agglomerates of silver nanoparticles anchored on the vermiculite substrate. Powder X-ray diffraction (XRD) was employed mainly to determine the interplanar spacings in the starting clay minerals and in the Ag- and/or Cu-V composites. The XRD patterns showed Ag (111) reflection of metallic silver. According to the basal reflection (001) intercalation of Ag and Cu into interlayer space of vermiculite was supposed.

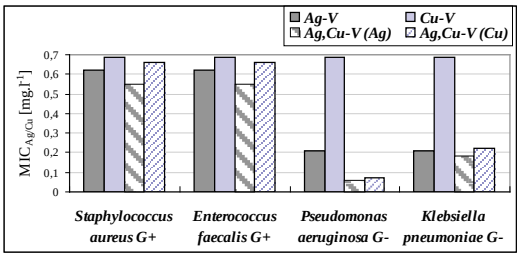

Fig. 2: The MIC Ag/Cu (Minimum Inhibitory Concentration of Ag and Cu) was determined by the lowest concentration that completely inhibits visible bacteria growth.

The antibacterial activity tests on the Gram positive (G^+) and Gram negative (G^-) bacteria strains showed dependence of antibacterial effect upon content of Ag and/or Cu with the result that the highest effect was observed against G^- bacteria (Fig. 2).

Preparation of oriented films of layered double hydroxides with photoactive properties

Kovanda, F.[1*], Jiřičková, M.[1] & Lang, K.[2]
[1]Dept. of Solid State Chemistry, Institute of Chemical Technology, Prague, Czech Republic
([*]Frantisek.Kovanda@vscht.cz)
[2]Institute of Inorganic Chemistry of the AS CR, v.v.i., Řež, Czech Republic

Layered double hydroxides (LDHs) represent suitable hosts for intercalation of various anionic species. The intercalated LDHs attract increasing attention in various medical applications as drug carriers, gene therapy, etc. [1]. Photoactive molecules such as porphyrins can be excited by visible light to the triplet states that rapidly interacts with molecular oxygen by energy transfer to form singlet oxygen, $^1O_2$, a highly reactive oxidation agent with cytotoxic effects enabling its application in photodynamic therapy. In our recent reports [2,3], the structural and photophysical properties of LDH powders and oriented films with intercalated porphyrin sensitizers were described and the formation of singlet oxygen followed by its diffusion to solid-liquid or solid-gas interfaces was proven.

The oriented LDH films were prepared on quartz substrates by deposition from a colloidal suspension of delaminated LDH particles. Two colloidal suspensions were prepared. The first one was obtained by delamination of coprecipitated Mg-Al-NO_3 LDH in formamide. Second, the acetate form of Mg-Al LDH was used for the preparation of a colloidal suspension in water: nitrate anions in Mg-Al-NO_3 LDH were exchanged in an aqueous solution in an excess of sodium acetate and the washed product was dispersed in distilled water [4]. Porphyrins 5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin or Pd(II)-5,10,15,20-tetrakis(4-carboxyphenyl)porphyrin were embedded in oriented LDH films prepared by the layer-by-layer technique. The absence of non-basal diffraction lines in powder XRD patterns confirmed a preferential arrangement of LDH particles parallel to the substrate surface. Transparent films were obtained, their absorbance in visible light increased gradually with the number of deposition steps (Fig. 1). The photophysical properties of the prepared LDH/porphyrin films including the formation of singlet oxygen are discussed.

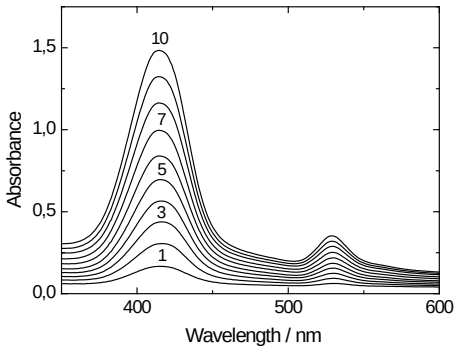

Fig. 1: Absorbance of the oriented LDH/porphyrin film increasing with the number of deposition steps (up to 10 deposition steps were applied).

Potassium acetate-intercalated kaolinite obtained by mechanochemical and aqueous suspension techniques – a comparative study

Makó, É.[1*], Kovács, A.[1], Kristóf, J.[2] & Horváth, E.[2]
[1]Institute of Materials Engineering, University of Pannonia, Veszprém, Hungary ([*]makoe@almos.vein.hu)
[2]Institute for Environmental Engineering, University of Pannonia, Veszprém, Hungary

Intercalation complexes of a high-defect kaolinite have been prepared by direct reaction with potassium acetate solution as well as by co-grinding with potassium acetate in the absence of water (mechanochemical intercalation). Potassium acetate-intercalated high-defect kaolinite has been aged for up to 2 months. The aged and non-aged complexes were studied by X-ray diffraction, thermal analysis, DRIFT spectroscopy and electron microscopy. Ageing of the mechanochemically intercalated kaolinite increases the degree of intercalation [1] by almost 20 %, as well as decreases the structural deformation of the intercalation complex. At the same time, the aqueous suspension technique creates kaolinite–potassium acetate intercalation compound which shows practically no change after ageing.

Time- and pH-dependent sorption of veterinary antimicrobial sulfamethoxazole to bentonite and organobentonite

Netzkár, A.[1], Kilár, A.[1], Páger, Cs.[1], Kilár, F.[1], Klumpp, E.[2] & Pernyeszi, T.[1*]
[1]Dept. of Analytical and Environmental Chemistry, Faculty of Science, University of Pécs, Hungary ([*]ptimea@ttk.pte.hu)
[2]Research Centre Jülich GmbH, Institute of Chemistry and Dynamics of the Geosphere IV, Agrosphere, Jülich, Germany

Sulfonamide antimicrobials comprise a class of synthetic sulfanilamide derivatives which are used in human therapy, livestock production and aquaculture. Substantial amounts of sulfonamides, ionizable, polar veterinary, may reach the environment through grazing livestock and spreading of manure on agricultural soils. Further pathway into the environment is direct use in aquaculture. Residues of sulfonamides have been found in soils and adjacent environmental compartments [1,2]. In soils, parts of added sulfonamides are retained over months [1]. Sorption to soils and sediments is a crucial but not sufficiently understood process influencing the environmental fate of sulfonamides.

The objective of this study was the influence of contact time and pH on sulfomethoxazole sorption to native bentonite (Rátkai Pettyes, Hungary) and surfactant-modified bentonite. The sulfamethoxazole (pK_a = 4.7) was analyzed by capillary electrophoresis using Tris (tris(hydroxy-methyl)aminomethane) at pH of 8.3. Organobentonites were prepared from bentonite by using benzyldodecyldimethylammonium (C_{12}) bromides. The degree of modification was 100 % (C_{12}-100-B) and 50 % (C_{12}-50-B) of the cation exchange capacity. Adsorption kinetics and isotherms determined in aqueous suspensions using batch technique were modelled.

The bentonite sorbent was expected to interact mainly with cationic sulfonamide at pH < 4.7, above this pH value little adsorbed amount could be measured (q_s = 1.5 - 2 mg/g at pH 6.4 in natural form without pH adjustment). Modification of bentonite surfaces by benzyldodecyldimethylammonium assisted the sulfamethoxazole adsorption (q_s = 4 - 5 mg/g at pH 6.4 in natural form without pH adjustment). Following the adsorption kinetics five days was needed to reach the adsorption equilibrium.

Our results imply that inorganic sorbents compared to organic substances can play a minor role for sulfonamide sorption in many soils and sediments. Especially the potential of organic sorbents for increased sorption with contact time would be important. On the other hand organobentonite (modified by benzyldodecyldimethylammonium bromide) could be used as biosorbent material in soil and sediment remediation.

Spectroscopic study of intercalated cationic dyes into montmorillonite with different layer charge

Pustková, P.[1*], Klika, Z.[1] & Malý, P.[2]
[1]Dept. of Analytical Chemistry and Material Testing, VŠB-Technical University of Ostrava, Czech Republic
([*]petra.pustkova@vsb.cz)
[2]Dept. of Chemical Physics and Optics, Charles University, Prague, Czech Republic

Modified montmorillonites with cationic dye exhibit unique optical properties. These novel materials enable many applications in photochemical and photophysical branch [1]. Generally, cationic dyes form the aggregates on surface and/or in the interlayer of montmorillonite. Dye loading and layer charge of montmorillonite are control elements of dye aggregation [2].

In this study a Ca^{2+}-montmorillonite with high (SAz) and reduced charge (RC-SAz(210)) were used for the preparation of cationic dye/montmorillonite complexes. The RC-SAz(210) was prepared from parent material (SAz) by Li^+ saturation and subsequent heating at 210°C. The exchanges in fluorescence and Vis electron spectra of the complexes were observed.

Vis absorption spectra of four cationic dyes (CD), i.e. methylene blue (MB), crystal violet (CV), nile blue (NB) and rhodamine B (RB) were measured. The percentage distribution of non aggregated and aggregated CD species in variously concentrated aqueous solution was calculated using equilibrium stepped aggregation constants K_n. The study showed that nile blue forms the higher aggregates in aqueous solution already at relatively low concentration compared with the other tested dyes.

Vis electronic spectroscopy and X-ray diffraction analysis revealed that cationic dye in fully intercalated CD/SAz complex is located in the interlayer of montmorillonite mainly in form of higher aggregates. The higher aggregates of dye are effective quenchers of fluorescence hence these complexes exhibit a very low fluorescence intensity. The reduction of montmorillonite layer charge and low dye loading in the CD/RC-SAz(210) complexes cause suppression of dye aggregation and huge increase of fluorescence (Fig. 1).

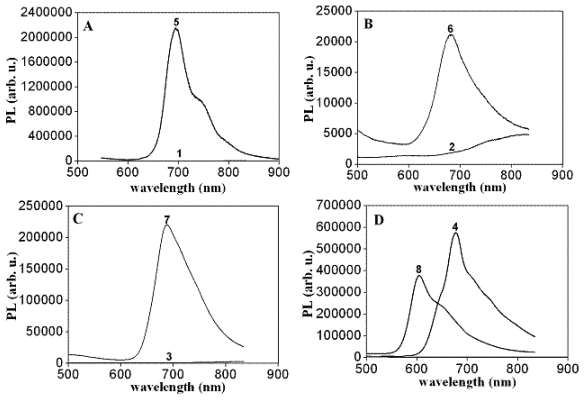

Fig. 1: Fluorescence spectra of fully intercalated CD/SAz complexes (spectra 1, 2, 3 and 4) and spectra of CD/RC-SAz(210) prepared by 10% dye loading (spectra 5, 6, 7 and 8). A- Methylene blue; B- Crystal violet; C- Nile blue; D- Rhodamine B.

Wettability of clay mineral surfaces – molecular dynamics study

Šolc, R.[1*], Tunega, D.[1,2], Pašalić, H.[2], Gerzabek, M.H.[1] & Lischka, H.[2]
[1]Inst. of Soil Research, University of Natural Resources and Applied Life Sciences, Vienna, Austria
([*]roland.solc@boku.ac.at)
[2]Inst. for Theoretical Chemistry, University of Vienna, Austria

Wetting properties of soil and soil components affect a wide variety of soil processes including infiltration, preferenti al flow and surface runoff [1]. The wetting ability of a solid surface is mainly determined by its chemical composition and structure and is directly related to the solid surface free energy [2]. The solid-liquid contact angle method is often used to characterize wettability of surfaces and to determine its surface energy. In soil chemistry, contact angle measurements are influenced by many factors because of the heterogeneous and complex nature of soil particles. Therefore, it is important to know how individual soil components behave with respect to polar liquids like water.

Clay minerals represent an important inorganic part of soil mineral phases and significantly affect overall properties of soils. Owing to compositional variability ad structural complexity various clay minerals behave considerably differently with respect to wetting.

In order to elucidate structural and compositional factors affecting hydrophilic/hydrophobic character of clay minerals we studied interactions of water nanodroplets with basal surfaces of selected clay minerals (particularly kaolinite and phlogopite) by means of classical molecular dynamics simulations at room temperature. From the behaviour and shape of the nanodroplet it was possible to characterize hydrophobic/hydrophilic character of studied surfaces. In case of the kaolinite octahedral surface formed from surface hydroxyl groups, the water droplet was completely spread and a monomolecular network of hydrogen-bonded water molecules was formed. In opposite, the tetrahedral surface, which is formed from basal oxygen atoms, is less interacting with the water nanodroplet and the shape of the droplet is partially preserving. The molecular simulations clearly showed a difference between both basal surfaces of kaolinite. While the octahedral surface is strongly hydrophilic, the tetrahedral surface has partially hydrophobic character. Structural and energetic aspects of both surfaces are obtained as well.

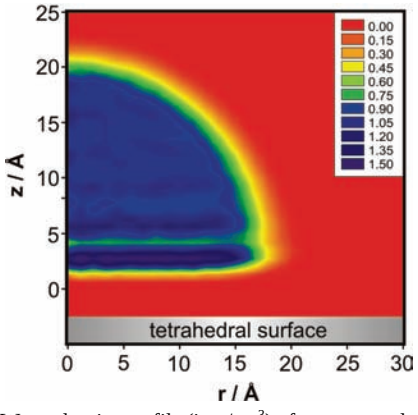

Fig. 1: Water density profile (in g/cm^3) of water nanodroplet on tetrehadral kaolinite surface. (500 water molecules, 2 ns MD, 300K).

Organic modified montmorillonite supported cobalt catalyst for Fischer–Tropsch synthesis

Su Haiquan[1,2*], Zhang Bingbing[1], Ding Ning[2], Li Xuefen[1], Zhang Xiaohong[1,2] & Zeng Shanghong[2]
[1]College of Life Science, Inner Mongolia University, Hohhot, P.R. China
[2]Inner Mongolia Key Laboratory of Coal Chemistry, School of Chemistry and Chemical Engineering, Inner Mongolia University, Hohhot, P.R. China ([*]haiquansu@yahoo.com)

The Fischer-Tropsch synthesis (FTS) is a process that converts syngas into mixtures of higher molecular weight hydrocarbons. Supported cobalt catalysts are the preferred catalysts because of their high F-T activity, high selectivity for linear hydrocarbons, low activity for the water gas shift reaction, and relatively lower cost. In this paper, organically modified montmorillonite as a novel support is first applied to cobalt-based Fischer-Tropsch synthesis.

Normally, XRD is a good method for identification and characterization of the F-T active phases. However, only the in-situ XRD shows reliable data about the structure of cobalt active phases present in the reduced and working catalysts because of easy reoxidation of cobalt species in the air. Our results show that ex-situ XRD was also an effective method for the active phase identification of the Co/ OMMT catalysts after F-T synthesis (see Fig. 1), because there was no reoxidation on the catalysts after F-T reaction due to the formation of carbon protective layer outside the metallic cobalt, which was from decomposing of the organic component inside the layer of montmorillonite. This retains precious information about cobalt dispersion and reducibility under the FT reaction conditions.

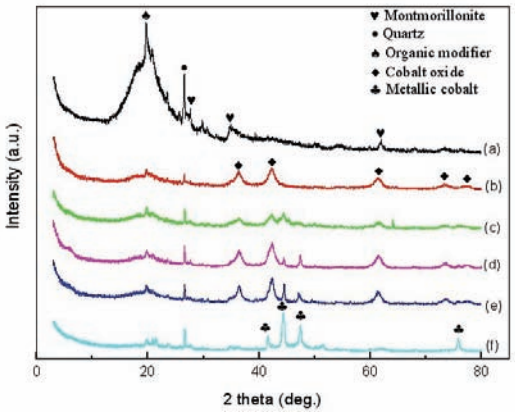

Fig. 1: XRD patterns of the samples (a: organically modified montmorillonite (OMMT); b: Co/ OMMT; c–e: Co/ OMMT catalysts after different Fischer-Tropsch reaction conditions).

Table 1: Catalytic performance of catalysts for F-T synthesis reaction

Sample	CO conversion (%)	CH_4 selectivity (%)	C_2-C_4 selectivity (%)	C_5^+ selectivity (%)
c	24.48	19.98	6.67	73.35
d	14.65	16.53	0.78	82.69
e	26.27	7.08	2.45	90.47
f	15.84	94.28	1.69	4.03

The data in table 1 show that the C_5^+ selectivity was improved with the increase of metallic cobalt content in catalysts c–e. The C_5^+ selectivity of the catalyst f was the worst on the highest metallic cobalt content, due to the catalyst producing more carbon under these conditions.

A molecular dynamics simulation studies of ethylene glycol intercalated in smectites

Szczerba, M.[1*], Kłapyta, Z.[2] & Skiba, M.[3]
[1]Institute of Geological Sciences, Polish Academy of Sciences, Kraków, Poland (*ndszczer@cyf-kr.edu.pl)
[2]Faculty of Geology, Geophysics and Environmental Protection, University of Mining and Metallurgy, Kraków, Poland
[3]Institute of Geological Sciences, Jagiellonian University, Kraków, Poland

Intercalation of ethylene glycol in smectites is widelly used to discriminate smectites from other clays. This technique has been known since pionnering work of MacEvan [1], however still little is known about the structure of ethylene glycol between smectite sheets. The work by Reynolds [2] gave some insights into the structure, hovewer since that time no significant input into the understanding of this structure has been done.

Molecular dynamics simulations allow to find that the structure proposed by Reynolds [2] should be a bit different. Ethylene glycol forms two distinct layers between sheets, but ions forms inner and outer sphere complexes, not only the outer ones as it was described in [2]. Moreover water in this structure was found not to form distinct layers but is rather spread out and concentrated around ions. There is also no tendency to form water bridges between ions, water and ethylene glycol.

Molecular simulations were carried out using the DLPOLY computer program using CLAYFF and CVFF force fields to describe clay and ethylene glycol, respectively.

Formation of a second-staged alkylammonium-sericite complex

Tamura, K.[1*], Hatta, T.[2], Morimoto, K.[1] & Yamada, H.[1]
[1]National Institute for Materials Science, Tsukuba, Japan
([*]TAMURA.Kenji@nims.go.jp)
[2]Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

The intercalation dynamics of layered materials, such as graphite, clays, and transition-metal dichalcogenides, has been reported in detail, both experimentally and theoretically. In particular, the phenomenon of staging has generated a large amount of interest in these materials. Staging is a process by which layered host materials intercalate guest compounds. A staged layered compound has a regularly repeating series of interlayers, alternating periodically between an intercalated layer and non-intercalated layer. In the present study, the staging phenomenon was investigated for the organic/sericite complexes.

We have conducted ion exchange experiments using sericite (SE) and dehydrated sericite (dhSE) with dodecylammonium (DDA) solutions of various initial concentrations (7.3, 21.9, and 73.3 mM, corresponding to DDA^+/K^+ mole ratio = 1.0, 3.0 and 10.0, respectively), at 70°C. The dhSE sample was prepared by dehydration of a SE powder (medium particle diameter: 7.8 μm) at 800°C for one hour [1]. The staging phenomenon was studied by X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and infrared absorption spectra. Typical XRD patterns of DDA-SE and DDA-dhSE prepared by ion exchange with a low DDA concentration (DDA^+/K^+ = 1.0), are shown in Figure 1. In the case of the SE complexes, two separated phases, 1.0 and 2.3 nm, were obtained, which were ascribed to the non-intercalated layers, and vertical (perpendicular to the layers) orientations of the incorporated DDA, respectively. On the other hand, in the case of the dhSE complexes, a large basal spacing of 3.3 nm was observed (Fig. 1b). The 3.3 nm basal spacing is close to the sum of the basal spacing for the vertical (perpendicular to the layers) orientations and that for the non-intercalated layers, so it can be interpreted as regular alternation of the 2.3 nm layer and the 1.0 nm layer, exhibiting *c* =3.3 nm supercell ("1:1 ordered interstratifications" or "second-staging").

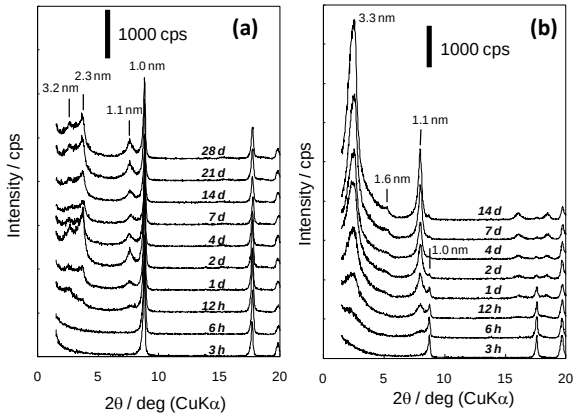

Fig. 1: XRD patterns of (a) DDA-SE and (b) DDA-dhSE complexes prepared by ion exchange with DDA^+ (DDA^+/K^+ mole ratio = 1.0) at 70°C for various duration times.

Alteration mineralogy, geochemistry and genesis of volcanic rocks of the Hasandağ area (Giresun), NE Turkey

Kadir, S.[1*], Acarlıoğlu, S.[1], Abdioğlu, E.[2] & Arslan, M.[2]
[1]Dept. of Geological Engineering, Eskişehir Osmangazi University, Eskişehir, Turkey ([*]skadir_esogu@yahoo.com)
[2]Dept. of Geological Engineering, Karadeniz Technical University, Trabzon, Turkey

The Eocene subvolcanic and volcanic rocks of the Hasandağ (Giresun) area in the eastern Pontides (NE Turkey) have undergone several stages of hydrothermal alteration. The rocks of the area comprise andesitic flows, andesitic pyroclastic rocks, phreatomagmatic breccia, andesite dykes and granodiorite-syenogranite intrusions. Development of phreatomagmatic breccias was related to penetration of silica-rich hydrothermal fluids along fractures. Consequently, silicification and scarce argillisation are widespread main types of hydrothermal alteration in the area. These units were studied via standard petrography, reflected-light polished-section microscopy, X-ray diffractometry (XRD), scanning electron microscopy (SEM-EDX), and geochemical analysis. Alteration of plagioclase and iron-oxidation in amphibole and biotite are widespread. Development of silicification, advanced argillisation (alunite±kaolinite), argillic (smectite±illite) and propyllitic zones (chlorite±sericite±calcite) – associated with decreasing alunite±kaolinite and some increase in chlorite±sericite±calcite from the central to the outer part of the study area – indicate acidic hydrothermal activity. The operation of these hydrothermal processes is also evidenced by geological and geochemical determinations. In the study area, pyrite, visible gold and native elements were all determined via ore microscopy. The pyrite is of three types; type 1 is coeval with the host rocks, the other two types of pyrite occurrence developed via epithermal activity. Pyrite crystals are 1-1000 microns, gold 2-15 microns, and native elements 1-20 microns in size. Hypogene minerals include goethite and lepidocrocite. Based on geochemical analyses, the trace- and rare-earth element patterns of the volcanic rocks (except the phreatomagmatic breccia) are similar to each other, and all resemble arc volcanic rocks. Thus, geological, petrographic, mineralogical and geochemical data on these Eocene volcanic rocks and their hydrothermally altered equivalents indicate an epithermal system.

Geology, mineralogy and depositional environment of the Pliocene Cappadocian Volcanic Province, Yeşilhisar (Kayseri, central Anatolia, Turkey)

Kadir, S.[1*], Gürel, A.[2], Göz, E.[1] & Külah, T.[1]
[1]Dept. of Geological Engineering, Eskişehir Osmangazi University, Eskişehir, Turkey ([*]skadir_esogu@yahoo.com)
[2]Dept. of Geological Engineering, Niğde University, Niğde, Turkey

Pliocene alluvial and lacustrine deposits characterize the so-called Kısladağ Formation of the Cappadocian Volcanic Province (central Anatolia). The Güzelöz Plateau (Yeşilhisar) in the central part of the Cappadocian Volcanic Province contains many ignimbrite levels, andesite, and basalt intercalated with paleosols, calcretes, lacustrine carbonates, fluvial sediments, diatomaceous clayey sediments and pyroclastic sedimentary levels. The presence of root traces and remnants, paleosols, and calcrete indicate fluvial and shallow-lake environments. These environments are dominated by feldspar, quartz, calcite, opal-CT, serpentine coexisting with smectite, illite and accessory palygorskite. Smectite predominates in paleosols and calcrete units. Development of microsparitic to sparitic calcite cement between irregular clay nodules in paleosol and calcrete samples, and dog-tooth-type sparitic calcite crystals in fractures and cracks, indicate alternating dry and wet periods, that resulted in the development of paleosols and calcretes. The $\delta^{18}O$ values of the calcretes range from –9.13 to –10.69 ‰ PDB, reflecting their formation under the influence of meteoric water. $\delta^{13}C$ values of the calcretes are between +4.97 and +3.00, and may have been related to drought conditions, increase in C_4 biomass, and decrease in atmospheric CO_2 concentrations below a threshold that favoured C_3 plants [1]. $\delta^{18}O$ and $\delta^{13}C$ isotope values from limestone samples vary between –9.81 to –10.71 and 1.85 to –4.84 ‰ PDB, respectively. Negative $\delta^{18}O$ values and low [MgO/(MgO+CaO)] ratios indicate low salinity and freshwater influx into the lake [2]. The negative calcite $\delta^{13}C$ values of the limestones clearly indicate a biogenic origin, lake expansion and increased through-flow conditions, whereas positive values indicate lake contraction, decreased through-flow conditions and biogenic activity. The Pliocene interval, represented by paleosols, calcretes and lacustrine carbonate rocks in Cappadocia region, is of special interest insofar as it included global changes in vegetation (C_3 to C_4 ecosystems) and drought-wet fluctuations.

Investigation of magnetic and adsorption properties of natural and magnetic sepiolite

Dikmen, Z.* & Orhun, O.
Dept. of Physics, Anadolu University, Eskisehir, Turkey
(*zdikmen@anadolu.edu.tr)

In this study, we investigated a sepiolite sample obtained from Sivrihisar region (Eskisehir-Turkey). Firstly, instrumental characterization of the clay sample was performed by various techniques such as XRD, XRF, TG/DTA, SEM. Magnetic modified forms of clay minerals have been prepared and then adsorption and magnetic properties of unmodified and modified clays were compared with each other. The magnetic modified forms of clay samples have been prepared in the following way: The fractions of clay samples that have dimensions smaller than 63μm have been separated by sieving. They were mixed and intensively ground with powder forms of magnetite in a mortar. The resulting powder mixture was slowly heated up to 950°C at 1°C/min and maintained at this temperature for 6 hours. The solid sample was cooled and washed with de-ionized water until no Cl^- ions were detected in the eluted water, and then dried at 80°C during 16 hours [1].

The adsorption isotherms of nitrogen gas on natural and magnetic modified clays have been obtained by means of Quantachrome Nova 2200E model high speed gas analyzer. The magnetic properties of the samples have been determined by means of LakeShore 7307 model Vibrating Sample Magnetometer.

Table 1: Comparison of specific surface areas, average pore diameters for natural and magnetically modified clays

Forms of Clay	Specific Surface Area(m^2/g)	Average Pore Diameter (Å)
Sepiolite	293.52	84,38
Sepiolite-Fe	68.34	92,17

As shown Table 1, the specific surface areas of magnetically modified clays are smaller than the specific surface areas of natural clays. The average pore diameters of magnetically modified clays are greater than the average pore diameters of natural clays.

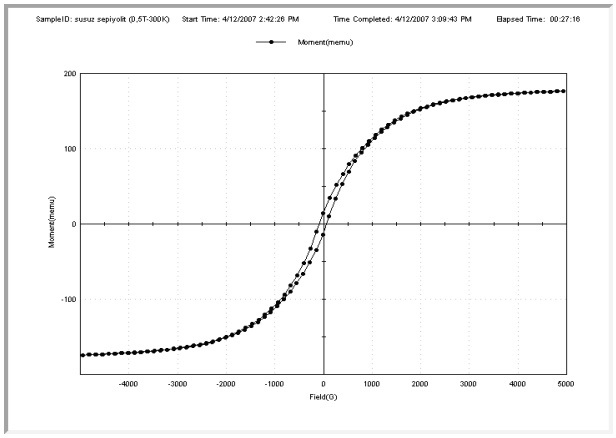

Fig. 1: Magnetization versus applied field curve at room temperature (max. magnetic field 0.5T) for the magnetic modified sepiolite.

The magnetic clay sepiolite is characterized by the maximum magnetization value of 176,4 memu (Fig. 1). Similar results could be obtained for other natural clays and porous materials.

Hungarian contribution to mineralogy and geology of clays

Viczián, I.
Hungarian Institute of Geology, Budapest, Hungary
(viczian@mafi.hu)

The Hungarian Clay Minerals Group was founded in 1960. On the occasion of the *50th anniversary* the main results of the Hungarian clay research in the field of earth sciences is reviewed.

A *general textbook* on clay minerals was published by the founder of the Clay Group, professor Nemecz. In a broader sense the fundamental books of Bárdossy on bauxites belong to the clay research. Soil clay minerals were discussed in the textbooks of Stefanovits, Szendrei and Nemecz, and recently by Nagy and Kónya.

Specific clay minerals. The famous illite mineral of Füzérradvány, the "second illite of the world" was described by Maegdefrau & Hofmann as early as 1937 and later reviewed by Nemecz & Varjú. Weiszburg and E. Tóth contributed much to the chemical systematics of celadonite, glauconite and "Fe-rich montmorillonite" series. Serpentine minerals were extensively studied by Erdélyi and in the last years by Dódony (structural analyses of antigorite and polygonal serpentine).

Determinative methods in clay mineralogy. A method of quantitative analysis by X-ray diffraction was introduced by Náray-Szabó. A special apparatus for thermal analysis called "Derivatograph" was developed by Paulik & Paulik. Atlas of thermal analysis was created first by Földvári-Vogl. The application of the method was later continued on a high level by M. Földvári.

Soils and rocks. Stefanovits and Dombóvári published the map of clay minerals in Hungarian soils. Red clays, mostly relict fossil soils were studied by Bidló. Fekete published book on recent tropical soils. *Fossil lake sediments* of basaltic craters were recognised by Solti and analysed by Földvári, Barna and others. Mostly rhyolite-related bentonite deposits of the Carpathian Basin were studied by Kovács-Pálffy.

Lithostratigraphic application. Clay minerals of Hungarian sedimentary formations were systematically characterised by Viczián. Today this line is continued by Raucsik, Varga and Szakmány. The *diagenetic transformation* of smectite to illite was widely applied for CH prospecting by Viczián, J. Mátyás and others. The *very low grade metamorphic stage* is studied by Árkai and his co-workers M. Tóth, Judik etc. He introduced the parameter "chlorite crystallinity" (Árkai index), studied index minerals, applied textural analysis etc. His studies extended to Hungary, the Swiss Alps, and to SE-Europe.

Zones of *hydrothermal alteration* in the Tokaj Mts. were first recognised by Széky-Fux, later intensively studied by Nemecz and Varjú and recently by Molnár. *Economic clay deposits* were studied for several decades by E. Mátyás and Zelenka, their colloidal properties by Juhász, Szántó and their students. Model experiments of *environmental pollution* by heavy metals are carried out by Németh. Clay liners for communal *waste depositories* were developed by Szabó. Pelitic host rocks for radioactive waste depositories are studied in Mecsek Mts.

Mineralogical and chemical composition of clayey deposits in caves

Klimova, E.V.* & Matrenichev, V.A.
Institute of Precambrian Geology and Geochronology, RAS, St. Petersburg, Russia (*katya_kli@list.ru)

Clay deposits in caves are quite specific in nature due to their origin and therefore are not well investigated.

For the purposes of this research samples from: Sumgan-Kutuk Cave (Bashkortostan, the Urals), Kapova Cave (Bashkortostan, the Urals), Canyon Cave (Krasnodar region, the Caucasus), Voronya Cave (Abkhazia, the Caucasus) and Cascade Cave (the Crimea, Ai Petri) have been considered.

Analysis of particle size distribution showed that in all the caves studied there are two types of deposits: sandy silt, where percentage of clay fraction (less than 0.002mm) is 3.7% with predominant silt fraction (0.002 to 0.01mm) of 50-75%; and clayey silt where the percentage of clay fraction is 12.6%, with silt (0.002 to 0.05mm) being dominant (70-80%).

The mineral composition of the clay fraction is dominated by illite-smectite interlayerings (35-50%) with predominant illite layers, kaolinite (4-10%), chlorite (approximately 6%), smectite (approximately 1%), calcite (approximately 1%), iron hydroxides (approximately 1%). The amount of detrital quartz reaches 40% in the <0.002 mm fraction.

Further chemical analysis of the alumo-silicates from the clay fraction, carried out using a Jeol JSM-5300 scanning electron microscope equipped with EDS, showed that: *Illite* has high potassium content and characterized by 52.27% SiO_2, 26.49% Al_2O_3, 3.92% Fe_2O_3, 4.90% MgO, 3.58% of CaO, 2.44% Na_2O and 6.40% of K_2O. *Chlorite* is represented by the magnesium type and contains 31.23% SiO_2, 27.43% Al_2O_3, 5.89% Fe_2O_3, 29.05% MgO, 0.51% CaO, 4.91% Na_2O and 0.99% K_2O. *Smectite* is defined by high iron content and has 32.35% SiO_2, 22.84% Al_2O_3, 32.13% Fe_2O_3, 5.81% MgO, 2.86% CaO, 2.09% Na_2O and 1.91% K_2O. The clay minerals from the studied deposits have similar chemical compositions, regardless of the sampling site.

The chemical composition of clay fraction of the main type deposits is presented by: SiO_2 55.81%, Al_2O_3 27.41%, Fe_2O_3 4.94%, MgO 3.44%, CaO 1.35%, Na_2O 2.27%, K_2O 4.78% for clayey silt; and SiO_2 54.19%, Al_2O_3 27.73%, Fe_2O_3 3.66%, MgO 5.38%, CaO 0.90%, Na_2O 2.36%, K_2O 5.77 for sandy silt.

As shown in Fig. 1, REE spectrum of clay fraction in sandy and clayey silt (average of all samples) is quite similar.

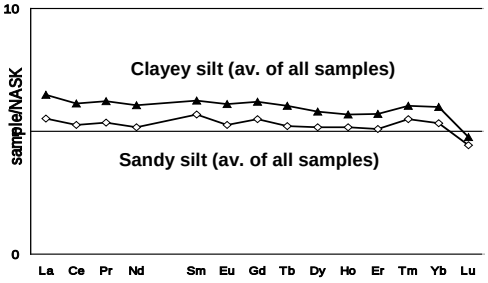

Fig. 1: REE spectrum of clay fraction in sandy and clayey silt (average of all samples).

Taking into account the results of mineralogical and chemical composition of clayey deposits from caves in Caucasus, Crimea, and the Urals, the following conclusion can be made. Clayey deposits from all considered caves are represented by two types of sediments (sandy silt or clayey silt) that show differences in the micro-facies of their deposition environment. Mineralogical composition of clay fraction is similar for all analyzed samples, with predominant illite-smectite mixtures with a percentage of smectite layers < 35%.

Montmorillonitic alteration of tourmaline from the Quintos de Baixo pegmatite, Borborema Pegmatite Province, NE Brazil

Strmić Palinkaš, S.[1], Bermanec, V.[1*], Žigovečki Gobac, Ž.[1], Palinkaš, L.A.[1], Kampić, Š.[1], Wegner, R.[2] & Odúlio, J.M.M.[3]
[1]Institute of Mineralogy and Petrography, Dept. of Geology, University of Zagreb, Croatia (*vberman@public.carnet.hr)
[2]Centro de Ciências e Tecnologia, Dept. de Min. e Geol., Universidade Federal de Campina Grande, Brazil
[3]HR Exportação e Importação de Minérios, Governador Valadares, MG, Brazil

Tourmaline is a common boron-rich mineral in granitic pegmatites [1]. It is resistant to weathering and typically occurs as a detrital mineral in sedimentary rocks and soils. However, tourmaline in pegmatites may be partially altered to various aluminous minerals. Alterations are mostly associated with late magmatic and hydrothermal fluids [2].

Tourmaline from the Quintos de Baixo pegmatite, Borborema Pegmatite Province, NE Brazil, displays zonal structure with Li-Al-rich core (elbaite) and Fe-rich rim (schorl). The core is frequently altered to clay minerals. The matrix between tourmaline crystals comprises clay minerals as well. According to X-ray powder diffraction (XRPD) analysis the principal clay mineral is montmorillonite with cation exchange capacity (CEC) of 75.5 ± 0.4 mEq/100g.

The following reaction illustrates the breakdown of tourmaline (elbaite) into Li-montmorillonite:

$$Na(Li,Al)_3Al_6(BO_3)_3Si_6O_{18}(OH)_4 + 5H_4SiO_4 + 3H^+ \leftrightarrow 3[Al_3(Si_{3.67}Al_{0.33})O_{10}(OH)_2]Li_{0.33} + 3H_3BO_3 + 2Li^+ + Na^+ + 6H_2O \quad (\Delta_rG^0 = -69.7 \text{ kcal/mol})$$

The reaction requires increased activity of H_4SiO_4 and points to the influence of late magmatic or hydrothermal fluids (Fig. 1). Alternatively, the weathering of spodumene can represent an important source of montmorillonite:

$$7LiAlSi_2O_6 + 6H^+ + 6H_2O \leftrightarrow 3[Al_3(Si_{3.67}Al_{0.33})O_{10}(OH)_2]Li_{0.33} + 3H_4SiO_4 + 6Li^+ \quad (\Delta_rG^0 = -2.6 \text{ kcal/mol})$$

Gibbs free energies for above mentioned reactions (Δ_rG^0) have been estimated according to the thermodynamic data published by Woods & Garrels [3], Tardy & Garrels [4] and Ogorodova et al. [5].

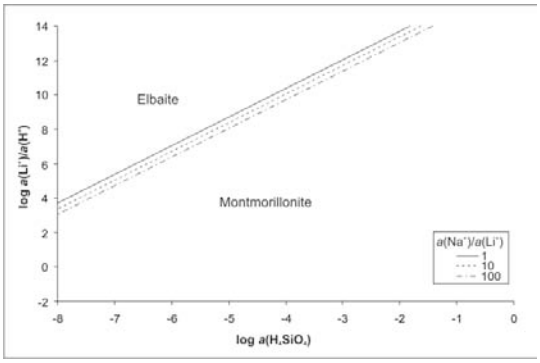

Fig. 1: Logarithmic activity diagram, constructed for standard conditions (1 bar, 25°C).

The mineralogical and petrographic study of zeolitic tuffs around Karamürsel, NW Turkey

Uz, B.[1], Bacak, G.[2*] & Özdamar, S.[1]
[1]Dept. of Geology, Istanbul Techical University, Istanbul,Turkey
[2]Dept of Geololgy, Karaelmas University, Zonguldak, Turkey
([*]bacakgur@karaelmas.edu.tr)

Paleocene pyroclastic rocks of the volcano-sedimentary sequence which disconformably overlie Triassic conglomerates and sandstones underwent locally a strong alteration in the area around Karamürsel, NW Turkey (Fig. 1).

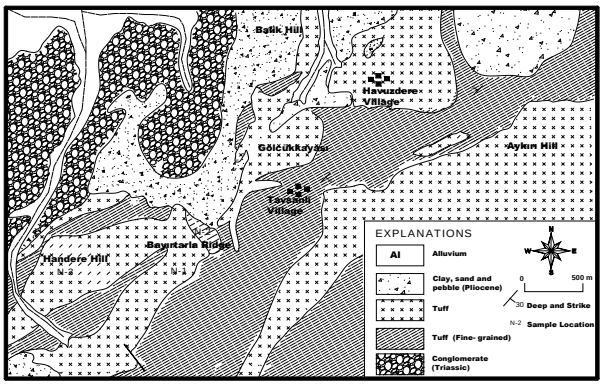

Fig. 1: Geological map of the study area [3].

Volcanic tuffs, which have the composition from andesite to rhyolite, underwent diagenetic alteration. Zeolites (clinoptilolite, heulandite), clay minerals and micas (smectite, illite, celadonite, glauconite and biotite), siliceus minerals (opal-CT, quartz), carbonate minerals (calcite) and feldspars are authigenetically formed. Thermal stability studies indicate that the zeolite types are clinoptilolite and heulandite-2 (Ca-clinoptilolite). Clinoptilolite is stable at 550°C. Si/Al ratios of selected 3 zeolite samples range from 4.70 to 5.84. Heulandites have been distinguished from iso-structural clinoptilolites on the basis of their Si/Al ratios, heulandites having Si/Al <4 and clinoptilolites having Si/Al>4 [1,2]. XRD studies indicate that Karamürsel samples contain typical heulandite with d(060) spacing higher than 1.51Å (Fig.2). Glauconite (Al-glouconite) identified with celadonite-glauconite distinguishing methods was found to be a mixed-layer mineral.

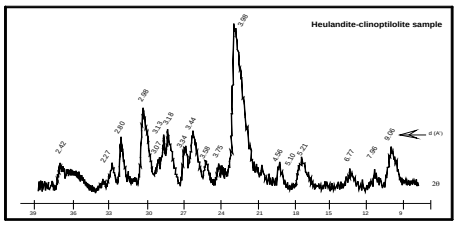

Fig. 2: XRD pattern of heulandite-clinoptilolite bearing tuff

Cationic values were recalculated on the basis of 72 oxygen atoms, providing the following average half unit cell composition of the glauconite: $K_{0.53}(Fe_{0.89}, Al_{0.53})$ $(Mg_{0.48}, Fe_{0.17})$ $(Si_{3.65}\ Al_{0.35})\ O_{10}\ (OH)_2$.

Effects of dry grinding on kaolinite powders

Valášková, M.[1*], Barabaszová, K.[1] & Plevová, E.[2]
[1]Nanotechnology Centre, VŠB-TU of Ostrava, Czech Republic
([*]marta.valaskova@vsb.cz)
[2]Institute of Geonics AS CR, Ostrava-Poruba, Czech Republic

Particle size reduction in clays and clay minerals is produced by grinding, which plays an important role in the physicochemical properties of the resulting powders and in the further processing steps. Most papers report that short-time milling of kaolinite flakes causes fracturing along the basal planes coupled with an increase of the specific surface. Several author teams examined the mechanochemical effects of grinding of kaolinite on its structure and thermal behavior and subsequent thermal transformations. Physicochemical changes of the material were observed after applying grinding friction forces, such as present in vibratory, oscillating, and planetary mills [1]. The effects of different times of dry grinding using ball-milling on the structure of kaolinite powders KGa-1 and KGa-2 from Georgia showed that the peak temperatures of the endothermic DTA effects shifted slightly to lower temperatures as grinding time increased. The exothermic peaks were affected only after longer grinding periods [2].

Well-ordered (KGa-1) and low-ordered (KGa-2) kaolinite powders from Georgia were compared after 15 min jet- and ball –milling. The surface area increased, the particle size distribution and the weight loss on heating were different in dependence on the type of milling. he DTA effects did not change after milling.

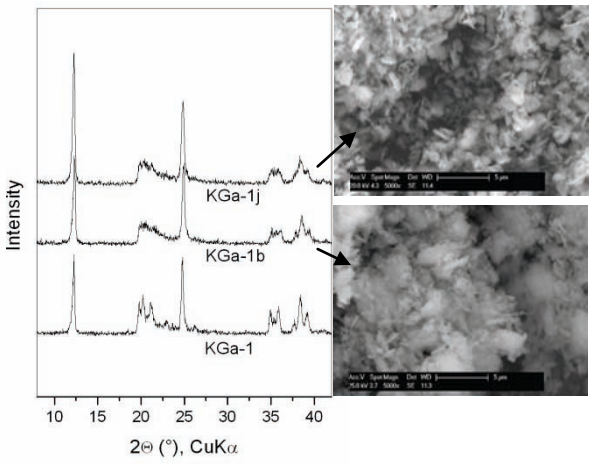

Fig. 1: XRD patterns of KGa-1, ball-milled KGa-1b, jet-milled KGa-1j and SEM micrographs of KGa-1b and KGa-1j.

The X-ray powder diffraction (XRD) patterns (Fig. 1) show the loss of resolution of the peaks near 21.5 °2Θ which is some evidence for a small disorder in the ordered phase [3].

Detailed clay mineralogy of a continuous, marine Tr/J boundary section at Kendlbachgraben, Austria

Zajzon, N.[1*], Kristály, F.[1], Pekker, P.[2] & Pálfy, J.[3]
[1]Institute of Mineralogy and Geology,University of Miskolc, Hungary (*nzajzon@uni-miskolc.hu)
[2]Institute for Nanotechnology, Bay Zoltán Foundation for Applied Research, Miskolc, Hungary
[3]Research Group for Paleontology, Hungarian Academy of Sciences–Hungarian Natural History Museum, Budapest, Hungary

A marine Triassic/Jurassic boundary section is exposed at Kendlbachgraben in the Northern Calcareous Alps. It is located in the Eiberg basin, similarly to the Kuhjoch section, which has been chosen as the Global Stratotype Section and Point for the base of Jurassic.

Selected samples of the Kendlbachgraben section were investigated for clay mineral species determination. Routine oriented specimen diagnostic procedures were followed. Cation exchange for Mg and K was performed. Peaks of X-ray diffraction patterns were resolved by deconvolution procedures. Observed species are ~15 Å smectite (Mg>Fe), together with vermiculite (K-bearing) and chlorite (Fe>Mg) (14,2–14,5Å), illite and kaolinite. The identified "14Å type" minerals are Mg-dominant, with varying Fe, K and Ca content. Chlorite is evident only after heating to 560°C and diminishes upwards in the section. Kaolinite shows a decrease in quantity and degree of crystallinity upwards in the section. Cation exchange and glycerol saturation indicates the mixing of high and low layer charge smectites, with the dominance of the high-charge type. Vermiculite is of the low layer charge, expanding type.

The lowermost sample of section (KB1) has a very different clay mineral content compared to the other samples. It contains dominantly high-charged smectite and also vermiculite. These clay minerals may be formed by the alteration of mafic and ultramafic rocks. Upwards in the section (KB8) smectites has a Ca–Na enrichment and vermiculite (chlorite) becomes dominant. In the boundary shale the clay mineral distribution is the following: kaolinite≥ illite + muscovite >> smectite. This suggests weathering under humid climate, and intensive terrigenous input. Above the boundary interval the clay mineral pattern changes to illite + muscovite >> kaolinite >> smectite, which corresponds to a less humid, mainly moderate climate.

Some pale-green, opaque or slightly transparent grains, 70–80 μm in size, are found in the topmost layer of the Triassic Kössen Formation (KB1). Their shapes vary from the perfectly spherical (Fig. 1) to the angular. They are identified as illite/aluminoceladonite, their average EDX composition is $K_{0.49}Na_{0.08}Ca_{0.07}Mg_{0.65}Fe^{2+}_{0.07}Al_1Fe^{3+}_{0.41}[Al_{0.4}Si_{3.6}O_{10}(OH)_2]$. They presumably represent alteration products of volcanic material, on the basis of their shape and size. Most probably the rounded grains were altered from volcanic glass spherules.

Archaeometrical investigation on glass beads coming from Villanovian excavations in Bologna (Italy)

Arletti, R.[1*], Bertoni, E.[2], Vezzalini, G.[2] & Mengoli, D.[3]
[1]Dipto. di Scienze della Terra, Università degli Studi di Ferrara, Italy ([*]rossella.arletti@unimore.it)
[2]Dipto. di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia, Modena, Italy
[3]Lares s.n.c., Pisa, Italy

Excavations performed in seventies around the actual fair area of Bologna brought to light remains of VII-VIII century civilizations [1]. The archaeological work allowed the collection of a large number of objects which clearly indicate the presence of a large Villanovian village. The archaeological excavations on the annexed necropolis are still in progress and the study is unpublished. The necropolises of Bologna Fair are dated from 800 to 750 BC (Villanovian II) and from 750 to 680 BC (Villanovian II).

Several glass beads were recovered during the excavations. Twenty-seven blue, turquoise, black and dark green glass beads were selected and analysed. The chemical analyses of major and minor elements were obtained by WDS-EMPA, while the analyses of eventual opacifiers dispersed in the matrix were carried out with the combination of XRD and SEM-EDS observations.

The chemical data of the samples allow identifying a group of four beads characterized by a mixed alkalies composition, typical of the Final Bronze Age production found in [2,3]. All the other samples show low levels of K_2O (<2 wt%) and rather high Na_2O (>15 wt%). Some of these samples can be classified as natron-based glass, while for a number of beads the classification is not straightforward, since they contain, along with low K_2O, a high amount of MgO (about 3 wt%). These low potassium high magnesium glasses show, in addition, extremely high levels of Al_2O_3. These results indicate that the glass found in this site derive at least from three different melts. Regarding the opacity of the samples, in most of the cases the effect is due to the dark colour of the glass (i.e. in blue, dark green and black beads) which prevent obliterate the transmission of light. Only in the turquoise samples, crystalline particles of calcium antimonate were found.

An advanced methodology for Remote Operation Vehicle magnetic survey to delineate buried targets and estimate medium magnetization

Eppelbaum, L.V.
Dept. of Geophysics and Planetary Sciences, Raymond and Beverly Sackler, Faculty of Exact Sciences, Tel Aviv University, Tel Aviv, Israel ([*]levap@post.tau.ac.il)

A role of iron in the Earth evolution and investigation of the present environment is extremely important (e.g., [1]). Magnetic survey is one of most applied geophysical method for searching and localization of any objects with contrast magnetic properties (for instance, in Israel detailed magneric survey has been succesfully applied at more than 40 archaeological sites [2]). However, land magnetic survey cannot be performed in swampy and karstic areas, districts with dense natural growth and in some other districts. Conventional airborne magnetic measurements are limited by a flight level, too high velocity of flight, heightened danger for the aircraft crew by low-altitude survey, and financial considerations. At the same time the new Remote Operation Vehicle (ROV) generation – small and maneuvering vehicles – can fly at levels of few (and even one) meters over the earth's surface (flowing the relief forms or straight) with simultaneous precise magnetic field measurements. Such geophysical investigations should have an extremely low exploitation cost. Finally, measurements of geophysical fields at different observation levels could provide new unique geological-geophysical information [2].

The developed interpretation methodology for magnetic anomalies advanced analysis [3] may be successfully applied for ROV magnetic observations. This methodology includes: (1) non-conventional procedure for elimination of secondary effect of magnetic temporary variations, (2) calculation of rugged relief influence by the use of a correlation method, (3) estimation of medium magnetization, (4) application of various logical-heuristic and informational algorithms for revealing small anomalies against noise background, (5) advanced procedures for magnetic anomalies quantitative analysis (they are applicable in conditions of rugged relief, inclined magnetization, and an unknown level of the total magnetic field for the models of thin bed, thick bed and horizontal circular cylinder; some of these procedures demand performing measurements at two levels over the earth's surface), (6) advanced 3D magnetic-gravity modeling for complex media, and (7) development of 3D physical-geological (or magnetic-geological) model of the studied area. ROV observations also permit to realize a multimodel approach to magnetic data analysis [4]. Results of performed 3D modeling confirm an effectiveness of the proposed ROV low-altitude survey.

Khesin's methodology [3] for estimation of upper geological section magnetization consists of land magnetic observations along a profile disposing under inclined relief with the consequent data processing (this method cannot be applied at flat topography). It was suggested that integrated ROV straight and inclined observations will help to obtain parameters of the medium magnetization even over the flat relief.

Mineralogy and archaeometry: fatal attraction

Artioli, G.
Dipto. di Geoscienze, Università di Padova, Italy
(gilberto.artioli@unipd.it)

The difficult and fascinating relationship between archaeometry and mineralogy continuously offers challenges and topics for research, though it is often troubled by the sectorial organization of academic structure, at present also severely limited by budgetary cuts [1,2]. The existing competition between traditional academic disciplines in the field of cultural heritage is often pernicious and poorly effective as far as information and knowledge transmission is concerned. The continuity in the employment of highly trained researchers and the poor strategy in the data publication are issues of great concern. Centralised research facilities could have a leading role in the management of multi-disciplinary research, though they have a limited practical effect in a shrinking budget world.

Within this frame, disciplines such as mineralogy and petrology, intrinsically used to deal with complex systems, found new natural areas of applications in cultural heritage materials. Archaeometry-oriented applications rose from the status of exotic studies to widely diffused areas of research within the last decade, partly because of the fascination of the involved problems, and partly because of the limited funding in the traditional fields of research. It is argued that mineralogy as a discipline at the crossroad between the core Earth Sciences, crystallography, materials science, and geochemistry might be a key area of innovation for cultural heritage studies.

A few case studies will be discussed to convey a personal view of mineralogical applications within the broader context of cultural heritage investigations [3]. Key issues are: the use of combined techniques for the characterization of complex systems, the optimization of non-invasive techniques, the appropriate use of data bases in archaeometry.

On the origin of the green colour of archaeological bone artefacts of galloroman period

Ferrand, J.[1], Rossano, S.[1*], Rollet, Ph.[2], Farges, F.[3], Allard, T.[4], Pont, S.[3] & Catillon, G.[1]
[1]LGE, Université Paris-Est Marne-la-Vallée, France
([*]rossano@univ-mlv.fr)
[2]INRAP Reims, France
[3]LMCM, Museum National d'Histoire Naturelle, Paris, France
[4]IMPMC, Paris, France

Bone artefacts of the Gallo-Roman period have been discovered in the Reims city in 2004 in a place that was identified as a workshop dedicated to bone objects. Among the bone pieces, some of the finished objects are coloured in green by copper. However, the colouration cannot be due to a long contact with a metallic object made of bronze or copper. The understanding of the origin of this colour is very important to decipher if the colouration was made intentionally and to get knowledge about the processes developed by the craftsman.

In this work, two archaeological green objects from the site of Reims, one archaeological bone coloured by contact with a metallic object and fresh bones coloured in the laboratory are compared. Infra-red spectroscopy was used to get information on the organic part of the samples while X-ray diffraction allowed us to characterize the crystalline part. X-ray absorption spectroscopy at the Cu K-edge was used to obtain information about the environment of Cu in the artefacts. Finally, SEM-EDS experiments have been used to localize the copper in the bone structure.

Ancient metals provenancing: a geochemical database of Alpine copper mines

Giunti, I.[1*], Angelini, I.[1], Artioli, G.[1], Nimis, P.[1] & Villa, I.M.[2,3]
[1]Dipto. di Geoscienze, Università di Padova, Italy
([*]ilaria.giunti@unipd.it)
[2]Dipto. di Scienze Geologiche e Geotecnologie, Università di Milano Bicocca, Milan, Italy
[3]Institut für Geologie, Universität Bern, Switzerland

The provenance of ore minerals used in prehistoric and historic times for copper smelting and extraction is one of the basic questions that archaeologists pose to modern analytical archaeometry [1]. To aid metal provenancing studies, a database of fully characterized Alpine copper mineralisations is being developed as the fundamental reference frame for metal extraction and diffusion in the past.

The abundances of about 60 minor and trace elements, including most transition metals and chalcophile elements, and Rare Earths Elements were measured in all samples via ICP-Q-MS. Furthermore, the feasibility of the routine reliable measurement of the $^{65}Cu/^{63}Cu$ isotope ratio [2] and its eventual use as a possible ore tracer was tested. Multicollector ICP-Mass Spectrometry was used to determine precise Pb isotopic ratios ($^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, $^{208}Pb/^{204}Pb$).

Advanced strategies based on multivariate analysis were then used to discriminate the ore mineral provenance. Data were treated with the chemometric software "The Unscrambler Version 9.5" (CAMO AS, Trondheim, Norway). Data pre-treatment, PCA [3] and PLS-DA [4,5] models were performed as implemented in the software. Moreover, mines dataset was analyzed using inferential multivariate nonparametric methods [6,7].

Application of statistical analysis to the geochemical and isotopic database proved to be a very powerful tool to discriminate the ore source areas with very little ambiguity.

The applications to archaeometallurgical copper and slag specimens from the Agordo area (Veneto, Italy) and the recently found prehistoric slags from Millan (SüdTirol, Italy) indicate that the approach is successful in provenance and trade route investigations.

Mineralogy of slags from South African prehistoric tin smelting activities

Heimann, R.B.[1*], Chirikure, S.[2] & Killick, D.[3]
[1]Am Stadtpark 2A, D-02826 Görlitz, Germany
([*]robert.heimann@ocean-gate.de)
[2]Dept. of Archaeology, University of Cape Town, South Africa
[3]Dept. of Anthropology, University of Arizona, Tucson, AZ, USA

A suite of vitreous slag remains from two prehistoric tin smelting sites at Rooiberg, Limpopo Province, South Africa were analyzed by wavelength-dispersive X-ray fluorescence spectrometry (WD-XRF), energy-dispersive X-ray spectroscopy (EDX), and electron microprobe analysis (EMPA). The cassiterite ore utilized at the Smelterskop site (ca. 1650-1850 cal CE) is associated with iron-rich tourmaline (schörl) and was mined from fracture fillings of rocks associated with the Precambrian granite intrusion of the Bushveld Magmatic Province. Evidence exists that the cassiterite feed was carefully beneficiated by panning of the crushed ore. Ore containing some zircon and rutile smelted at the Elandsberg Ledge site (15^{th}-17^{th} centuries cal CE) was presumably collected from alluvial placer deposits**.**

The mineralogical composition of the Smelterskop slags comprises skeletal cassiterite and complex spinels, as well as metallic tin prills ranging in size from a few to tens of micrometers. The spinels contain substantial amounts of tin, titanium and vanadium. The larger tin prills frequently contain Sn-Fe intermetallic compounds called 'hardhead' whereas the small, generally spherical blobs are essentially pure tin. Owing to the different composition of the ore feed processed at the Elandsberg Ledge site these slags contain in addition zirconium-rich minerals such as zirkelite, zirconolite and baddeleyite, and ilmenite.

In the presentation emphasis will be devoted to the role tin (II) and (IV) species appear to play during formation of the glassy slags as well as to the characterization of the complex spinels precipitated from the molten slag. From this study a consistent picture arises of the technology of prehistoric tin smelting in this part of the world.

Provenance determination of raw materials and production technology used in ancient mortars from Tournai (Belgium)

Mertens, G. & Elsen, J.*
Dept. of Earth and Environmental Sciences, Katholieke Universiteit, Leuven, Belgium (*jan.elsen@ees.kuleuven.be)

At the Cathedral of Tournai in Belgium, archaeological excavations are exposing structures from Roman to Medieval age. Samples from these excavations have been subjected to a detailed investigation as part of a broader study considering the transition of ancient cities and their rural territories from Roman to late Roman society and the transformation to the early middle ages. Masonry mortars and mortars used for flooring have been characterized from the Imperial Roman period, the Carolingian style period and the Romanesque style period (4^{th} -11^{th} century AD) to trace the origin of the raw materials and to study the traditional knowledge on mortar production technology.

Computer assisted image analysis techniques were applied on thin sections of the mortar samples to obtain the grain size distribution curve of the aggregate [1]. The results were compared as a fingerprint with the grain size distribution curves of locally available sands, obtained with the same methodology. Based on the resemblance of the curves, it appears that locally available, fine glauconitic quartz sand was used integrally as an aggregate in some mortars, whereas it could not be excluded that somewhat finer sand, present in some mortar samples was sieved before use. However, no clear correlation could be established between the nature of the aggregate and the age or function of the mortar in which it was used.

To identify the origin of the binder a great number of binder related particles were investigated in detail using SEM/EDX and microprobe methods to investigate their nature. Three types of binder-related particles could be distinguished; underburned fragments, overburned fragments and lime lumps (sensu stricto). Underburned fragments as relicts of incompletely burned limestone helped to retrace its source, both Cretaceous marls/chalk and Carboniferous limestone have a highly variable Si- and Al-content and can therefore both yield a hydraulic or air-hardening lime. The presence of characteristic fossils and glauconite helped to refine the provenance of the chalk/marls used for the lime production. Overburnt particles gave helpful information about the burning and slaking of the lime. Overburnt particles containing wollastonite and rankinite associated with a C-S-H phase have been identified in several of the post-Palaeo-Christian mortars. These cathodoluminescent particles are scarcer in Roman and Palaeo-Christian mortars. They could be indicative for the selectivity of the ancient builders towards source materials and/or processed products.

Fingerprinting of Cornish gold for provenancing prehistoric gold artefacts from Central Europe

Ehser, A.[1*], Borg, G.[1] & Pernicka, E.[2]
[1]Inst. of Geosciences, Martin-Luther-University Halle-Wittenberg, Halle, Germany (*anja.ehser@geo.uni-halle.de)
[2]Curt-Engelhorn-Centre for Archaeometry, Mannheim, Germany

Previous studies of possible sources of gold used for the Bronze Age Sky Disc of Nebra initially pointed towards South Eastern Europe by indirect evidence, i.e. similar geochemical compositions of gold artefacts from this region [1]. The relatively high tin content in the gold of the Sky Disc, however, suggested a mineral association of gold and tin, similar to the one found in Cornwall. In this study, one lode and seven placer gold deposits from Cornwall have been analysed by LA-ICP-MS to determine the trace element signature of the natural gold for comparison with the gold inlays on the Sky Disc.

To characterise the locally heterogeneous composition of individual deposits as well as their nuggets, a minimum of ten nuggets per deposit as well as three points or lines per nugget were measured after pre-ablation had cleaned the surface. To compare the natural gold with the artefact gold, specific elements were selected, which, besides being useful for individual "fingerprinting", tend to show a low relative standard deviation (RSD) and a high stability during geological (fluvial transport) and metallurgical (smelting) processes. Mn, Co, Ni, Cu, Ru, Pd, Ag, Sn, Sb, Pt, Ir together with Au seem to be the most suitable elements, based upon the results of previous studies. The relatively strong natural variability of Au and Ag contents in natural gold, however, can result in a limited comparability with artefact gold. Artefact gold, on the other hand, can be alloyed with Cu, which is commonly geologically associated with elevated concentrations of Co, Ni, Ag, and Sb. The limited applicability of Ru and Ir for provenance studies is predominantly caused by their concentrations within natural gold being below the detection limits of the LA-ICP-MS instrument. The behaviour of elements that tend to partition into the slag during smelting, such as Mn, still needs further consideration. Since the geochemical signature of individual gold deposits gets homogenised during smelting, the mean value of each deposit has been calculated and used for correlation with the artefact gold.

For Cornwall, the trace element composition of the analysed natural gold strongly correlates with that of the gold inlays on the Sky Disk of Nebra. No similarly well matching "fingerprint" has been detected for previously studied gold deposits from Central and parts of South Eastern Europe. The best correlation is observed in the trace element pattern of the prehistorically important alluvial tin and (minor) gold deposit of the Carnon valley in South Cornwall, strongly suggesting this deposit as the source of the gold used for the Sky Disc. Recent studies of tin isotopes [2] suggest that the tin for the bronze of the Sky Disc also originates from Cornwall supporting the presumed concept of trade of metals from the Atlantic region towards central Germany during the Bronze Age. Further investigations, however, will need to be carried out based on the results of this study and the initial indications for a South Eastern European source of the gold as some important prehistoric gold mining districts have not been studied yet within this context.

Archaeological gold provenance studies based on SR-XRF and micro-PIXE analyses

Constantinescu, B.[1*], Bugoi, R.[1], Vasilescu, A.[1], Radtke, M.[2], Calligaro, T.[3], Salomon, J.[3], Pichon, L.[3], Röhrs, S.[3], Ceccato, D.[4] & Pop, D.[5]
[1]National Institute of Nuclear Physics and Engineering, Bucharest, Romania (*bconst@nipne.ro)
[2]Federal Institute for Materials Research and Testing (BAM), Berlin, Germany
[3]Laboratoire de Recherche et de Restauration des Musées de France, CNRS UMR 171, Paris, France
[4] INFN, Laboratori Nazionali di Legnaro, Italy
[5]Babes-Bolyai University, Cluj-Napoca, Romania

The territory of today Romania was one of Europe main gold-producing areas since the Antiquity, mostly due to the deposits from the "Golden Quadrilateral" in the Apuseni Mountains, and less to the Eastern and Southern Carpathians deposits. The goal of the study is to find out if so-called "Transylvanian gold", originated either in the Apuseni Mts. or/and in the Southern Carpathians was used to manufacture some archaeological objects i.e. the twelve Dacian gold bracelets (Fig. 1). For gold artifacts, trace elements such as Te, Sb, Hg, Pb, Cu, as well as Platinum Group Elements (PGE), Sn, Ta and Nb are more significant for provenance than the main components i.e. Au, Ag. On the other hand, Sb, Te and Pb are specific for the Apuseni Mts. gold, whereas the presence of Sn might be characteristic for the alluvial gold from the Southern and Eastern Carpathians. Each bracelet weights around 1 kg and consists of a thick gold rod, 6 to 8 times coiled in the shape of a spiral. The rods range from 2.30 to 2.80 m in length and end with palm leaf-like ornaments. The SR-XRF analyses (Berlin BESSY synchrotron) show various Au (78.2 to 92.9 wt.%), Ag (6.3 to 20.3 wt.%) and Cu (0.3 to 2.1 wt.%) content [1]. Sn, up to 0.15 wt.%, and traces of Sb were also detected.

The data obtained for archaeological artifacts were compared with analyses of 22 native "Transylvanian gold" samples. The latter were studied by means of both SR-XRF (Berlin BESSY synchrotron) and micro-PIXE (Paris AGLAE accelerator and Legnaro micro-beam) techniques. The results show high Ag (8 to 30 wt.%) and low Cu (0.2 to 1 wt.%) amounts in all studied samples. In particular, gold from Southern Carpathians placer deposits contains Sn (150-300 ppm) whereas gold from the Apuseni Neogene hydrothermal deposits (veins) have a highly variable content of Te (200-2000 ppm) and Sb (150-300 ppm).

Fig. 1: One of the Dacian gold bracelets.

Due to the high possibility that the artifacts were manufactured from a mixture of native and previous gold object(s), it can be only presumed that at least partly, the metallic material used for the Dacian bracelets originated from the placer deposits from the Southern Carpathians and alluvial and Neogene veins from the Apuseni Mts. This is supported by the presence of Sn (for placers) and Sb (for veins).

Acknowledgements: Study supported by PN 91-020 project (Romanian Ministry of Education).

Mineralogical and geochemical characterization of ceramic "sugar jars" ("formas de açúcar") from Aveiro town (Portugal)

Morgado, P.[1] & Rocha, F.[2*]
[1]Geobiotec Unit, University of Aveiro, Portugal
[2]Geosciences Dept., Geobiotec Unit, University of Aveiro, Portugal (*tavares.rocha@ua.pt)

During the 15th to 19th centuries, the old pottery centre from the Aveiro town produced one typical form of ceramic called "formas de açúcar" ("sugar forms") or "cerâmica do açúcar" (Fig. 1), used only in the cycle of sugar production, specifically for the stage of the purge of the sugar cake. These ceramics were exported to sugar production areas, such as Madeira Island and Brazil.

Fig. 1: Two ceramic "sugar jars" ("formas de açúcar") from Aveiro town (Portugal).

Such ceramics, including integrally preserved forms, were found at a sub aquatic archaeological site in a channel of Aveiro coastal lagoon. Same ceramics was found in the old urban areas, where mostly shards but also whole forms were used as construction materials for the walls.

In this work we present a synthesis of the main results obtained so far in the mineralogical and geochemical characterization of the ceramic "sugar forms" found in Aveiro (NW littoral region of Portugal).

Mineralogical analysis with X-ray diffraction was carried out on bulk samples, and on suspensions and oriented aggregates of <63 and <2 μm on air-dried, glycolated and heated samples. Scanning electron microscopy with elemental analyses was also done on selected samples. Chemical composition was assessed by X-Ray fluorescence and provided the major elements chemical data: SiO_2, Al_2O_3, Fe_2O_3, TiO_2, MnO, CaO, MgO, K_2O, Na_2O, P_2O_5 and Loss-on-Ignition. Some trace elements such as: As, Sb, Cd, Co, Cu, Pb, Ni, Zn, Se, Te, Tl, and Ba were also analysed.

Multivariate statistical methods were applied, in particular, Cluster, Principal Components and Discriminant Analysis, the later being a statistical method that assigns samples to one or more of previously/-defined groups. The application of Discriminant Analysis, by means of the *Statistica* Software Program, implies that only the variables that exhibit variance in each defined group are used, leading to the exclusion of all others. The acceptation of both, the discriminant function and the variables that define it, is based on the interpretation of the Wilk's Lambda associated to each variable, and on the Classification Matrix. After verification of the validity of the determined function the Classification Matrix of each sample based on the posterior probabilities determined was interpreted.

The obtained results of composition have given important information about the provenance of the studied materials, and also about their raw materials. Mineralogical and chemical data obtained so far point to local production, using local and regional Upper Cretaceous (Maastrichtian) clays and sandy clays as main ceramic raw materials.

Prospecting for archaeological pottery provenance: experiences on Middle Neolithic Bükk culture pottery from Hungary

Szilágyi, V.[1*], Csengeri, P.[2], Szakmány, Gy.[3], Taubald, H.[4], Tóth, M.[5], Leno, V.[4], Zöldföldi, J.[4] & Biró, T.K.[6]
[1]Inst. of Isotopes, HAS, Budapest, Hungary
([*]szilagyiv@iki.kfki.hu)
[2]Herman Ottó Museum, Miskolc, Hungary
[3]Dept. of Petrology and Geochemistry, Eötvös Loránd University, Budapest, Hungary
[4]Dept. of Geochemistry, University of Tübingen, Germany
[5]Inst. of Geochemical Research, HAS, Budapest, Hungary
[6]Hungarian National Museum, Budapest, Hungary

Provenance investigations of archaeological pottery mean the tracking a complex manufacturing process which can involve both natural (sediments) and artificial (tempering) mixture of components. In addition, significant changes can affect the mineralogical and chemical composition turning from the raw material to the fired pottery (e.g. levigation of clay, tempering, firing, using, burial in sediment/soil). A possible and reasonable way of observation is to sample the possible raw materials and to compare them to the pottery. Investigation of silt-sand sized components (aplastics, temper) is based on petrography, but fine-grained constituents (clayish paste) require instrumental mineralogical and geochemical analysis.

Taking these aspects into consideration, our research group investigated Middle Neolithic Bükk culture pottery and natural samples of fine-grained soil-sediment profiles from different archaeological sites in Hungary (Aggtelek-Baradla cave, Bodrogkeresztúr, Felsővadász, Garadna, Boldogkőváralja, Sajószentpéter) [1,2]. Local sediments, mapped as Quaternary and Neogene in age, and partly soils were sampled by ca. 2 m deep hand drillings close to the archaeological sites. The samples were investigated as possible raw materials for pottery-making, shaped and fired accordingly. From the little "bricks", thin sections and powdered samples were made, same as for the archaeological pottery samples. Results of petrographic (PM), mineralogical (XRD) and geochemical (XRF) analyses were compared.

Based on our results, it can be stated that

(1) the near surface sediments/soils (similar to raw materials exploitable from shallow clay pits) can differ very much from the pottery found at the same site;
(2) in the 2 m lithological columns, there is large variety concerning mineralogical and chemical composition, which means that any similarity with the pottery material suggests intentional selection of raw material from the available local sources;
(3) mineralogical and geochemical data of pottery from various sites seem to cluster more tightly than that of the sediment/soil samples; even from one borehole;
(4) fabric and grains size properties suggest a definite physical quality requirement for the pottery raw material or specific treatment of that to reach the appropriate properties;
(5) fineware is even more consistent than average household ware;
(6) coarse household pottery shows more petrographic and geochemical affinity to the local soil samples than fineware.

Written sources and archaeometric results: from fiction to truth

Maggetti, M.
Dept. of Geosciences, University of Fribourg, Switzerland
(marino.maggetti@unifr.ch)

Ancient and modern ceramic products can be studied from different perspectives. To the petrologist, they are artificial rocks which have been subjected to relatively high temperatures and have recrystallized to become thermometamorphic products, analogue to those naturally formed through metamorphism and anatexis. In contrast to natural rockforming processes, pressure is insignificant in the genesis of such objects, because the kiln can be considered as a technical system. In such open systems, neither pore solutions, present before firing, nor gaseous reaction products, which may have been produced during the high temperature process, have an influence on the transformation, because they can leave the system at any time. Similar to natural rocks, ceramic objects consist of an assemblage of crystalline and amorphic phases, which can be analysed with the same petrographic, mineralogical and chemical methods such as micaschists, which are formed from clay during metamorphism. Any ceramic fragment, how insignificant it may appear, can be compared to a potential 'book', because it contains, as if stored on pages, a wealth of information about its history. The lifespan of a piece of pottery can be divided into five steps: (1) extraction of the clay from the pit; (2) manufacture of the object (processing of the clay, firing); (3) use, with subsequent breakdown; (4) burial; (5) excavation, cleaning, treatment and analysis [1]. During all these steps, the sherd has stored information, and this 'memory' can be activated by a variety of chemical and physical methods [2,3]. Why study "young" ceramic objects, i.e. those from the 18th and 19th c. AD, when all aspects concerning the provenance and/or the specific technique are accessible in written, published or unpublished sources? Recent archaeometric projects showed contradicting results to the written convictions. Some of these studies of French and Swiss whiteware will illustrate the potential of mineralogical, petrographical and chemical methods in deciphering the real origin, the real recipe and the real technique of the studied objects. In all these cases, apparently firmly established written evidences are not reliable and must be revised.

Characterization of the Copper Age ceramics of the Cucuteni-Tripolye culture (Ruginoasa site, NE Romania) by ICP-MS and EMP

Ionescu, C.[1*], Hoeck, V.[2,1], Ghergari, L.[1], Simon, S.[1], Precup, C.[1], Lazarovici, M.[3] & Lazarovici, Gh.[4]
[1]Babeş-Bolyai University Cluj-Napoca, Romania
([*]corina.ionescu@ubbcluj.ro)
[2]Paris Lodron University, Salzburg, Austria
[3]Institute of Archaeology, Iaşi, Romania
[4] Eftimie Murgu University, Reşiţa, Romania

The Copper Age pottery exhumed at Ruginoasa, 60 km west of Iaşi (Romania) was assigned to the so-called Cucuteni-Tripolye cultural complex. It extended in the V-IV milenium BC from the central and north of today-Romania towards east, into Moldavia and Ukraine. Geologically, the region consists of Sarmatian clays, marls and sands, being part of the Eastern European Platform.

The elegant-shaped light red to orange pots, painted with white, red and brown-black geometric patterns are characteristic for this culture. Optical microscopy shows a red, porous ceramic body, with oriented texture. The matrix ranges from microcrystalline to amorphous. The non-plastic inclusions consist of quartz, plagioclase, K-feldspar, muscovite, biotite. Characteristic is the high number of fragments consisting of different clays and siltitic clays, partly calcareous. Other lithoclasts are scarce and consist of mainly metamorphics, some granite, grauwacke and silicastone. Granulometrically, the pottery classifies as fine ceramics, with maximum 3-4% arenitic grains.

The ceramics shows an intermediate to acidic chemistry, with 58.46-64.77 wt.% SiO_2, 12.78-16.64 wt.% Al_2O_3, 5.28-6.33 wt.% Fe_2O_3, 4.31-7.51 wt.% CaO and 2.73-3.48 wt.% K_2O. The content of Rb, Cs, Nb, Th, U and in particular Au (1.9 to 54.1 ppb) is relatively high.

The Backscattered Electron images revealed, besides the large non-plastic inclusions, a highly inhomogeneous matrix, consisting of a fine grained groundmass of clay minerals, amorphous phases and glass in which tiny, smaller than 0.02 mm non-plastic inclusions are embedded. The latter include quartz, feldspar, muscovite, some chlorite and calcite. Accessory minerals such as titanite, anatase, apatite, epidote and hematite occur as well.

Electron Microprobe analyses show that upon softening and possible partial melting the quartz grains, in particular along their rims, incorporate variable amounts of Al and K, with a trend in the direction of K-illite. The alkali-feldspar ranges from pure K-feldspar to anorthoclase and albite. Ca-bearing plagioclases are extremly rare. Muscovite varies from Al-rich compositions to phengitic micas with variable Fe and Mg content. They show a systematic decrease of Al and K and an increase of Mg, Fe and Ca. This transformation process of muscovite has a trend towards compounds with considerably less K and Al than usually measured in K-illite. The final firing products of clay minerals are crystalline, amorphous or glassy. Their composition resembles an intermediate compound between K-illite and a hypothetical Ca-illite with a wide range of composition. Such thermal transformations are obviously not unique in ceramics. They were also found in ceramics from Ilişua - a Bronze Age settlement in north Romania.

The non-stoichiometry of the newly-formed phases gives an insight into a fast firing, whereas their composition indicates a high temperature of firing, between 850 and 950°C.

Mineralogical and geochemical „fingerprints“ of historical bricks from Vienna

Ottner, F.[1*], Fröschl, H.[2], Mitterlehner, C.[1], Hartinger, S.[1] & Holawe, F.[3]
[1]Institute of Applied Geology, University of Natural Resources and Applied Live Sciences, Vienna, Austria
[2]Seibersdorf Labor GmbH, Seibersdorf, Austria
[3]Institute of Geography and Regional Research, University of Vienna, Austria

Vienna has an at least 2000 years old tradition in making and use of bricks. The first bricks were probably produced by Romans in order to have enough construction material to fortify the Petronell and Vindobona military camps. We assume that the first brick-kilns were situated at the banks of the Alserbach River, where excellent raw material for bricks was available. During medieval times huge amounts of building material were needed to build and preserve the town walls. In particular, the urban expansion in the 19th century is a highlight in historical brick use.

Mineralogical and petrographical parameters as well as technological properties were analysed on several 100 to 300 years old brick (samples) from the surroundings of Vienna. In addition, elemental analyses were performed on total digestions of the powdered materials using inductively coupled plasma mass spectrometry (ICP-MS) as powerful technique for the determination of the trace element composition of the samples.

In the present work we aim to characterise which parameters are the most significant for tracing the origin of historical bricks. In archeometry it is a big task to determine the provenance and get information about the production technology in historical times.

Like in forensic studies, we are using an interdisciplinary approach to detect markers like „fingerprints“ which are significant for the materials. The natural elemental distribution, characterised by the geochemical and geological environment and the technological process during the brick making, influences the chemical and mineralogical composition of the material. Additionally, different inclusions in the bricks like by-products or recycling material can be typical for different production places. Further to the variables measured, the signs – possibly the symbols of the producer – are available.

Several multivariate statistical methods like factor analysis, cluster analysis and discriminant analysis were performed on the data set. The available variables are manifold. There are more variables available than objects to be classified. It is therefore necessary to reduce the dimensionality and the multicolinearity. This is done with factor analysis. The factors are then used in the classification process. There are about 5 to 7 different sources and/or production sites for the 36 bricks. Discriminant analysis is used in two ways. One way takes the results of the cluster analysis as classes which are tested with the same variable set. Second the symbols on the upper side of the brick stones are used as different classes and the measured variables as explanatory variables to find out if the symbols could be used as hints about the different sources and production sites, which is obviously not the case.

Protohistoric amber in Europe: new data from Italy and state of the art

Angelini, I.* & Artioli, G.
Dipto. di Geoscienze, Università degli Studi di Padova, Italy
(*ivana.angelini@unipd.it)

The main European sources of amber are located in the Baltic region. Several Palaeolithic amber objects and the earliest workshop have been found in this area. In Southern Europe amber as workable material is employed much later, it appears in Italy in the Aeneolithic, and it is widely diffused in the Mediterranean word during the Bronze Age [1]. Amber deposits are also present elsewhere in Europe, but generally they supply a much smaller quantity of material with respect to the Baltic region, and the amber nodules are normally of limited size. The trade of Baltic amber is well documented during Roman times, whereas the hypothesis of Baltic amber diffusion throughout Europe since the Pre- and Proto-history has been long supported by archaeometric investigations [2,3].

The earlier archaeometric characterizations of the minor European amber deposits and of a few archaeological finds have not been followed by systematic investigations. Common knowledge that virtually all archaeological amber was imported from the Baltic regions has not been adequately supported or challenged by appropriate characterization of the materials, until very recent studies performed both on amber deposits and on archaeological objects. In some instances the use of local amber sources is proved since the Palaeolithic [4]. Our research is focused on the investigation of the amber sources of the earliest Italian materials, and on the change of sources and trade routes from the Aeneolithic to the beginning of the Iron Age [1,5].

The analyses have been carried out by infrared spectroscopy (FTIR), as a fast, inexpensive, poorly invasive and reliable technique for the characterization of amber [2,6,7]. The use of the Diffuse-Reflectance Infrared Fourier Transform Spectroscopy (DRIFT) mode allows non invasive characterization or the use of a minimal amount of sample. About 200 objects have been analysed by DRIFT. The data show that succinite is indeed the principal amber type present in Italy during protohistory, though in a few sites the contemporary use of different amber sources is observed, especially in sites dated to the earliest Iron Age. As a matter of fact the archaeological objects found in two important Italian sites show the substantial presence of non Baltic amber [1,8].

The recent results on protohistoric Italian ambers will be presented and discussed as a function of material's age and geographic distribution, and compared to the available data on coeval European finds.

Discrimination of prehistoric polished stone tools from Hungary by non-destructive chemical analyses

Szakmány, Gy.[1*], Kasztovszky, Zs.[2], Szilágyi, V.[2], Starnini, E.[3], Friedel, O.[4] & Biró, T.K.[4]
[1]Dept. of Petrology and Geochemistry, Eötvös L. University, Budapest, Hungary (*gyorgy.szakmany@geology.elte.hu)

[3]Dept. of Archaeology and Classical Philology, University of Genova, Genoa, Italy
[4]Hungarian National Museum, Budapest, Hungary

Prehistoric polished stone tools with fine to very fine grained texture may show striking similarities in their macroscopic appearance by texture and colour. Therefore, it is very difficult to distinguish the different rock types by the naked eye. Prompt Gamma Activation Analysis (PGAA) is one of the powerful, absolutely non-destructive chemical methods for the analysis of archaeological materials. Contrary to other non-invasive chemical methods this technique measures bulk composition. As regards polished stone tools, PGAA measures all major elements and few trace elements [1].

189 polished stone tools from different collections and localities of Hungary, and 25 geological samples from potential raw material sources were analyzed by PGAA. To interpret the results, bivariant and ternary diagrams, as well as statistical analyses were used. To control the method, several broken pieces were studied also by destructive methods, mainly thin section petrography. Our aims were:

1) to obtain chemical composition of the analyzed artefacts;

2) to create an initial database of PGAA results of the most important raw materials of polished stone tools occurring in Hungary;

3) to explore the potentials and limitations of PGAA in the determination of the raw materials used for the polished stone tools.

As a result, several different raw material groups, basalt – dolerite – metadolerite, greenschist – metabasite – amphibolite, blueschist, hornfels, "white stone" (siliceous magnesite, siliceous siltstone, micritic limestone, tuff, diatomic schist) [2,3], ultrabasic rocks, acidic-intermediate volcanics, could be distinguished. Moreover, different rock types and their compositional varieties were recognized within each group (e.g. greenschist-metabasite, basalt-dolerite). It turned out that weathering or alteration can essentially change the chemical composition beyond the limit of recognisability of the rock.

Macroscopic description combined with PGAA will help to determine raw material types of polished stone tools. However, in some cases other methods are also necessary to achieve precise determination.

Copper Age polished stone shaft-hole axes in Caput Adriae: archaeological implications

Bernardini, F.[1*], De Min, A.[2], Velušček, A.[3], Eichert, D.[4], Montagnari Kokelj, E.[5] & Tuniz, C.[1]
[1]The 'Abdus Salam' International Centre for Theoretical Physics, Trieste, Italy ([*]fbernard@ictp.it)
[2]Dept. of Geosciences, University of Trieste, Italy
[3]Institute of Archaeology, ZRC SAZU, Ljubljana, Slovenia
[4]Elettra Sincrotrone Trieste, Basovizza, Trieste, Italy
[5]Dept. of Antiquity Sciences 'Leonardo Ferrero', University of Trieste, Italy

During the Neolithic-Copper Age transition, production of polished stone axes in the Caput Adriae (northeastern Italy, central and western Slovenia and northwestern Croatia) underwent a drastic change in terms of raw materials and typology of the artefacts. Shaft-hole axes, mainly produced from meta-dolerites (A), serpentinites (B) and meta-ultramafites (C), became increasingly important in the Copper Age, spreading all over the region. However, the above mentioned rock types do not show a homogeneous distribution. Group A is concentrated in the southern part of Caput Adriae, group B in the northern one, and group C, not yet completely investigated, was unearthed mainly in the Karst and in central Slovenia.

Chemical, mineralogical and textural analyses, by Inductively Coupled Plasma-Mass Spectrometry, X Ray Diffraction, Electron Microprobe Analysis, Synchrotron Radiation Fourier Transform Infrared Spectroscopy, Optical Microscopy, were carried out. The results give evidence of a strong connection between provenance areas of the raw material and main copper mineralizations close to Caput Adriae. In particular, meta-dolerites come from Banija Ophiolite Complex at the northernmost edge of the Central Dinaric Ophiolitic Belt [1], while serpentinites probably originate in the Hohe Tauern area [2].

On the basis of these results, the position of Ljubljansko Barje (central Slovenia) - between eastern Alpine and Balkan copper-rich deposits - could contribute to explaining the importance of this area as metallurgical district at least from IV millennium BC, and, consequently, its important bridging role between Eastern Europe and the Mediterranean.

Finally, a possible source of raw material for the meta-ultramafites has not yet been recognized, even if preliminary indications suggest they could originate in Eastern Austria or Czech Republic.

Archaeometric analysis on limnic quartzite-limnic opalite raw materials and chipped stone tools (Tokaj Mountains, NE-Hungary)

Szekszárdi, A.[1*], Szakmány, Gy.[2] & Biró, T.K.[3]
[1]Dept. of Exploration and Production, MOL Ltd., Budapest, Hungary ([*]aszekszardi@mol.hu)
[2]Dept. of Petrology and Geochemistry, Eötvös Lóránd University of Budapest, Hungary
[3]Dept. of Archaeology, Hungarian National Museum, Budapest, Hungary

Late-Badenian-Sarmatian siliceous sedimentary rocks from limnic basins of the Tokaj Mountains were commonly used for chipped stone tools in prehistory. These rocks have perfect physical and mechanical properties for this purpose. Due to the richness of the raw materials in several outcrops, they were accessible to the inhabitants of the area. Studying these tools helps to understand the history of the culture in this region. These facts demand a basic work to describe the outcrops, identify and characterise the siliceous rock types (generally with petrographic analysis).

The main goals of this study are comparing the limnic-quartzite, limnoopalite raw materials to chipped stone tools made from similar rock types, identifying the sources of the artifacts, extending the range of the technical methods and working out the methodology to identify the outcrops and quarries of the stone tools made of limnic quartzite or limnoopalite. To approach these goals, petrological, geochemical, mineralogical analysis of the artifacts and the possible raw materials were used and the results were compared. Detailed macroscopic and microscopic petrographic descriptions were made. XRF, NAA, PGAA were used as geochemical analysis and XRD, FTIR as mineralogical methods.

There is a clear relationship between raw materials and artifacts studied, according to the results of this study. A quarry could be assigned for most of the artifacts. The knowledge about the sorting method of raw materials for the stone tools was extended. Evidence for the suggestion of sorting parameters (phase/rate of silification, chalcedony content, opaline content) were found.

Petrographic and mineralogical methods were useful to identify the source of the stone tools in the Tokaj Mountains and to extend the technological knowledge (f.e. well thought selection of the raw materials). The geochemical methods should be useful for further exploration comparing more rock samples from the surrounding mountains (Matra Mt., Bükk Foreland, Börzsöny Mt. and Cserhát Mt.).

Different classes of matt-painted pottery from the sanctuary of the archaeological site of "Timpone della Motta" in the Sibaritide area (CS) Calabria – Southern Italy

Andaloro, E.[1*], De Francesco, A.M.[1] & Jacobsen, J.K.[2]
[1]Dipto. di Scienze della Terra, Università della Calabria, Rende, Italy ([*]eliana.andaloro@unical.it)
[2]Groningen Institute of Archaeology, Groningen, Holland

This study presents the comparison between three different classes of Matt-Painted pottery attributed to the 8th century BC from the sanctuary on the Timpone della Motta in the Sibaritide (CS), Calabria – Southern Italy.

Matt-Painted pottery was widely produced in southern Italy during the early Iron Age and finds from many indigenous sites underline that it was one of the favored pottery types both for dining and storage purposes. The term Matt-Painted refers to handmade vessel of typical indigenous shape with applied decoration in a matt dark paint.

Traditional archaeological research divides Matt-painted pottery into a range of regional classes based on the decorative styles of each region. The thousands of fragments from the sanctuary on the Timpone della Motta, together with the finds of Matt-Painted vessels in indigenous graves and houses, show that two predominant styles were present in the Sibaritide. These two styles have been named the "Undulating Band Style" and the "Fringe Style" based on their many decorative elements. In addition, another range of stylistic groups may be observed in the local indigenous pottery production. Recent research has, however, documented a group of Matt-Painted pottery on the Timpone della Motta, which is notably different from all other Matt-Painted vessels on the site. These vessels display a high level of craftsmanship in being very thin-walled and decorated in a miniaturist and very elaborated style. The closest typological and stylistic ceramics are found among the Matt-Painted pottery productions in the southern Salento region, which naturally raises the question if the vessels from the Timpone della Motta were imported from the Salentine area. In that case the fragments from the Timpone della Motta constitute the only example of deliberated export of Salento Matt-Painted pottery.

Twenty nine fragments of Matt-Painted pottery (one sample was misfired) have been submitted to petrographical analysis applying optical microscopye, mineralogical XRD analysis and chemical analysis in XRF with the aim to investigate on different ceramic productions. The results show that the composition of the "Undulating Band Style" and "Fringe Style" fragments is analogous, while is different the composition of the six ceramic fragments with characteristics similar to the Matt-Painted potteries of the southern Salento region.

Another important aim is to clarify possible correspondence between the used raw material and local clay deposits. For this purpose the clay sediments collected around the archaeological site have been submitted to mineralogical analysis in XRD, chemical analysis in XRF and granulometric analysis. The SEM morphological study of the fragments is devoted to the distinction between different workshop techniques.

Analysis of bricks from Brazilian historic places

Asfora,V.K.[1], Barreto, S.B.[2*], Khoury, H.J.[1], Lavalle, H.[3] & Araujo, R.[4]
[1]Dept. of Nuclear Energy, Federal University of Pernambuco, Recife, PE, Brazil
[2]Dept. of Geology, Federal University of Pernambuco, Recife, PE, Brazil ([*]bsandra@ufpe.br)
[3]Dept. of Archeology, Federal University of Pernambuco, Recife, PE, Brazil
[4]Center of Advanced Studies on Integrated Environmental Protection, Olinda-PE, Brazil

This contribution presents results of the qualitative determination of the chemical elements in Brazilian and Dutch bricks found in historic places in the State of Pernambuco, located in the Northeastern Region of Brazil. Seven bricks, two dated in the 17th century (Dutch bricks), one from the 18th century, three from the 19th century, and one from the 20th century, were analyzed by means of energy dispersive X-ray fluorescence (EDXRF) and X-ray powder diffraction (XRD) in order to identify the mineral phases. The XRD results are displayed in Table 1.

Table 1: Mineral phases identified in the brick samples by XRD

Red-brick (Dutch)	Yellow-brick (Dutch)	Building "Convento de Santo Antônio"	Building "Casa de Câmara e Cadeia"	Building "Casa de Câmara e Cadeia" Nº 03
(17th century)	(17th century)	(18th century)	(19th century)	(20th century)
Quartz	Quartz	Quartz	Quartz	Quartz
Kaolinite	Kaolinite	Illite	*	Illite
	Anorthite	Anorthite		Rutile

*evidence of kaolinite with low crystallinity.

To identify possible patterns in the data, the Principal Component (PC) analysis was applied. For each brick, four points were measured by EDXRF. The results illustrate the differences in the composition among the samples, and allow a Fe and Ca based discrimination. Five distinct clusters resulted and they reflect the inter-correlation or covariance degree among few of the principal components, as shown in Fig. 1.

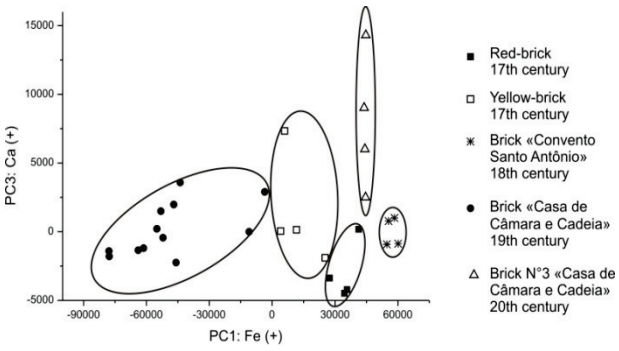

Fig. 1: Principal component analysis based on EDXRF data: PC1: Fe(+) (positive influence) versus PC3 Ca(+) (positive influence).

These results indicate that the bricks were manufactured from different raw materials, i.e. clays, in different times and places.

Microstructure and composition of glaze of Haban ceramics from Sárospatak (NE-Hungary)

Bajnóczi, B.*, Tóth, M. & Nagy, G.
Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary (*bajnoczi@geochem.hu)

Production of tin-glazed ceramics (faience) in Central Europe, thus in the historical Hungary as well, was established by Haban (Anabaptist) potters. In the 16th century Anabaptist ceramists had to emigrate from Switzerland, South Germany and Italy due to religious repression, and they moved to Austria, Moravia and Hungary and in the 17th century to Transylvania and further. They brought their skills and implanted a local pottery production under the influence of their new artistic language.

Notable settlement of Habans in Hungary occurred after 1620. In 1645 one of their groups moved from Moravia to Sárospatak (NE-Hungary) where they lived until 1680. One of the main activities of the settled Habans in Sárospatak was pottery, among others faience production.

Archaeological excavations in the last years revealed a 17th century cannon and bell casting workshop in the yard of the Sárospatak castle. During the excavations fragments of tin-glazed ceramics were found, which were most probably produced by the local Haban workshop.

There are no written sources from the 17th to 18th centuries about the production technology of Haban (tin-glazed) ceramics. Our archaeometric research focuses on the mineralogical, petrographic and geochemical investigation of the ceramic body, the white, tin-opacified glaze and the decorations of different colours, and aims to identify the used raw materials and to reconstruct the production technology.

Preliminary electron microprobe analyses indicate that white glaze of the Sárospatak faiences is lead-alkali type with ~38 wt% PbO, 2.2 to 4.4 wt% SnO_2 and 4.9 to 5.8 wt% K_2O+Na_2O content (according to EDS spot analyses). The opaque glaze layer contains tin oxide particles and aggregates (SnO_2 is present in orthorhombic and tetragonal forms according to X-ray diffraction analysis), and relict grains with Sn-Pb-Si composition. Rounded to subangular quartz and feldspar particles are also present.

Decorations were made by using coloured (yellow, blue, green and black) glazes. Blue decoration is associated with cobalt (0.7 to 1.4 wt% CoO) and contains significant amounts of arsenic, nickel and iron as well (1.6 to 2.1 wt% As_2O_3, up to 1.3 wt% NiO, 1.3 to 1.8 wt% FeO) suggesting use of impure cobalt ore (zaffre). Yellow decoration contains lead antimonite particles ($Pb_2Sb_2O_7$ according to X-ray diffraction analysis) and significant amount of dissolved iron (>3 wt% FeO) is also present in the matrix. Black decoration was prepared by using manganese colorant (>2.5 wt% MnO).

A metabasite shaft-hole axe from Grotta Azzurra di Samatorza (Trieste Karst): first evidence of connections between northeastern Italy and central Europe during Neolithic

Bernardini, F.[1*], De Min, A.[2], Šída, P.[3], Velušček, A.[4], Montagnari Kokelj, E.[5] & Tuniz, C.[1]
[1]The 'Abdus Salam' International Centre for Theoretical Physics, Trieste, Italy (*fbernard@ictp.it)
[2]Dept. of Geosciences, University of Trieste, Trieste, Italy
[3]Institute of Archaeology, Faculty of Arts, University in Hradec Králové and West Bohemian University in Plzeň, Czech Republic
[4]Institute of Archaeology, ZRC SAZU, Ljubljana, Slovenia
[5]Dept. of Antiquity Sciences 'Leonardo Ferrero', University of Trieste, Italy

A fragment of a shaft-hole axe, made from a metabasitic rock, was found in the second half of last century in the Grotta Azzurra di Samatorza in Trieste Karst (northeastern Italy). The artefact, without stratigraphic information, was previously attributed to a general Dinaric origin.

Recently, thanks to the systematic interdisciplinary study of polished stone axes from Caput Adriae (northeastern Italy, central and western Slovenia and northwestern Croatia) [1;2], it has been discovered that the artefact is texturally and mineralogically indistinguishable from the Jizera Mts. fine-grained amphibole-rich metabasites [3]. These rocks belong to Krkonoše-Jizera Crystalline Unit (Bohemian Massif).

This material has been largely employed for the production of polished stone axes during the Neolithic of central Europe [3]. The distribution of the Jizera Mts. raw material includes a wide area - Bohemia, Moravia, western Slovakia, southern Poland, Germany and probably northern Austria and Netherlands.

According to the available data the axe from Grotta Azzurra is the southernmost ever found. It is a rare archaeological proof of early connections between Caput Adriae and central Europe (whose directions still have to be fully understood). This is also testified by a few occurrences of Carpathian obsidians in the Danilo/Vlaška archaeological sites of Caput Adriae.

Analysis of some ancient Roman mortars from Ulpia Traiana Sarmizegetusa (Romania)

Cherata, I.[1*], Mertens, G.[2], Benea, M.[1] & Alicu, D.[3]
[1]Dept. of Geology, Babeş-Bolyai University, Cluj-Napoca, Romania ([*]iulian_cherata@yahoo.com)
[2]Dept. of Earth and Environmental Sciences, Catholic University of Leuven, Belgium
[3]National History Museum of Transylvania, Cluj-Napoca, Romania

Ulpia Traiana Sarmizegetusa was the capital of the Roman province Dacia. The city was founded by the emperor Trajan in the early 2nd century AD, and deserted in 271-274 AD under the rule of emperor Aurelian. At its maximum development, it had over 20,000 inhabitants.

This study focuses on several samples of mortars from different walls and structures (probably a bone-processing workshop, the prison, the pedestal of Trajan's statue and the school of gladiators). In the case of the samples from the recently unearthed bone-processing workshop larger samples of mortar from the walls were collected (up to 7 cm in thickness), where we could observe different layers meant to level the surface of the walls, from the other locations smaller pieces from the outer parts of the walls were selected.

The collected samples were studied by optical microscopy (thin sections), XRD and thermogravimetry.

The mortars have a porphyroclastic texture and in general the aggregate includes 1 to 5 mm-sized lithoclasts, crystalloclasts and ceramoclasts. One notable exception is represented by the mortar from the thick walls of the workshop which additionally contains fragments of ceramics in the centimetric range (up to 3.5 cm in length). The crystalloclasts are mainly represented by calcite, quartz, plagioclase and K-feldspars, muscovite, epidote, magnesiohornblende and pyroxene. Quartz clasts fissured due to thermal shock were identified in some thin sections. Feldspars are frequently transformed into clay minerals and sericite. The whole matrix is carbonatic, with secondary calcite deposited in pores and fissures. The lithic fragments consist of quartzites, micaschists, gneisses and limestones. In one thin section fossil remains could be observed. Two samples contain visible straw and plant remnants.

The ratio between CO_2 and the structurally bound water from the thermogravimetric data suggests that some mortars were of hydraulic type. Others were probably of subhydraulic type: lime was obtained from a purer limestone and therefore the mortar did not yield a hydraulic binder.

According to the identified mineralogical composition we presume that the raw material which was used has a local provenience. The metamorphic material used as aggregate comes from the nearby Retezat Mountains (Southern Carpathians), and is common in the alluvia of small rivers. It was probably extracted from pits. Limestones were most likely quarried 5 km west of the city.

Mineralogical and chemical study of ceramic sherds and clay samples from Cameroon

Epossi Ntah, Z.L[*], Sobott, R. & Bente, K.
IMKM, University of Leipzig, Germany
([*]epossi@uni-leipzig.de)

This work is a contribution to the archaeometry of ceramics from Cameroon. Ceramic sample material together with regional clay material were collected in three regions of Cameroon: Mfomakap-(Central region), Mombal-(Eastern region), and Zamala-(Far North region). The purpose of this work is to find answers to the questions of the provenance of the ceramics (local production, imported ware?) and the production techniques (processing of raw material, moulding of vessels, firing temperature and conditions).

The polarized light microscopy, X-ray diffraction, X-ray fluorescence spectrometry, differential thermal analysis, thermogravimetry, and X-ray computer tomography were used as analytical methods.

The results of thin section analyses show that quartz is always the most abundant component (70-80%) of the temper. Additional minerals are micas, mainly biotite, scarce K-feldspars and very rare plagioclase in Mombal, plagioclase, some K-feldspars and rare biotite in Zamala, hornblende, K-feldspars, biotite and plagioclase in Mfomakap. These mineral combinations suggest that the potter's workshops were situated in a landscape with more or less acidic magmatic rocks.

The mica-flakes and the arrangement and shape of pores in the sherds from the three regions do not show any preferred orientation, as one would expect if the objects had been shaped by means of a potter's wheel. All the ceramic artefacts were probably hand moulded.

The X-ray diffraction analyses of sherds show the presence of quartz, K-feldspars and biotite in all three areas. Additionally, kaolinite is observed in Mombal, hornblende and plagioclase in Mfomakap, and plagioclase in Zamala.

According to the results of X-ray fluorescence analyses of ceramics and raw material, local clay as it comes from the pit was used for making the pottery in Mombal and Zamala. In the case of sherds from Mfomakap the chemical data suggests that the raw material was obtained by mixing two types of clay, one rich in Al_2O_3 and rather low in SiO_2 and the other rich in SiO_2 and rather low in Al_2O_3.

Firing experiments in conjunction with DTA/TG and X-ray diffraction analyses with clays from the three locations showed that kaolinite disappears through an endothermic reaction between 400 and 500°C (onset temperature 470°C), illite breaks down between 900 and 1000°C, and mullite forms in the range of 1000 – 1100°C. Comparing the phase assemblages of the sherds with the phase assemblages of fired clay samples, the firing temperatures were deduced.

In conclusion, the pottery of the three regions seems to be a local production. The firing temperature was always below 900°C. In Mombal the presence of kaolinite in the ceramics indicates a firing temperature below 500°C. In sherds from Mfomakap and Zamala micas are still present and this finding points out to firing temperatures below 900 - 950°C.

Archaeometric study of the Neolithic pottery from the "Le Grottelline" site (Spinazzola, Italy)

Fabbri, B.[*], Gualtieri, S. & Lorenzi, R.
CNR, Institute of Science and Technology for Ceramics, Faenza, Italy ([*]bruno.fabbri@istec.cnr.it)

The archaeological site of "Le Grottelline", in the territory of Spinazzola, province of Bari (Southern Italy), dates back to the ancient Neolithic Age. Abundant ceramic materials were recovered, which mainly belong to the Culture of "Archaic-Impressed Pottery" and appear similar to those found in other Neolithic sites of the area [1].

The archaeologists recognised four ceramic classes: coarse, semi-depurated, depurated and *figulina*, even though in many cases it was difficult to make a clear distinction between them. In fact, coarse and semi-depurated ceramics differ between them only for the dimensions of the inclusions, while depurated ceramics differ from *figulina* mainly due to its macro-porosity. Semi-depurated and coarse ceramics represent the main part of the recovered pottery (about 80%).

Three samples were selected for each of the four classes for the archaeometric investigation, which was carried out mainly by means of optical microscopy in thin section, WDS-X-ray fluorescence, and X-ray diffractometry.

The results individuate two ceramic classes: coarse pottery and fine pottery, and three isolated samples. Coarse pottery is constituted by large silicate inclusions in a fine carbonate-poor clay matrix and includes samples from the archaeological coarse and semi-depurated classes. Fine pottery includes the *figulina* ceramics, together with one 'depurated' sample and one semi-depurated sample, and is characterised by medium calcium contents (10-13% wt CaO). The three isolated samples differ from the previous ones both for the microstructure and the chemical composition. The crystalline phases allow to hypothesize a firing temperature <800°C for the coarse pottery and the isolated samples, and 800 to 900°C for the fine pottery.

Comparing our archaeometric results with those of other Apulian Neolithic sites, great similarities have been registered in particular with pottery from Pulo di Molfetta, considered as local production [2]. On this base, also the main part of the "Le Grottelline" pottery has to be considered as local. In addition, the raw materials show geological features typical of the Murge Plateau that is characterized by the presence of calcareous-arenaceous-argillaceous deposits with frequent fossiliferous levels and shaley marl horizons are present.

The variations in the microstructural and chemical characteristics could be attributed to different collecting areas and/or to the nearness to the Bradanic Hole, in which fine quartz-rich micaceous sands are present.

On the base of all the obtained results, the pottery of "Le Grottelline" site shows the technological characteristics of the Ancient Neolithic productions, that used raw materials not so far from the housing areas, often without purification. The firing process was carried out by means of systems with low-medium temperatures and prevalently oxidant firing atmosphere, even if fluctuations were possible, which are responsible of the chromatic variations of the pieces.

The browning phenomenon of medieval stained glass windows

Ferrand, J.[1], Rossano, S.[1*], Loisel, C.[2], van Hullebusch, E.[1], Orial, G.[2], Bousta, F.[2] & Munoz, M.[3]
[1]LGE, Université Paris-Est Marne-la-Vallée, France ([*]rossano@univ-mlv.fr)
[2]LRMH, Champs sur Marne, France
[3]LGCA, Grenoble, France

Manganese is a chemical element which has long been used as a colouring or a bleaching ingredient in the glass industry. Its existence at various oxidation states is at the origin of a large variety of colours. This latter can evolve according to environmental parameters such as radiations or the atmospheric pollution. In some ancient stained glass windows, the simultaneous presence of manganese and iron, coupled with the alteration by water and micro-organisms, can induce a browning and, consequently, a loss of transparency in stained glass windows.

To better understand this browning phenomenon, ancient stained glass windows displaying a browning are characterized using optical microscopy, SEM-EDS, microprobe analysis and XAS at the Fe *K*-edge. The ancient glasses that present the browning phenomena appear to be potassic glasses and more precisely calco-potassic samples that contain equivalent quantities of CaO and K_2O. In these potassic glasses, the brown zones are very rich in Mn as compared to the fresh glass but also to the altered glass. In parallel, the Mn-oxidizing bacteria (*Burkolderia Cepacia* [1]) present on the historical samples are isolated and cultivated. Finally, simplified model glasses of various compositions but containing the Fe/Mn couple will be altered in presence of these microorganisms.

A petrographical study of lithic tools from Petreşti archaeological site (Romania)

Filipescu, R.* & Benea, M.
Dept. of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania (*roro_fili@yahoo.com)

The present study focuses on ten lithic tools recovered from Petreşti archaeological site, located 4 km south of Sebeş (Southern Carpathians), now in custody of Sebeş Town Museum. The objects belong to the Petreşti Neolithic culture, dated between 2400–2100 B.C. [1] and famous mainly for its painted ceramics. The objects were submitted for a mineralogical-petrographical study, in order to establish the rock types and, furthermore, to identify possible source areas for the raw materials.

Based on the definition of typical functional Neolithic tools (i.e. simple axes, truncheons, fighting axes and hammers [2]), nine samples classify as axe-hammers (according to the criteria defined by Iuliu [3]), and one is a truncheon with three bumps. For the truncheon-shaped one, a decorative purpose is presumed. In order to determine the shape, size and colour of the objects, macroscopical investigations with the naked eye or with a magnifier were carried out. The tools are made of rocks with relatively high hardness. They are very well polished and all but one have similar shape. Predominantly their colours are dark (grey, brown, black), but in three cases lighter hues were observed.

For the optical microscopy investigation, small fragments of the lithic objects were sampled by wet coring with an electrical drill (10 mm in diameter) to a maximum depth of 15 mm, and prepared as thin sections. Mineralogical and petrographical (structure and texture) features were observed by using a Nikon Eclipse E200 Pol microscope with an attached digital camera. A dominant microgranular massive texture was revealed, with local porphyric varieties. One sample has orientated texture. All the three main genetic rock types were used as raw materials (in brackets, number of tools within the group): igneous (diorite, andesite with hornblende and basaltic andesite) (3), metamorphic (sericite-chlorite schist, metapsammite, serpentinite, hornfels with quartz) (5), and sedimentary (chemical precipitation limestone, sandstone with quartz and feldspar) (2).

In order to identify possible sources of raw materials for the investigated lithic objects, the geological structure of the area was studied. According to the geological map, Orăştie sheet (1:200.000), not all the rock types identified as raw materials in this study can be found around Petreşti village. The area is mostly covered with Holocene sediments. Therefore, knowing the petrographic nature of the ten tools, it can only be concluded that most of the raw material (metamorphic and sedimentary rocks) was either transported by Sebeş River, which springs in the Southern Carpathians. Regarding the provenance of the igneous rocks, they could come from the Mureş River alluvia. This river collects similar rocks from the Apuseni Mts. The exact structural units delivering all raw materials have to be further investigated.

Provenance of graphite in Celtic graphitic ceramics from North-west Romania

Havancsák, I.[1*], Bajnóczi, B.[1], Tóth, M.[1] & Németi, J.[2]
[1]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary (*havancsaki@geochem.hu)
[2]Piata Eliberarii Bl. 33. Ap. 41, Carei (SM), Romania

The Celts settled in the Carpathian basin in the 4th century B.C. (Iron Age, La Tène period) from Western Europe. Their expansion took place in two main directions leading to two significant settlement areas: the Transdanubian region, along the Danube towards Serbia as well as the Hungarian Northern Mountains, the North-west Romania and the southern territories [1].

Peculiarity of the Celts was the production of graphitic (i.e. graphite-bearing) situla-type ceramics. Graphitic ceramics are found not only in the close vicinity of the geological occurrences of graphitic rocks, but also on archaeological sites scattered all around Europe, which suggests an extensive trade of graphitic ware or graphitic raw material. Former archaeometric studies [2,3], carried out on Celtic graphitic ceramics from the Transdanubian region, indicated that graphitic rock temper was probably originated from the South Bohemian Massif (from the Variegated unit in the Southern Czech Republic).

The present archaeometric study focuses on graphitic ceramics from several archaeological sites of North-west Romania [4,5] to determine the source (provenance) of the graphitic temper. Vessels investigated derive from 9 localities: Érendréd / Andrid (1), Kálmánd / Căminˇ (2), Börvely / Berveni (3), Piskolt-Kincsverem / Pişcolt-Lutărie (4), Mezőfény / Foieni (5), Bere-Nyúlvár / Berea-Nyúlvár (6), Piskolt-Gárdovány / Pişcolt-Gárdovány (7), Nagykároly-Bobáld / Carei-Bobald (8) and Lázári / Lazuri (9) (Fig. 1).

Fig. 1: Location of the archaeological sites of the studied graphitic ceramics in North-west Romania.

Graphitic rock fragments found in the studied north-west Romanian ceramics consist of graphite, quartz, K-feldspar, plagioclase, kyanite, sillimanite and altered mica. The graphitic rock used as temper for ceramics is medium to high grade metamorphic rock, graphitic paragneiss. Formerly studied graphitic ceramics from the Transdanubian region show similar mineralogical composition [2,3].

Based on metamorphic grade and mineralogical composition, the potential provenance of the graphitic rock fragments is the Variegated Unit in the Moldanubian zone of the Bohemian Massif. Celts in North-west Romania used the same trade network for importation of graphite (graphitic rock) or graphitic ceramics as the Transdanubian population.

Provenance and technology study on a collection of loose garnets from a late 5th century Gepidic grave in Northeast Hungary

Horváth, E.
Inst. of Archaeological Sciences, Dept. of Archaeometry and Archaeological Method, Eötvös Loránd University, Budapest, Hungary (sztr.horvath@gmail.com)

Red gemstones identified mostly as garnets generally occurred in the 5th-6th century Europe as decoration of fine metal works. They are known mainly in mounted form, the loose, unmounted pieces are very rarely found. Therefore, it is of great importance that seventeen such loose red gemstones were unearthed at a rescue excavation at Hajdúnánás-Fürj-Halom-dűlő (Hajdú-Bihar County) in a late 5th century cemetery of the Gepids, an East Germanic tribe settled on the eastern bank of the Tisza River from the late 4th century. The discussed pieces considered as remains in a robbed grave were investigated in order to identify the mineral species, its provenance and the technology of cutting. The lack of any related goldsmith's artefact and the visible different phases of the gem-cutting process allow us to regard them as independent pieces of a collection. The noticed inclusions and the measured refractive index revealed that the discussed gemstones are garnets. In addition to the gemmological observation, the analysis was focussed on the chemical composition. The resulting spectra were obtained by a scanning electron microscope (SEM) equipped with an energy dispersive spectrometer (EDS) and display characteristics of Fe-rich as well as Fe-Mg-rich garnets, i.e. *almandine* and *rhodolite*. The comparison of the concentration ratios of the major constituents with the literature data suggests that while the almandine garnets may have been imported from Rajasthan, North India, the rhodolite garnets may have been mined in Sri Lanka [1]. The image analysis based on optical and scanning electron microscopy clearly showed traces left by polishing and shaping. All of the six flat cabochons and seven of the flat plates look like semi-finished products where final steps of shaping were not carried out. Besides, the other four plates may be regarded as finished products with regular shapes. In some cases intentionally engraved outlines were noticed running along the edges. These straight shallow grooves were interpreted as an indirect proof for the use of a template or a sort of pointed marker. Based on our observations, the cutting process could be reconstructed, and the following steps were inferred: 1) cutting the raw surfaces to the desired steepness and thickness; 2) polishing these surfaces on the top and base; 3) designing the shape and size of the prepared pieces by a marker (occasionally) and finally 4) cutting off or breaking the unnecessary edges. Considering the semi-finished pieces characterized by irregular edges, the final steps of their shaping were apparently carried out in a satellite or local workshop. This observation contributes to the recurring debate about the character of imported garnets [2]. The discussed findings suggest that in the Early Middle Ages garnets for inlays were traded in the Carpathian Basin both in pre-cut and ready-to-set form. While mounts and cell walls usually make the accurate observation difficult, the loose character of these pieces permitted us to perform an extensive investigation focussing both on the raw material and the technology. Results may clarify or identify the geographical origin as well as the applied equipment and the organisational aspects of gem-cutting.

Mineralogy and geochemistry of Bronze Age potsherds: weathering influence of a Mediterranean climate (Cres Island, Croatia)

Ilijanić, N.[1*], Miko, S.[1], Hasan, O.[1] & Posilović, H.[2]
[1]Croatian Geological Survey, Zagreb, Croatia
([*]nikolina.ilijanic@hgi-cgs.hr)
[2]Geological Dept., Faculty of Science, University of Zagreb, Croatia

The aim of this study was to study the causes of well preserved status of potsherds in Bronze Age hill forts on Cres island (Northern Adriatic Sea) exposed to Mediterranean climate and their buried equivalents in colluvial deposits. The island of Cres has a long history of settlement and hosts some very important Mesolithic, Neolithic and Bronze Age sites. Due to erosion large areas are bare karst lacking soil cover and prehistoric potsherds can be found in stonewalls of hill forts or caves.

The potsherds were analyzed by microscopy methods as well as geochemistry to study the weathering process in both exposed and buried potsherds. The colluvial soil containing potsherds was dated and a calibrated ^{14}C AMS date ranging from 2030 to 1870 BC was obtained. Under the optical microscope, the potsherds are texturally homogeneous and display inclusions of similar type, abundance, and grain size. XRD analyses show that they contain quartz and calcite as dominant mineral phases, and fewer amounts of micas and feldspars (K-feldspar and plagioclase).

The enrichment of Ca in exposed potsherd rims is accompanied by depletion of light REE's and enrichment of heavy REE's. The results show that potsherds exposed to the Mediterranean climate for four thousand years have an improved durability due to calcite re-crystallization and notable change in the chemical composition of potsherd rims which have to be considered when using bulk geochemistry for provenance studies.

Mineralogical investigations of clay-bricks from Árpád-age (11th-14th century A.D.), southern Hungary

Kristály, F.[1*], Rózsa, P.[2] & Kelemen, É.[2]
[1]Institute of Mineralogy and Petrology, University of Miskolc Hungary ([*]askkf@uni-miskolc.hu)
[2]Dept. of Mineralogy and Geology, University of Debrecen, Hungary

During the so-called "Árpád age" (11th-14th century A.D.) clay-bricks were a common building material in the southern region of The Great Hungarian Plain (Szeged-Békéscsaba region). In the area, it was mainly the local production that provided bricks for churches and monasteries.

Brick samples from nine archaeological sites (churches and monasteries from the Great Hungarian Plain), now in the custody of "Munkácsy Mihály" Museum of Békéscsaba, were selected for the study. Representative specimens were obtained by sectioning and weight reduction of samples. Optical and Scanning Electron Microscopy, Electron Microprobe and X-Ray Powder Diffraction (XRPD) investigations were used to determine the mineralogical composition of samples, and to constrain the firing temperature.

Although the archaeological sites are closely located, for the purpose of comparison between different groups of sites, the samples were separated in four groups: I. Örménykút (Ö)-Décse (D), II. Kamuth (K)-Megyer (Me)-Gerla (Ge), III. Gyula (Gy) and IV. Bánkút (B).

The mineralogical composition of all brick samples is highly similar and points to illitic clays. The abundant use of vegetal tempering materials (wheat chaff) in most of the studied bricks is characteristic. The presence of dolomite is only observed in one of the Örménykút samples.

Several neoformation phases due to firing, such as K-feldspars (anorthoclase–sanidine), anorthite, gehlenite, diopside were detected (Fig. 1).

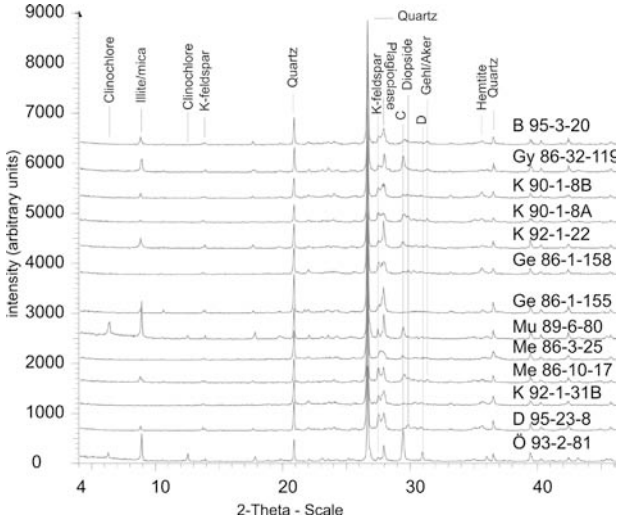

Fig. 1: XRPD diagrams of the investigated samples (Cu-Kα radiation).

The mineralogical composition of primary components, as well as the newly-formed phases upon firing, suggests the use of similar raw materials, i.e. Ca-rich illitic clays.

The type and amount of firing phases indicate temperatures in a range of 900-950°C. Only one sample from the group II shows a lower firing temperature, around 850°C.

The mechanism of thermal decomposition of dolomite and its implications in pyrotechnology: new insights from 2D-XRD and TEM analyses

Kudlacz, K, Ruiz-Agudo, E., Arizzi, A., Rodriguez-Navarro, A. & Rodriguez-Navarro, C.[*]
Dept. Mineralogía y Petrología, Universidad de Granada, Spain ([*]carlosrn@ugr.es)

Dolomite has been thoroughly used for ceramic and building purposes (e.g., dolomitic lime mortars) since ancient times. Pyrotechnology of dolomite ($CaMg(CO_3)_2$) involves its thermal decomposition into CaO and MgO. This process, called calcination, influences the physicochemical properties of dolomitic limes and affects the textural properties of dolomite-based ceramic materials. Although the thermal decomposition of dolomite has been studied for more than one century, the mechanisms of this reaction still remain obscure.

Here, single crystals of dolomite were calcined in air atmosphere at a *T* range of 500°C-1100°C, and analyzed by XRD, 2D-XRD, FESEM and TEM. Decomposition was also studied in-situ, by the TEM, by irradiating dolomite crystals with the electron beam. The decomposition is pseudomorphic and topotactic, and results in oriented CaO and MgO ((Ca,Mg)O) nanocrystals, which aggregate and grow as *T* increases. In-situ TEM shows that the first step of decomposition involves the formation of a face centred cubic (Mg,Ca)O mixed oxide, with the following orientation relationships: $[-441]_{dolomite}//[001]_{oxide}$ and $(110)_{dolomite}//(110)_{oxide}$ (Fig. 1). 2D-XRD results are consistent with in-situ TEM results, and show the presence of highly oriented oxides in the dolomite pseudomorph. Unlike the case of the in-situ TEM decomposition, the range of (Ca,Mg)O solid solution is very limited (up to 8%) and only occurs at low *T* (500°C – 750°C). A further *T* increase leads to the formation of oriented, pure CaO and MgO nanocrystals. In air, thermally activated ion diffusion favours de-mixing (spinodal decomposition) of the initial (Ca,Mg)O phase as *T* increases. Conversely, "cold" in-situ TEM decomposition prevents de-mixing of the initial (Ca,Mg)O.

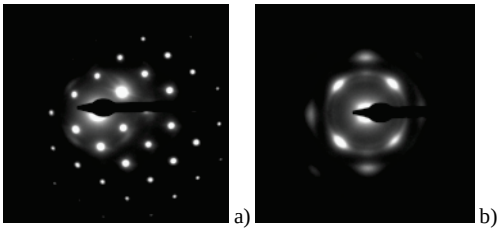

Fig 1: Selected area electron diffraction (SAED) images before decomposition of (a) dolomite ([-441] zone axis), and after its decomposition into (b) a mixed Ca-Mg oxide ([001] zone axis).

These results show that the thermal decomposition of dolomite involves its direct transformation into a mixed Ca and Mg oxide (at low *T*), and subsequent separation into two oxides (spinodal demixing) with increasing *T*. The reaction is topotactic and independent of pCO_2. Formation of $CaCO_3$ during the so called "half decomposition" of dolomite was observed in some runs. However, either calcite or vaterite formed. The fact that vaterite has no structural relationship with dolomite suggests that previous models based on the transformation of dolomite into $CaCO_3$ plus MgO (i.e., "half decomposition" of dolomite) are flawed. Apparently, $CaCO_3$ formed during re-carbonation of highly reactive CaO nanocrystals. This solves the problem of the so-called "two-stage" decomposition of dolomite. These results may help in constraining processing parameters (e.g., calcination *T*) in ancient dolomite-based ceramics, and may also help defining appropriate processing parameters during preparation of modern dolomitic lime-based conservation mortars.

The raw materials and manufacture of pottery during Bronze Age-Early Iron Age in the North-Western Russia

Kulkova, M.A.[1*], Yushkova, M.A.[2] & Subetto, D.A.[1]
[1]Herzen State Pedagogical University, St Petersburg, Russia
([*]kulkova@mail.ru)
[2]Institute for the History of Material Culture, Russian Academy of Sciences, St Petersburg, Russia

The ceramic artifacts are the main material which can be used for reconstruction of prehistoric people life and different cultural traditions. Numerous settlements of Bronze Age – Early Iron age (2000 cal. BC – 500 cal. AD) were excavated in the area of basin of Volkhov River basin (Shkurina Gorka, Porogi sites:800cal BC-400 cal.BC, Kholopii Gorodok site: 800cal.BC-500cal AD); Ilmen Lake (Prost' site: 800calBC-400 cal.AD, Gorodok na Lovati site: 10cal.AD-500cal.AD, Sel'tco site: 800calBC-400cal. AD); Ladoga Lake (Ust'-Ribezgna II site: 2000cal.BC-1500cal.BC), located in the North-Western Russia. It is one of the perspective regions of archaeological works on the North-Western of Russia in the present time. The main problem is the chronology and cultural attribute of different sites and their connection with sources of raw materials.

The investigation of pottery included a complex approach. To determine the cultural and historical belonging of ceramics the archaeological methods (typology and morphology) were applied. The mineralogical and geochemical methods (optical microscopy, XRD, thermal analysis, XRF) were used for the determination of the ceramic composition, the manufacturing technology and the sources of row material (more than 70 samples of ceramic sherds and 16 samples of clay raw material).

Based on both the mineralogical composition and geochemistry of ceramic material and the archaeological typology, a number of ceramic type groups were distinguished. The ceramics of Bronze Age (Ust'Ribegna II site) consist of montmorillonite clay and disintegrated plant remains; the estimated firing temperature was about 650°C. The ceramics of Volkhov type (Shkurina Gorka, Porogi, Prost', Kholopii Gorodok, Sel'tco sites) consist of kaolinite-illite clay, crushed gravel of granite-plagioclase composition and grog; the estimated firing temperature was around 500-700°C. The Iron Age ceramics (Kholopii Gorodok, Gorodok na Lovati sites) consist of illite clay and a temper made of crushed granite-plagiogranite gravel; a firing temperature around 800°C could be infered. These characteristics give possibilities for identification the ceramics from different settlements and chronological periods.

The changes of environmental conditions about 1500 cal. BC (Ladoga Lake transgression) most likely influenced the prehistoric people life. The flood on Ust'Ribegna II site was one of the reasons of that the population has left this place and changes the raw material sources for pottery produced in this and successive periods.

Characterization of earthen building materials from a Phoenician site, Malaga (Spain)

López–Arce, P.[*], Gómez-Villalba, L.S. & Fort, R.
Group of Applied Petrology to Heritage Conservation,
Instituto de Geología Económica (CSIC-UCM), Madrid, Spain
([*]plopezar@geo.ucm.es)

Earthen building materials, adobe walls and pavements, were characterized to determine the materials composition and constructive techniques from a Phoenician site. Clay samples from the surroundings were also studied, to identify the raw materials used in their manufacture. X-ray diffraction, polarized light optical and environmental scanning electron microscopy (ESEM) with energy dispersive X-ray spectroscopy was used to study the composition. Mercury intrusion porosimetry was performed to obtain the total porosity and pore size distribution.

Adobe samples display a calcareous clay composition, with different proportion of clay minerals (27-39 wt%), quartz (21-45 wt%) and Ca and Mg carbonates (calcite 17-47 wt% and dolomite 2-11 wt%). Filosilicates are mainly kaolinite (24-34 wt%), smectite (31-46 wt%) and illite (20-45 wt%). Barium sulphate, various phosphates, iron oxides and hydroxides, bioclasts, pyrite, zircon and lithic fragments (Fig. 1) are also present. Iron oxides and iron hydroxides provides red and yellow colours.

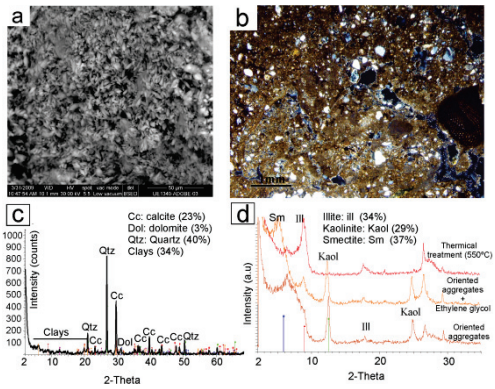

Fig. 1: Characterization of adobe. a) ESEM image; b) Polarized light microscopy image; crossed nicols; c) XRD of bulk sample; d) XRD of clay fraction.

Clay samples are very similar to the earthen materials and they could have been used as raw materials mixed with clays and sands from other geological sources (continental, fluvial and marine). The natural presence of roots and stems of plants, the cementation reactions of carbonates and silicates and intentional addition of grog (ceramic fragments) and organic materials in the clay paste could have improved the natural properties of the ceramic paste. Clays from the earthen pavement display white-yellow color (due to carbonate and hydrated iron hydroxides) being probably selected with aesthetic purposes. Difference in porosity between adobe and clay samples indicates compaction of the clays, with the consequent reduction in porosity and decrease in the pore sizes.

Understanding earthen construction methods and raw material selection has significant implications for understanding either the selection of settlement sites or the labour required to build in specific settings not directly adjacent to suitable raw materials [1]. These studies provide new insights to the knowledge of Phoenician construction techniques, since there are few or no other references available.

The building materials of Koule Castle, Heraklion, Crete (Greece)

Markopoulos, Th., Repouskou, E.* & Karampatsou, G.
Dept. of Mineral Resources Engineering, Technical University of Crete, Chania, Greece (*repusku@mred.tuc.gr)

This work is a primary study of the architectural elements and corresponding building materials of the Koule Castle in Heraklion, Crete (Greece). The characterization of the building materials of a historic structure is a necessary part of a conservation study.

Eighteen core samples of rocks and masonry mortars have been extracted by the 13th Municipality of Byzantine Antiquities from different parts of the monument, in order to determine their physical and technical characteristics as well as their deterioration state. Their morphological characteristics, granulometry, specific weight, water absorption index, compressive strength, as well as the mineralogical composition and the included fossils species have been determined.

The building stones of Koule Castle are sedimentary rocks, excavated nearby and in the island Dia. In their majority, they are biomicritic breccias and limestone conglomerates and bioclastic limestones with various marine fossils. In particular, the north monumental part is built of Triassic limestones, breccias and coarse conglomerates. Biomicritic breccia limestones show the highest strength values and lower water absorption index compared with the bioclastic limestones.

The old mortars have been studied by optical microscopy, X-ray diffraction (XRD) and scanning electron microscopy. Their examination revealed that beach sand has been used as inert material.

In some representative old mortars particle size analysis by wet sieving was carried out, in order to determine the nature of their constituents and evaluate the inert to binder material ratio. These data are necessary for simulation - reproduction of these materials used for restoration. The sum of the 2 mm - 0.125 mm fractions is regarded as inert material, whereas the material finer than 0.125 mm is regarded as the binder [1].

At least three types of mortars were identified and considered as the construction mortars during the different construction- reconstruction periods. Their basic mineralogical components are: calcite, portlandite, brucite, magnesite, dolomite, quartz and plagioclase. The presence of calcite in the binder of the studied mortars is a result of the carbonation of lime. The presence of portlandite and brucite is probably associated with the absence of adequate carbon dioxide in the interior parts and at the lower parts of the castle surrounded by sea, thus prohibiting the formation of calcite and magnesium carbonate correspondingly. Furthermore, the presence of both portlandite and brucite indicate the use of dolomites and Mg-rich limestones for the binder production.

Production and distribution centers of Serra-d'Alto-style pottery (4th millennium BC) in southeastern Italy

Marrese, G.[1*], Tucci, P.[2], Coppola, D.[3] & Lezzerini, M.[4]
[1]Centro di Ricerca per le Scienze Applicate alla Protezione dell'Ambiente e dei Beni Culturali, Sapienza Università, Rome, Italy (*giovannamarrese@live.it)
[2]Dipto. di Scienze della Terra, Sapienza Università, Rome, Italy
[3]Dipto. di Storia dell'Antichità, Università degli Studi di Bari Aldo Moro, Bari, Italy
[4]Dipto. di Scienze della Terra, Università degli Studi di Pisa, Italy

The Serra d'Alto pottery is a pot production occurring in southern Italy during the 4th millennium BC [1]. The use of depurated clays and firing temperatures around 700-800°C [2] suggest the presence of advanced ceramic technology, where the thin solid walls and the medium-to-large size of the products offer pictorial support to complex painted decorations [2]. These are black, and characterized mainly by spiral to meandrous motives with symbolic meaning. The Serra d'Alto style ceramic production coincides with a period of significant changes overall southern Italy, especially Apulia. The change to a hot-arid climate developed during the 4th millennium brings with itself the collapse of village agricultural civilization and the development of mobile communities of shepherds invading internal areas to find new pastures. Pottery is found in both cultural areas, thus not only in the villages, where it was presumably produced (need of depurated clays and appropriate ovens etc.), but also in internal sites such as caves. This testifies changes in the economy that involve population mobility and distribution of artifacts to mobile communities [3].

The archeometric study of a series of samples allows to define the production centers of Serra d'Altro ceramics and to follow the commercial distribution along the transhumance ways used by the ancient shepherds [4]. Together with the distribution of marine shell, the Serra d'Alto ceramics represents the oldest testimony of an exchange economy in Neolithic Italy. During the study, we evaluated technological aspects such as firing temperature, production and preparation of clay support, decoration and refining, all data indicating the state of art reached by the Neolithic workers [5,6]. The ceramic objects have been analyzed by OM and XRD for the minero-petrographic characteristics and by XRF and EDS/WDS for the chemistry. Moreover, a sampling of clays located near the ceramic production centers has been undertaken to establish a relationships between occurrence of the artifacts and local geology. The locating of clay extraction areas bears importance in reconstruction of the economic evolution in the 4th millennium BC.

Mineralogical and geochemical study of coloured and white marbles from Spain and Portugal in the provenancing of some marble artefacts from *Thamusida* (Kenitra, Morocco)

Origlia, F.[1], Turbanti Memmi, I.[1*], Spangenberg, J.[2], Gliozzo, E.[1] & Meccheri, M.[1]
[1]Dipto. Scienze della Terra, Università di Siena, Italy ([*]memmi@unisi.it)
[2]Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland

First results of an archaeometric study carried out in order to asses the provenance of marble artefacts from *Thamusida* (Kenitra, Morocco) have shown that local raw material exploitation was very rare. Most of the archaeological artefacts come from classical marble areas (Greece, Turkey, Italy), but not all the Mediterranean sources were successfully determined. Considering the possibility of a commercial exchange between Mauretania Tingitana and Betic and/or Lusitanian Roman Provinces, we focused our study on various types of marbles from those regions. Here, we present the results of a minero-petrographical and geochemical study on some of these marbles. The data obtained, combined with those already available from literature, represent a reliable basis for comparison with the undetermined artefacts. The marbles were collected from the Ossa Morena zone, including the Estremoz anticline (Spain-Portugal), and from Malaga and Almeria districts in the Betic chain (Spain). The specimens were investigated by XRD to detect the carbonate mineral type as well as by geochemical analyses to determine the carbon and oxygen stable isotope composition. OM observation and SEM-EDS analysis were carried out only on a representative selection of samples to find out the main textural features and the accessory mineral contents. We distinguished calcitic and dolomitic marble varieties. Dolomitic marbles mainly belong to Malaga district, but are sporadically present in other Spanish marble deposits.

The accessory minerals are quartz, plagioclase, muscovite/illite, phlogopite, Fe-Mg chlorite and tremolite (Viana do Alentejo, Almaden de la Plata), apatite, Fe and Ti oxides, titanite and Fe-sulphide. Dolomitic marbles usually have a scarce accessory mineral content, consisting of quartz and calcite. The geochemical data were reported in two different $\delta^{13}C$-$\delta^{18}O$ diagrams for Ossa Morena and Betic chain marbles. The isotopic values of Ossa Morena quarries overlap, mainly in the ranges $\delta^{18}O$: -9 and -5‰ VPDB and $\delta^{13}C$: 0.5 and 3‰ VPDB. The isotopic values of betic marbles fall in the range $\delta^{18}O$: -8.83 and 0.27‰ VPDB and δ^{13} C: 1.26 and 4.28‰ VPDB.

A preliminary comparison between the artefacts and the studied materials provided interesting results. The Malaga provenance seems highly probable; the Estremoz or Ossa Morena Almaden de la Plata quarry provenances are still uncertain. More analyses are needed to address the open questions and clarify the development of the commercial exchanges between Spain, Portugal and Morocco during Roman times.

Major element composition of Transylvanian gold: can it be used for archaeological provenance studies?

Pop, D.[1*], Ionescu, C.[2], Benea, M.[2], Tămaş, C.[2] & Forray, F.[2]
[1]Museum of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania ([*]dana.pop@ubbcluj.ro)
[2]Dept. of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania

Transylvanian gold is related to both epithermal ore deposits and their associated placer deposits in the Southern Apuseni Mountains (Romania). The primary deposits were formed during the Neogene volcanic event. Tens of economically-important ore deposits are concentrated in an area of about 900 km^2 known as the "Gold Quadrilateral" - a major source of gold for Europe throughout history. According to historical records, gold mining in Transylvania spans over more than 3,000 years. Between 1500–2000 t of gold were estimated to have been extracted in the Apuseni Mountains since prehistory [1].

Archaeological provenance studies are generally based on comparing the composition of the artefacts with that of the potential raw materials. No general consensus was reached yet concerning the most reliable correlation factors in the case of gold. As a first approach, we chose major elements chemistry and electron microprobe (EMP) measurements. Eight samples from the collection of the Museum of Mineralogy, Babeş-Bolyai University were selected: five samples from Roşia Montană (RM) (Fig. 1) and three from other historically-significant deposits: Trestia (T), Musariu (Mu), and Măgura (Ma). RM deposit is hosted by dacites, while the others by andesites [2].

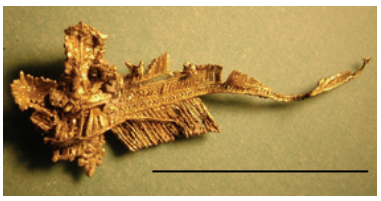

Fig. 1: Dendritic gold crystals from Roşia Montană, one of the IMA2010 logos (scale bar: 1 mm).

Au, Ag, Te and Cu contents have been measured. Based on 164 point EMP analyses, three compositional groups were outlined: a) low- (RM), b) medium- (RM, Mu, Ma), and c) high-Ag content (RM). Mineralogically, only the first group can be defined as gold, the other two are electrum (the full range of fineness is 577 to 875). For all groups, the same trend could be observed: whereas the Ag content is constant, Te (0.06–0.2 wt.%) and Cu (<0.02 wt.%) substitute Au. RM gold shows a remarkable compositional variability, ranging from $Au_{0.43}Ag_{0.57}$ to $Au_{0.79}Ag_{0.21}$. Thus, samples with the same origin plot into different groups, while those originating from different deposits plot in the same narrow compositional field (b).

Summarizing, the major elements in gold cannot be used for chemical fingerprinting, but EMP proved to be suitable for deciphering chemical mechanisms at micrometer scale. However, for gold provenance studies, hierarchical cluster analyses on larger sets of data for major, as well as trace elements and isotopes studies are required.

Acknowledgements: The study was supported by ID-2241 project funds (Romanian Ministry of Education).

Mineralogical-geochemical characteristics of the mammal skeletal remains from the selected archaeological sites in Poland

Rogoz, A. & Sawlowicz, Z.*
Institute of Geological Sciences, Jagiellonian University, Krakow, Poland (*zbigniew.sawlowicz@uj.edu.pl)

We have studied bones and teeth of woolly mammoths (*Mammuthus primigenius*) from the site Spadzista Street (B) in Krakow and bones of cave bears (*Ursus spelaeus)* from two caves (Bisnik and Nietoperzowa) in Southern Poland. The materials were studied using SEM-BSE, XRD, and FTIR methods. Samples from Spadzista Street and Biśnik are quite well preserved, in contrast to Nietoperzowa cave where only fragments of bones few centimetres long were found. In scanning electron microscope their histological structures (osteons, bone trabeculae, enamel prisms, dentine canaliculi) are easily seen. The studied skeletal remains are built of carbonate-rich apatite-(CaOH). The crystallinity indexes (calculated after Person et al. [1]) are rather low: 0.03-1.14 in woolly mammoth samples, 0.1-0.21 and 0.02-0.15 in cave bear samples from Biśnik and Nietoperzowa caves, respectively. Only in enamel the crystallinity indexes were much higher: 0.67-0.78 in woolly mammoth and 0.95 in cave bear samples. The typical range of Ca/P mole ratios of fresh bones is 1.59-1.67 [2]. The average ratios, calculated from EDS analyses of the studied samples, are different: mammoth bones - 1.92, cave bear bones from Biśnik and Nietoperzowa caves - 1.73 and 1.23, respectively. The higher values can be caused by replacement of PO_4^{3-} groups by CO_3^{2} and/or enrichment in Ca^{2+} ions which is not surprising because of common presence of calcite in those bones. The lower values can result from a decrease of CO_3^{2-} in apatite, which is one of the common diagenetic processes [3]. There are some differences in secondary minerals infillings between cave bears and woolly mammoth remains. In the bear bones Haversian canals are usually not infilled with minerals, only occasionally calcite is present. Fe-Mn (hydroxy)oxides coat or infill both the osteocyte lacunae and the dentine canaliculi. In addition, in the bones from Nietoperzowa Cave manganese is sometimes present in a form of dendrites. In the woolly mammoth remains Haversian canals, bone trabeculae and cracks are commonly infilled with calcite or carbonate sediment. The dentine canaliculi are coated or infilled with secondary apatite. The Fe-Mn (hydroxy)oxides are present occasionally in osteocyte lacunae. It is worth to note that in woolly mammoth bones the bacterial alterations were found. In some samples they are very common, whereas in the cave bear bones we have not found any microbial changes. It seems that differences between studied bones are caused by different burial environment.

Iron age pottery from Garvão votive site (SW Iberia) – an interdisciplinary study

Rosado, L.[1], Candeias, A.E.[1], Schiavon, N.[2*], Lopes, M.C.[3], Mayet, F.[3], Tavares, D.[4], Alfenin, R.[3,4] & Mirao, J.[2]
[1]HERCULES Laboratory and Chemistry Centre of Evora, University of Évora, Portugal
[2]HERCULES Laboratory and Geophysics Centre of Evora, University of Évora, Portugal (*schiavon@uevora.pt)
[3]University of Coimbra, CEAUCP, Coimbra, Portugal
[4]Alentejo Regional Directorate of Culture, Evora, Portugal

The Iberian Peninsula was a highly sought after area in ancient times due to its abundance in geological resources. Hence, the Iberian Iron Age was a period of successive social and political transformations, sometimes resulting in conflicts. These began with the earliest Celtic invasions (or migrations) that imposed a strong continental influence in Iberia against the oriental inspired societies like the Tartessos kingdom. The movement of these populations toward south is constant throughout the entire period. Simultaneously, the Semitic civilizations (i.e. Phoenician and Punic) control was maintained in south Iberia through the presence of autonomous cities with strong commercial and cultural connections to the Mediterranean. This political framework was broken in 218 AC by Romans disembark in the context of the second Punic war.

In this general context, at around 200 AC, Garvão probably belonged to the Conii territory corresponding to the current SW Portugal or "Baixo Alentejo" and the western Algarve. It is believed that this region, although inhabited by populations of Celtic origin, was characterized by a very strong Mediterranean cultural influence. It seems that Garvão was an important Iron Age II holy site where an impressive votive deposit was discovered. The materials recovered (mainly pottery) were intentionally deposited, carefully arranged in order to optimize the available space.

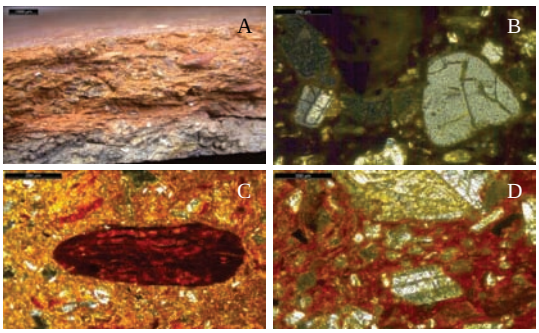

Fig. 1: Iron-age Garvão pottery. (A) Chromatic heterogeneity in cross section. (B) OM micrograph NX. Plagioclase and rounded quartz in black matrix, (C) OM Micrograph NX. Ceramic fragment. (D) OM Micrograph NX. plagioclase in red matrix.

A detailed study of the pottery based on stylistic analysis was carried out allowing the classification into different clusters. As the ceramics mineralogical and chemical composition depends also on technological know-how and social environmental parameters, a combined analytical approach was adopted to characterize the pottery samples by means of Optical (OM) and Electron microscopy (SEM + EDS), Fourier Transform Infrared Spectroscopy (FT-IR) and X-ray Diffraction (XRD). The combination of these techniques applied to selected Gãrvao pottery allowed the recognition of the ceramic phase composition, firing temperature, kiln atmosphere, ceramic manufacturing processes and origin of raw materials.

The chemical and mineralogical results suggest that the Gãrvao region was characterised by strong connections both with Mediterranean as well as with local production areas reflecting its role in ancient times as a rich and important multicultural centre.

On the use of Earth Materials in SW Iberia mortars – an historical perspective

Santos Silva, A.[1], Adriano, P.[1], Cruz, T.[2], Veiga, R.[1], Candeias, A.E.[3] & Mirao, J.[2*]
[1]National Laboratory of Civil Engineering, Lisbon, Portugal
[2]HERCULES Laboratory and Geophysics Center of Evora, University of Évora, Portugal ([*]jmirao@uevora.pt)
[3]HERCULES Laboratory and Chemistry Center of Evora University of Évora, Portugal

Traditional and historic mortars are composite materials consisting of a binder (usually lime or hydraulic lime), aggregates (quartz sand, calcite or dolomite) and some additives (e.g. brick dust, volcanic ash) in order to increase adherence, workability, strength and durability [1]. The characterization of mortars allows the identification of their phase and chemical compositions and the characteristic features related to the physical properties. Moreover, sometimes it is possible to identify the alteration products and, in some cases, establish the provenance of materials used in the manufacture of mortars [2].

Thus, the study of the ancient mortars composition, using techniques of chemical, mineralogical and microstructural characterization, plays a major role in the preservation of cultural heritage, guiding all actions for the conservation and restoration. On the other hand, it gives a very deep knowledge about the techniques of construction, previous repairs and their performance. This type of information is likely to be historically integrated, contributing to the knowledge of the societies that constructed the buildings.

The similarity between traditional mortars and sedimentary clastic rocks are evident (Fig. 1). In both, it is possible to figure out cement that sustains together the clasts (in sedimentary rocks) or the aggregates (in mortars). Nevertheless important differences are obvious. Additives are frequently present in order to get better mechanical properties and the very alkaline environments during the merging of the lime and the aggregates cause frequently the partial dissolution of quartz aggregates.

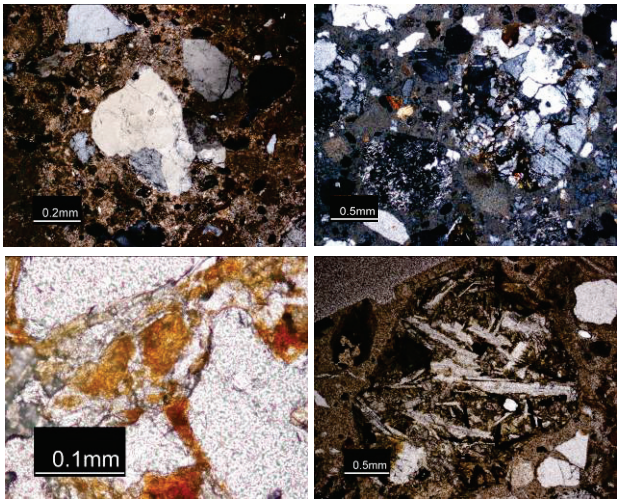

Fig. 1: Microphotos of Southwest Iberia ancient mortars. A-Concufate villa (Roman), B-Evora (Medieval), C- Elvas (16th century), D-Lisbon (18th century). A, B – crossed polarizers; C, D – one polarizer.

Methods like XRD, TGA, optical microscopy, SEM-EDS and chemical analyses techniques are currently employed. The results can be assigned to the society's capability to manage technology and to access and select raw materials. Over the past few years research applied to roman, Islamic and medieval mortars will be revisited and an evolutionary trend to the use of earth materials in SW Iberia mortars will be presented.

Rock crystal artefacts and determination of their provenance

Slobodník, M.[*] & Přichystal, A.
Institute of Geological sciences, Masaryk University, Brno, Czech Republic ([*]marek@sci.muni.cz)

In Central Europe, there are numerous archaeological sites from which chipped rock crystal artefacts are known. The raw material is commonly considered of Alpine region provenance. However other possible sources could be mentioned in other areas (Fig. 1). The most important places are located in the Bohemian Massif, especially in the Moravian Moldanubicum (Sklené – Rousměrov SE of Žďár nad Sázavou and the vicinity of Brtnice), and there are proofs of their prehistoric exploitation. Another source area becomes evident in the Silesicum (Jegłowa near Strzelin, Žulová). We record also rock crystal sources in the Austrian Moldanubicum or within Lower Carboniferous rocks in N Moravia (Bílovec) [1].

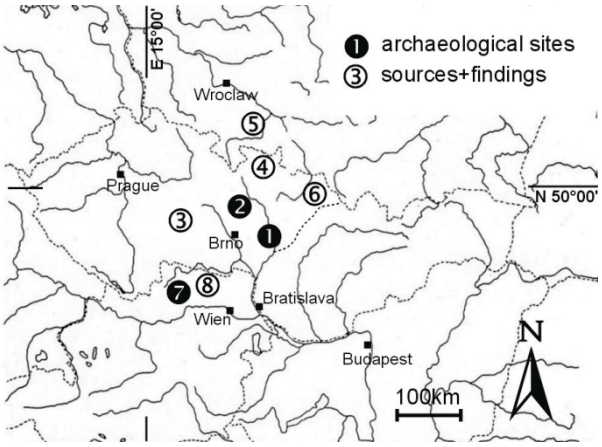

Fig. 1: The major occurrences of rock crystal sources and findings of artefacts. Sites: 1 – Nová Dědina, 2 – Žitného cave, 3 – Sklené, Brtnice (Moldanubicum area), 4 – Žulová area, 5 – Jeglowa, 6 – Bílovec, 7 – Gudenushöhle, 8 – Nödersdorf.

Microthermometry, Raman spectrometry and some other techniques have been applied on material from the Paleolithic (Aurignacian) site Nová Dědina (ND, no. 1 in Fig. 1) where several hundreds of rock crystal chips have been discovered and compared to the mentioned sources. The used methods, based on the investigation of fluid inclusions, can be considered as a model for progress in further research.

Fluid inclusions (FI) represent defects (cavities) in crystal lattice, being filled with liquids (L), gases (V), and solids (S). Trapped and sealed parental fluids in primary inclusions are regarded as isochoric systems telling story on genetic conditions at particular places. If we are able to decipher the genetic information from the fluid inclusions of the "lost" material (with unknown provenance) we have a chance to find the site of origin. The most important petrographic aspects have been revealed within FI assemblage from ND. Two types of 3-phase inclusions L+V+S1+S2 and L1+L2+V and their fluid properties enable to exclude the sources from the Alps, Silesicum and northern Moravia. Fluids nature coincides well with sources from Moldanubicum with pegmatite signature.

The used combination of genetic parameters, both from natural sources and archaeological sites, is a very sensitive methodological approach how to select and define the provenance of rock crystal raw material.

Acknowledgements: Our investigation has been supported by the research project MSM0021622427 and grant Kontakt 6-06-11.

Pietra ollare artefacts from Červar Porat (Istria, Croatia): composition and possible origin

Tibljaš, D.[1*], Balen, D.[1], Šimić-Kanaet, Z.[2] & Girardi Jurkić, V.[3]
[1]Inst. for Mineralogy and Petrology, Dept. of Geology, Faculty of Science, Zagreb, Croatia ([*]dtibljas@geol.pmf.hr)
[2]Dept of Archaeology, Faculty of Philosophy, Zagreb, Croatia
[3]International Research Centre for Archaeology, Medulin, Croatia

During archaeological excavations performed between 1976 and 1980 at a Roman villa rustica in Červar-Porat located close to the town Poreč (Istria peninsula, Croatia), among other Late Antique period fragments (glass, metal, ceramics), fourteen peculiar stone vessel fragments were discovered. They show characteristic tracks of the manufacturing by means of lathe. Vessels made by analogous processes from similar materials have already been found at several localities at Croatian Adriatic coast, but no systematic mineralogical study on this kind of material was performed so far.

Two of these vessel fragments were recently investigated in more detail by mineralogical methods. The first one (inv. no. 7912) is greenish-grey in colour (Fig. 1). X-ray powder diffraction revealed that the only constituent of this fragment is a chlorite group mineral. The mineral composition together with visible schistosity indicates that source material was chlorite-schist, a low–grade metamorphic rock. Such material is one of different lithologies included by Italian term *pietra ollare* and German *Lavez*.

The other fragment (inv. no. 7907) is dark greenish-grey on the fresh broken surface and brownish on outer and inner vessel surfaces. Distinctive bronze coloured flakes can be seen in some parts. The fact that XRD pattern of the second fragment was similar to the XRD pattern recorded on the material from the first fragment after heating to 1100ºC indicate that the second vessel was most probably used for cooking, and during that process it was exposed to elevated temperatures.

Fig. 1: Vessel fragment (inv. no. 7912), 8 cm wide, showing tracks of manufacturing by means of lathe.

In order to determine possible origin of analysed fragments their mineral and chemical composition was compared with those recorded for samples collected in Valle d'Aosta and Valli di Lanzo (north-western Italy) and literature data for *pietra ollare* originating from other localities in Italian Alps.

Mineralogical and experimental study by FTIR of archaic ceramics from Amathous (Cyprus)

Ventalon, S.[1*], Daniel, F.[2], Fröhlich, F.[3], Fourrier, S.[4] & Dubois, M.[5]
[1]GEOSYSTEMES, FRE 3298, Université Lille 1, Lille, France ([*]sandra.ventalon@univ-lille1.fr)
[2]CRPAA, UMR 5060, Université de Bordeaux 3, Bordeaux, France
[3]Centre de spectroscopie infrarouge, Muséum national d'Histoire naturelle, Paris, France
[4]HISOMA, UMR 5189, Lyon, France
[5]LGCgE, EA4515, Université Lille 1, Lille, France

Many ceramics of the archaic period have been found in the archaeological Amathous site, southern Cyprus (Fig. 1). Previous studies on these ceramics indicated a good agreement between chemical analysis and the typo-chronological classification [1]. However a geological survey and an experimental study were required in order to complete these data. The aim was to localize sources of raw materials (clay and temper) and to understand the manufacturing methods, especially firing processes.

The infrared spectroscopy and X-ray diffraction have been used to characterize 44 materials sampled around Amathous, 10 ceramics fragments and the results of firing experiments.

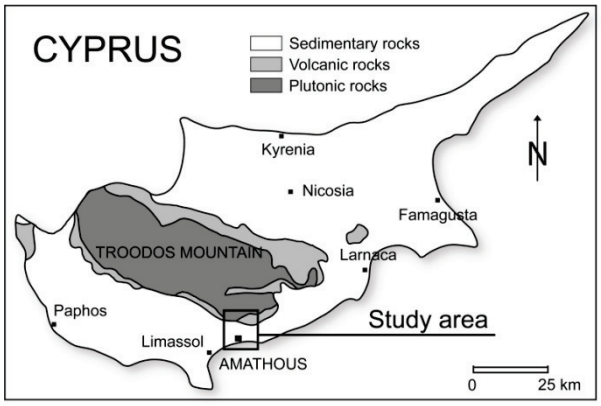

Fig. 1: Study area location within Cyprus territory

The Cretaceous marine clay ("Moni formation") and the black basaltic sand from the beach west of Amathous (used as temper) were identified as the source of raw materials. In addition, firing experiments show that ceramics were fired at 650°C (Fig. 2). The red-fabric pithoi ceramics were made from the same materials but firing temperatures are higher than 650°C.

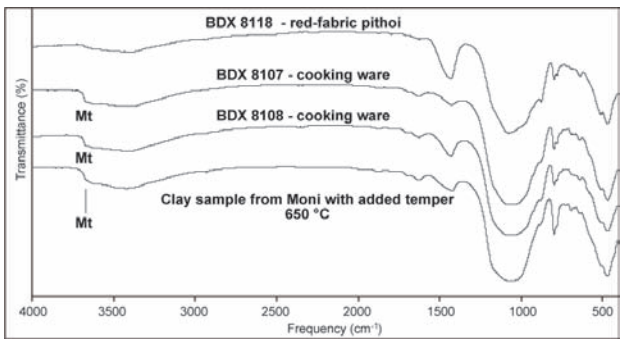

Fig. 2: Cooking ware and red-fabric pithoi spectra. Comparison with the spectra obtained through experimental firing of raw material samples.

Characterization and provenance of building stone from Notre-Dame-de-Grâce, Sérignan (southern France)

Ventalon, S.[1*], De la Boisse, H.[2], Raynaud, S.[2], Mazeran, F.[3] & Dubois, M.[4]
[1]GEOSYSTEMES, FRE 3298, Université Lille 1, Lille, France ([*]sandra.ventalon@univ-lille1.fr)
[2]Equipe Pierres et Monuments, Université Montpellier 2, Montpellier, France ([*]boisse@gm.univ-montp2.fr)
[3]Service du Patrimoine, Conseil général de l'Hérault, France
[4]LGCgE, EA4515, Université Lille 1, Lille, France

The restoration project of Notre-Dame de Grâce church (Sérignan, southern France, Fig. 1) was accompanied by a detailed study of the building materials. The aim was to characterize the various lithologies, their repartition on the frontage (linked or not with reconstructions and restorations) and their origin. Some substitution materials were also sought.

Fig. 1: Notre-Dame de Grâce: photography and plan (© Cabinet D. Larpin).

The macroscopic and microscopic investigation of 25 samples from the edifice permitted to characterize 5 different stone types: 1) bioclastic limestone, 2) sandy limestone, 3) Ostrea-bearing limestone, 4) red-algae-bearing limestone and 5) fine-grained limestone. All these materials were formed in the carbonate shelf during Miocene.

The (1), (2) and (3) limestones correspond to the most voluminous monument blocks and have a local origin. They are found in old quarries around Sérignan and Béziers (Fig. 2). The (4) and (5) types were respectively used for mullions of the church windows and for the four pillars of the western frontage. This two rock types originate in the still exploited quarries of Beaulieu (4) and Fonvieille (5) (Fig. 2).

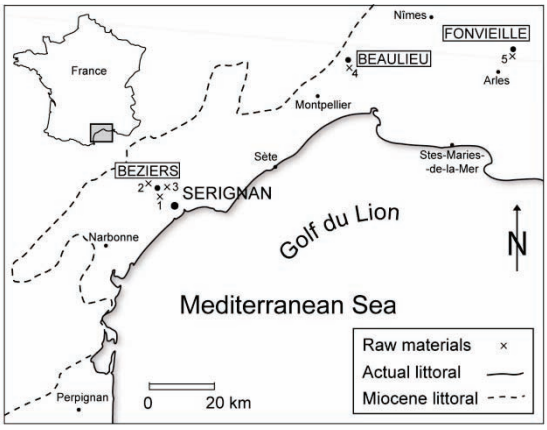

Fig. 2: Source of building materials used for Notre-Dame-de-Grâce, Sérignan. The insert in upper left shows the position of the map within France territory.

Traditional earthen building materials in the Western Himalayas

Wimmer-Frey, I.[1*], Peresson, M.[1], Gruber, M.[2] & Krist, G.[2]
[1]Geological Survey of Austria, Vienna, Austria ([*]i.wimmer-frey@geologie.ac.at)
[2]University of Applied Arts, Vienna, Austria

The Tibetan mountain village of Nako in the Indian Western Himalayas houses a Buddhist monastery temple complex dating from the 11th - 12th centuries, which reflects both significant aspects of Tibetan artistic and cultural history as well earthen building traditions. Within the "Nako Project" dedicated to saving the endangered temple buildings, the "Scientific study of the Artwork at Nako, India", funded by the Austrian Science Fund (FWF), addresses local clay raw materials used for the historic temple structures and in recent local building practice. The soils THAWA, TUA and SASSA make up the building materials, the adobe, joint mortars and plasters, as well as the supports of the sculptures in the four temples.

THAWA, meaning "earth" in local Bhoti language, consists mainly of poorly sorted, gravel- and sand-sized detritus derived from granitoids of the High Himalaya crystalline. THAWA has a yellowish brownish colour. The clay content, and thus its plastic component, is low. It is composed of quartz, K-feldspar, albite and abundant mica. The mineralogical composition suggests a granitic parent rock. The predominant clay minerals of the fraction < 2 µm are illite/muscovite and chlorite, both of detrital origin. Small amounts of kaolinite and traces of vermiculite occur. The plasticity index is low, the shear strength is rather high.

TUA is most likely a fine-grained deposit of a glacial lake. It is light grey in colour. The silt- and clay-content of TUA is high, which gives better plasticity properties, also expressed by a higher plasticity index. The bulk rock mineralogy consists of calcite, quartz, mica, chlorite and little feldspar. The clay mineral assemblage of illite/muscovite, chlorite and low amounts of kaolinite is very similar to THAWA.

SASSA is a greenish white, well-compacted, unstratified deposit, resembling a till. Similar portions of gravel, sand, silt and smaller amounts of clay produce extremely poorly sorted sediment. Varying amounts of dolomite, calcite, amphiboles and pyroxenes are the main constituents of the bulk mineralogy. Besides illite and kaolinite in traces, the predominant clay minerals are a mixed layered smectite/chlorite and/or a smectite. SASSA shows the highest plasticity index and the lowest shear strength of the three types.

Adobe, joint mortars, plasters, and sculpture supports show similar grain size distributions and similar mineralogical compositions. They consist of a mixture of THAWA and TUA and plot along a line indicating a mixing ratio of 4:1, which is still used as a recipe for plastering, passing on the tradition of the old building history of the temples. Additionally, fibres deriving from plants, animal hair and skin, ash, as well as proteinaceous binding materials were found admixed to the local soils in order to improve the strength and plastic qualities of the historic building and support materials. The use of organic additives correlates with Buddhist literature sources. SASSA, nowadays used as water resistant coating for indoor walls, was detected only in one case of a later sculpture repair.

Raman spectroscopic study of ancient potteries in Thailand: Wiangkalong pottery samples

Won-in, K.[1], Pongkrapan, S.[1], Dararutana, P.[1,2], Thawornmongkolkij, M.[3] & Wathanakul, P.[1,3*]
[1]Dept. of Earth Sciences, Faculty of Science, Kasetsart University, Bangkok, Thailand ([*]fscipww@ku.ac.th)
[2]The Royal Thai Army Chemical Dept., Bangkok, Thailand
[3]The Gem and Jewelry Institute of Thailand

The aim of this work is to explore the potential of Raman spectroscopy in assessing the chemistry and mineralogy of ancient potteries from Wiangkalong, a major ceramic-production city in northern Thailand, once colonized by the ancient Lanna Kingdom (1296 AD). Potteries from such locality were produced with shapes and designs resembled those of the Chinese Yuan and Ming Dynasties. Fragments of the pottery samples from Wiangkalong were analysed for the first time. Characterizations of clay minerals were also carried out using X-ray diffractometer and scanning electron microscope equipped with energy dispersive X-ray fluorescence spectrometer. These instruments in combination have been proved to be useful in archaeological science research.

The experiment results showed the peculiar components of ancient ceramic bodies. As for an example, the result of corresponding Raman spectra probed at specific areas on a fragment of an ancient bowl showed different absorption patterns (Fig. 1). This reflects the differences in matrix compositions, both chemically and mineralogically, of the areas measured. The research results based on instrumentations mentioned above showed that the body matrix mineralogy of the Wiangkalong potteries is highly heterogeneous, suggesting the presence of large variety of minerals and trace elements in the clay, as well as the variable conditions of firing control.

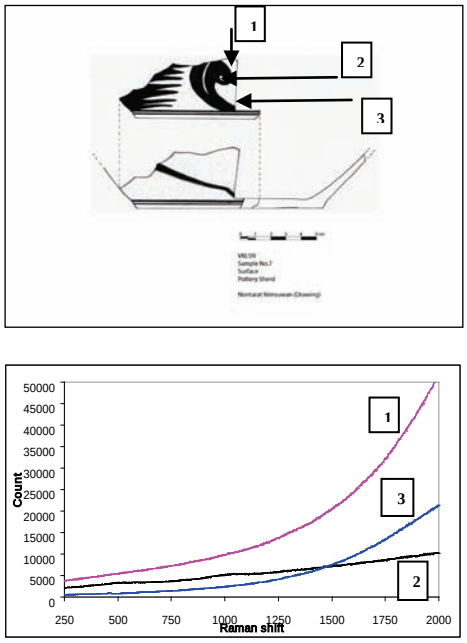

Fig. 1: Wiangkalong pottery fragment (upper image), and the Raman spectra corresponding to the specific areas pointed as 1, 2, and 3, which are the enamel, the flower muster, and the matrix respectively (lower image).

Implications of phase transitions on fire-generated decay of building granites

Gomez-Heras, M.[1,2*], Gomez-Villalba, L.S.[2] & Fort, R.[2]
[1]Depto Petrología y Geoquímica, Universidad Complutense de Madrid, Spain ([*]mgh@geo.ucm.es)
[2]Instituto de Geología Económica (CSIC-UCM), Madrid, Spain

Fire stands out among building stone decay agents because it generates irreversible disruptions, with long-lasting effects, in a very short period of time [1]. In the past few years, research on fire decay of building stone has drifted from mere observations of bulk changes after fires to focus mainly on mineralogical-scale processes as a key for understanding the larger scale decay effects of fire on stone.

This paper focuses on the effects of high temperature on building granites to show the key role of mineralogical phase transitions in the development of decay forms (such as cracking) during fires and in the long-term behaviour (through the modification of argilization patterns) of granites after a fire.

To achieve this, a series of experimental techniques with novel approaches, such as Environmental Scanning Electron Microscope (ESEM) with heating stage and X-Ray diffraction (also with heating stage) were used. These were combined to Transmission Electron Microscopy – Electron Diffractometry for mineral characterization before and after heating.

Additional studies were made to characterize changes in reactivity of feldspar after being heated and the relations between feldspar phase transitions and the increase of argilization observed in the burnt areas of building granites affected by historical fires [2].

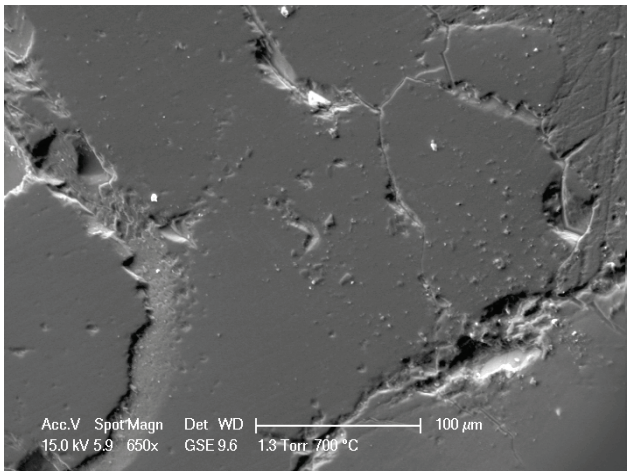

Fig. 1: ESEM image of quartz at 700ºC showing the cracking generated by the α–β quartz transition.

Results show that α–β quartz transition at 573ºC is the main process involved in the generation of cracking during both heating and cooling of granite. Together with this, the amount of defects in feldspar lattice changes during heating. The interaction of these deffects generate strains that contribute to exarcebate grain boundary disruptions, in addition to promoting textural changes in the feldspar that may be related to an increase of reactivity and contribute to the modification of argilization rates in the long term, as observed in samples of building granites undergoing historical fires.

Mineralogical indicators of the magnitude of sandstone decay on Scottish buildings

Duthie, L.[1*], Lee, M.R.[1], Phoenix, V.[1], Kennedy, C.[2] & Hyslop, E.[3]
[1]Dept. of Geographical & Earth Sciences, University of Glasgow, UK ([*]duthie@ges.gla.ac.uk)
[2]Historic Scotland, Edinburgh, UK
[3]British Geological Survey, Edinburgh, UK

Here we have asked how decay mechanisms and rates can be evaluated using the mineralogy, chemical composition and molecular structure of detrital and diagenetic minerals present within Scottish sandstones. This is important because to treat and conserve stone-built historic monuments, we have to understand the full depth and range of mineralogical change within the material. At what stage is the decay, are all minerals present suffering, or has only one mineral been affected?

The buildings of south-west Scotland (in particular City of Glasgow) have suffered much weathering in the 150-200 years since construction due to the cold wet climate and past industrial pollution. The main rock forming minerals within these blond Carboniferous sandstones are detrital quartz, Or-rich alkali feldspar and mica, with diagenetic kaolinite, quartz, ankerite and iron oxides. One key indicator of the magnitude of weathering is dissolution of ankerite cement, which sometimes leaves a skeletal iron oxide pseudomorph. These effects have been detected to a depth of 10 mm in a variety of sandstone samples.

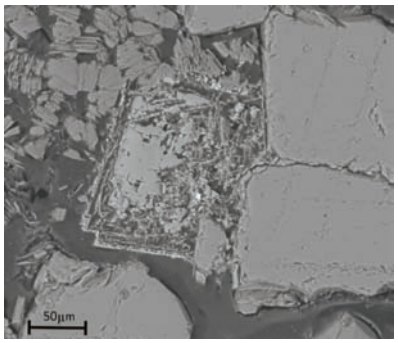

Fig. 1: SEM image of partially weathered ankerite.

Not all of the Glasgow sandstones have a carbonate cement, therefore other minerals have to be explored to help identify the full weathering profile. For example, the movement of iron oxides, mobilised from depth and reprecipitated close to the surface, has long been associated with Scottish stone decay [1], and we have explored whether Raman spectroscopy can be used to distinguish these different generations of oxides. Using Fourier transform infra-red spectroscopy, [2] concluded that during weathering of sandstones from Sydney, Australia, the original kaolinite had become unstable and polymorphs had formed within the weathered section. Using Raman spectroscopy we hope to identify these subtle alterations of the clay structure to pinpoint the depth to which weathering has penetrated. The sheet structure of mica means it may also be sensitive to weathering and may show different levels of alteration.

Our preliminary results confirm that these sandstones have been structurally weathered by decay and that different minerals have the potential to track these changes.

Composition of limestone weathering crust and associated dust in samples from urban and rural areas of Germany and Hungary

Török, Á.[1*], Licha, T.[2], Simon, K.[3] & Siegesmund, S.[4]
[1]Dept. of Construction Materials and Engineering Geology, Budapest University of Technology and Economics, Budapest, Hungary ([*]torokakos@mail.bme.hu)
[2]Dept. of Applied Geology, Geoscience Center, Göttingen, Germany
[3]Dept. of Geochemistry, Geoscience Center, Göttingen, Germany
[4]Dept. of Structural Geology, Geoscience Center, Göttingen, Germany

The weathering mechanism of limestone monuments located in urban, industrial and rural areas were studied. Black weathering crusts, settling dust and host limestone samples were collected in Hungary and Germany at 13 sites. Micro-fabric (microscopy, SEM), mineralogical composition (XRD) and trace element distribution (LA-ICPMS) were analyzed to understand the contribution of dust to the formation of weathering crusts.

The morphology of weathering crusts are very similar in urban and rural areas, meanwhile the micro-fabric rather reflects the morphology than the location (urban or rural). Laminar and dendritic black crusts have been found in both countries in urban, in industrial and in rural areas. Gypsum is the primary reaction product at the limestone/air pollutant interaction surface with different concentrations at urban and rural sites. Both weathering crusts and the dust found at urban sites are enriched in gypsum.

In dust samples siliceous fly-ash particles are more common, than carbonaceous ones in both countries indicating the longer term stability of these particles. Mineral fragments in dust are abundant and their composition represents the geology of the background area. Gypsum crystal aggregates were also identified within dust samples indicating the rapid sulphation process. Lead mostly accumulates in dust, but also in the black crust. According to LA-ICPMS analyses the highest lead concentrations were found not on the surface of the black crust but close to the crust/limestone boundary especially in the samples, which were collected from urban areas of Budapest and Cologne. As expected, lower levels of lead were found in samples of rural areas, having higher concentrations in the black crusts and lower ones in the host rock

The present study suggests that both settling dust and black crust samples collected from limestone buildings could be used as environmental indicators of past and recent pollution levels.

The role of calcium phosphates in calcium oxalate patinas

Vazquez-Calvo, C.[1*], Alvarez de Buergo, M.[1], Fort, R.[1] & de los Ríos, A.[2]
[1]Instituto de Geología Económica (CSIC-UCM), Madrid, Spain ([*]carmenvazquez@geo.ucm.es)
[2]Instituto de Recursos Naturales (CCMA, CSIC), Madrid, Spain

The calcium oxalate patinas found on historical monuments have long been studied [1-3]. On occasion, they have been associated with calcium phosphates. While some authors attribute the compound substantial or relative importance, others fail to mention its presence, perhaps because the methods used are not the most suitable for its detection.

The present study introduces a re-assessment of the presence of calcium phosphate in calcium oxalate patinas, as well as of calcium phosphate patinas in which no calcium oxalate was detected [4]. A number of hypotheses and theories about the origin of these patinas are discussed. The most suitable methods for identifying calcium phosphate are described, along with their drawbacks and the drawbacks to other methods. Recent reports of calcium phosphates on Spanish monuments [5,6] are compared to earlier findings and the possible origin of this compound is discussed. A classification of patinas based on their phosphorous content and characteristics is also put forward. Finally, a new nomenclature is proposed.

SO_2 exposure effect in monumental granitic stones

Vázquez, P.* & Alonso, F.J.
Dept. Petrología y Geoquímica, Universidad de Oviedo, Spain
(*pvazquez@geol.uniovi.es)

Granites are very durable materials. When they are placed in a building, their surface is exposed to a wide range of weathering agents, among which, pollution must be remarked [1]. SO_2 exposure may affect Ca-minerals such as plagioclase, or produce Fe-minerals oxidations [2].

Four granites (two grey and two pink granites) commonly used as ornamental stone all along the world, were exposed to SO_2 action. This test was carried out following the standard UNE-EN 13919:2003 but with some modifications. The test was divided into two parts, one for macroscopic evaluation with slabs to measure surface properties (colour, gloss and roughness), and another with smaller specimens for microscopic evaluation and chemical analysis. Both tests were carried out with different temperatures (20º and 60ºC) and concentrations of the solutions (150 and 350 ml of H_2SO_3 for 500 ml of total solution).

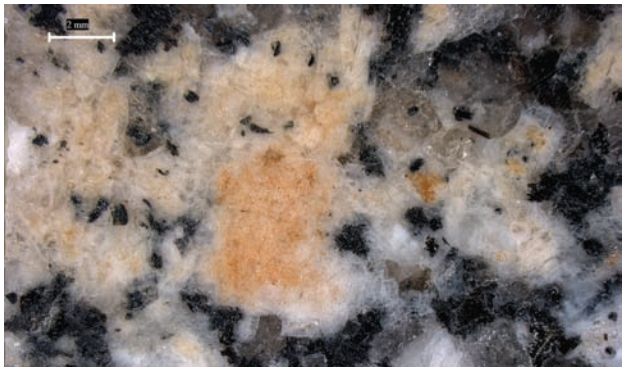

Fig. 1: Detail of plagioclase after SO2 exposure. The orange colour is due to Fe oxidation.

After three weeks of SO_2 exposure, changes in colour, gloss and roughness are measured. Colour changes are very remarkable in grey granites, showing a homogeneous yellowing, which is more intensive with higher temperature. Even orange spots may be observed on some slabs. Pink granites show and increase of red and yellow colours in the measurements, nevertheless with naked eye the variations are not very evident. Gloss exhibits a decrease in all the granites about 30% in relation to original values. Roughness shows an increase in peaks, due to the mica detachment. This effect is more evident in grey granites at low temperature, and in pink granites at high temperature.

The main characteristics found by microscopic evaluation are that there are a lot of crystal habits in all the tested specimens, but they are more developed in low temperature tests (at 20ºC gypsum crystals are rather prismatic and at 60ºC rather acicular). Crystals do not appear in all minerals equally, they tend to crystallise in Ca rich minerals or in those with higher relief. There are crystals with a lot of impurities not showing the typical gypsum habit.

Engineering properties and problems of rocks used in historical monuments: Tyana Aqueducts case, Nigde/Turkey

Korkanç, M.[1*] & Tuğrul, A.[2]
[1]Geological Engineering Dept., Nigde University, Nigde, Turkey (*mkorkanc@nigde.edu.tr)
[2]Geological Engineering Dept., Istanbul University, Avcılar-Istanbul, Turkey

There are many historical monuments constructed from past to present by different civilizations in Nigde region located in Central Anatolia. Tyana aqueducts as a continuation of the Roma Pool are one of these historical monuments. The aqueducts that carry the antique Roma Pool's water to Tynana thought to have been made by the Roman Emperors Trajan and Hadriyen. 1.5 km part of approximately 3 km long aqueducts is apparent, the rest of it is under ground and it is useless. In historical monuments determination of engineering properties of the rocks used is very important in terms of conservation of these historical monuments and transmitting these buildings to the next generations. In this study, the rock type, deterioration occured in the stone, the problems originated from the selection and use of stone was evaluated. In aqueducts travertines were used as a building block. Due to different textural properties five different block samples were complied. Laboratory studies were performed to determine the mineralogical, petrographic and geomechanical in the collected samples. To identify the mineralogical properties of travertines XRD analysis were performed. Petrographic properties of travertines were determined on thin sections using polarizing microscope. To determine the geomechanical properties of travertines dry and saturated unit weight, water absorption, effective porozity, stability index against dissolution in water, P- wave velocity and uniaxial compressive strength experiments were conducted. Moreover, Schmidt hammer hardness measurements were performed on site with the different levels and different textural characteristics of the belts on the travertines. The samples with fine-grained, massive-textured and low porous properties were found to show relatively higher strength values according to the experimental data obtained from these samples. In most of travertines used, the weathering effects are very low. In destruction of Tyana aqueducts, beside the human effects, selection of small sized stone dimensions (especially the sones used in belts as a keystone) and the stone usage from the same quarry but showing different and bad features are thought to be effective.

Stones for a monument: geological aspects of the rehabilitation of the Cuyahoga County Soldiers" and Sailors" Monument in Cleveland, Ohio, USA

Hannibal, J.[*] & Saja, D.B.
Cleveland Museum of Natural History, Cleveland, Ohio, U.S.A.
([*]hannibal@cmnh.org)

We have been involved with multiple geologically-related aspects of the rehabilitation of the interior of the Cuyahoga County Soldiers' and Sailors' Monument, a splendid 1894 Victorian Monument located in downtown Cleveland, Ohio. This has included identification of various stone types based on observations of in-situ stone, microscopic examination of broken pieces, and, in the case of marble, thin-section examination. We also conducted investigations of bowed slabs of marble inside the monument and we evaluated the latex product used in cleaning marble inside the monument. In addition, we researched archival and historical sources for information on the stone used for the monument, finding a key article that confirmed that most of the white marble had been colored and this led to its re-coloration. Our investigation of bowed marble and our observations related to the cleaning and coloring of the stone have been reported elsewhere. We here summarize these findings and provide additional observations and conclusions.

White marble used inside the monument is from Carrara or is a stone very similar to Carrara. Some of it was stained yellow, and before cleaning resembled Siena Marble. We identified a dark gray, crinoidal limestone used as trim inside the monument as one of the Belgian "marbles" or a stone very similar to the Belgian stone. Some of this had to be replaced, but an easily obtained black "granite" was used instead of limestone. The original gray trim had been stained black and was re-colored black, so the two stone types cannot be easily distinguished.

The latex product sprayed onto the stone as a cleaning agent did work effectively for the most part. Solidified latex pulled from the marble was analyzed using an environmental Scanning Electron Microscope. These samples showed grains of calcite attached to the latex as well as grains of Ca- and S-rich material, probably calcium sulfate. The sulfur-rich material was fuzzy-globular to bladed when seen with the microscope. It is likely that this material (probably gypsum) formed sometime in the history of the monument due to a chemical reaction of the calcium carbonate with acidic water or air. The sulfation of marble is well documented for the exteriors of buildings, but not interiors. Veining in the marble may have facilitated the movement of water through the stone.

The multiple facets of our work on the monument show that it is useful to have geologists involved with all stages of restoration projects that involve stone. Our work on the interior of this building also has broader implications as it shows that the same type of problems (bending of marble slabs; the formation of sulfur minerals) that are widely known to occur on the exterior of buildings may also occur within buildings.

Mineralogical and textural changes in historical lime mortars

López-Buendía, A.M.[1*], Rodriguez-Guanter, M.J.[1] & Urquiola, M.M.[2]
[1]AIDICO, Paterna, Valencia, Spain ([*]angel.lopez@aidico.es)
[2]Dept. Geologia, Universitat de València, Spain

Historical lime mortar suffers mineralogical and textural modifications since they are mixed and placed in the buildings. Carbonatation of lime produces calcite as stable mineral although other unstable carbonate mineral phases can also appear during the process of hardening to form a hard binder. In normal conditions, carbonatation is produced from external to internal section of the mortar. The transformation is not stable along the history of the building and the mortar suffers changes of dissolution and crystallization that are affected mainly by the water availability (humidity, capillarity, rain) and hydrodynamic in the mortar microstructure and environment.

Some studied core drill sections of mortars from historical buildings were selected and characterized with and X-ray diffraction and microscopy, having different concentration calcite and products of alteration along the section. Calcite from lime was identified also by X-ray diffraction with a high crystallinity and purity, compared with aggregates. The methodology can determine changes of the calcite binder along the mortar profile, indicating the dynamic of calcite dissolution and precipitation with internal dissolution domain to external precipitation. A sub-zone of dissolution also appears showing 2 cm of affected depth. The mechanical result is an external hard crust with high concentration of calcite and an internal part with a week wall mortar of a low content of a new precipitated generation of zoned calcite. This model is quite general and affect as much to the mortar of ashlars as the blocks masonry. This phenomenon affects mainly to the aerial lime mortar, but has been also detected in hydraulic lime and the stone.

Gypsum is generally assumed than is related with alteration of calcite in presence of pollution with high sulphur content. The results suggest that gypsum formation has been made from the calcium and bicarbonate rich water rather than the alteration of calcite directly.

A model of mineral mobilising in a masonry wall with lime-based mortar is proposed, as well as the degree of mechanical effect that this calcite dissolution and precipitation can produce into the building structure.

Removal of salts from clay rich and porous sandstones by sepiolite poultices

Herrero Fernández, H.[1,3], García-Talegón, J.[2,3*] & Iñigo, A.C.[1,3]
[1]Instituto de Recursos Naturales y Agrobiologia de Salamanca, CSIC, Salamanca, Spain
[2]Depto. de Geología, Universidad de Salamanca, Spain (*talegon@uasl.es)
[3]Unidad Asociada "Química del Estado Sólido" Universidad de Salamanca / IRNASA-CSIC, Spain

The effectiveness of the sepiolite poultices has been carried out for the extraction of salts (Cl^-, NO^-_3, $SO^=_4$) in clay rich and porous sandstones [1,2]. One of the most important decay processes in the monuments is salt crystallization. The aim in this study is to reproduce in the laboratory the situations usually found in practice in altered stones for which conservation desalting is recommended. Three varieties of Villamayor Sandstone, employed in the monuments of Salamanca (World Heritage City, NW of Spain) have been selected [3]. The Villamayor sandstone is an arkosic stone whose skeleton comprises grains of microcline, plagioclase and quartz, involved into palygorskite and illite/mica [4]. The varieties selected are: i) VAC: fine-grained, microporous, is partially cemented by dolomite, 27% (bulk porosity), ii) VF: ochre and fine-grained, microporous, with smectite, 30% (bulk porosity), iii) VHN: medium-grained, 38% (bulk porosity) [5].

Blocks 5x5x5 cm in size were studied and salts precipitated inside following the Vicente and Vicente-Tavera method [6]. The salt-extraction process is carried out by the consecutive application of three poultices of sepiolite. For every application, the samples were introduced in closed boxes of 7 cm of edge, completely submerged in the poultice during three days. The paste was removed and was performed following the Iñigo et al method [7].

The order of salt removal in the first extraction was according to the mineralogy of the phyllosilicates in each selected varieties, and porosity. Thus, the VHN variety (Fig. 1) was able to extract more anions (without smectite and highly porous), then the VF (smectite and medium porosity) and later on the VAC (contains dolomite and less porosity). The retention of the ions (Cl^-, NO^-_3, $SO^=_4$) for the phyllosilicates is higher than the poultice of sepiolite (agent to removal). This is explained because the skills of retention of anions are great in the dolomite than in the smectite.

Acknowledgements: Authors thank financial support from JCYL (SA024A07) and MCYT (CGL2007-62168).

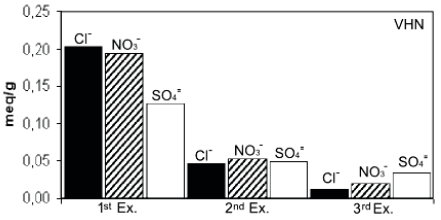

Fig. 1: Results of the analysis after the three extractions treatments on the Villamayor sandstone variety (VHN).

Mineralogy and micro-fabric of Hungarian building stones used in historic constructions at Székesfehérvár Ruin Garden (Hungary)

Theodoridou, M.[1,2*] & Török, Á.[3]
[1]Dept. of Petrology and Geochemistry, Eötvös Loránd University, Budapest, Hungary
[2]Dept. of Civil and Environmental Engineering, University of Cyprus, Nicosia, Cyprus (*mtheodo@ucy.ac.cy)
[3]Dept. of Construction Materials and Engineering Geology, Budapest University of Technology and Economics, Budapest, Hungary

Mineralogical characterization of the building materials provides valuable information on their use and provenance. Additionally, by analyzing mineralogical composition and micro-fabric alteration processes and possible changes related to former conservation actions are detected. Mineralogical studies are also crucial from the point of view of archaeology and art history since it gives us a picture of the construction methodologies followed in the past. At the same time, the achieved information is indispensable for the appropriate design of any intervention needed in the conservation of a monument.

The example of the Ruin Garden of Székesfehérvár in Hungary was selected for the demonstration of the importance of these methods. That assemblage of monuments in Székesfehérvár is of a great historic importance since it served as the coronation and burial church for most of the Hungarian kings in the Middle Ages. Moreover, its several reconstructions and expansions throughout history and the presence of several lithotypes found among the remained building and decorative stones makes the research related to the materials crucial not only for the conservation of that specific monument but also for a series of other historic structures in the Hungarian territory.

A total of 65 samples were collected both from left over pieces and the existing walls and went under mineralogical investigation. The microstructure and fabric of the samples were examined by polarizing microscopy, and Scanning Electron Microscopy (SEM). X-ray diffractometry (XRD) was applied for the identification of the main mineral phases. Limestone was found to be the prevailing stone type among the studied materials, including ooidal peloidal types of different grain sizes, red bio-micritic, shelly, foraminifera-bearing limestones and travertine. Polimict sandy calcarenite, marble, quartz-porphyre rhyolite and silica-cemented red sandstone were also found.

As a further step for understanding the behaviour of the three most relevant materials, additional samples were taken from local quarries with similar physical and mineralogical characteristics: a medium-grained and a coarse-grained oolitc limestone from Sóskút and a Red compact Limestone from Tardos, Hungary. When comparing the micro-fabric of the samples from the monuments and quarries under the SEM it is visible that the samples from the monuments show some alterations. The oolitic limestone is composed of micritic to micro-sparitic calcite crystals. The calcite crystals of the freshly quarried samples show clear crystal faces with no dissolution features, while the samples from the monuments display various forms of surfaced alterations. Besides micro-cracks small crystal aggregates and secondary calcite crystal growth was detected on weathered samples of the monument by using SEM.

Contact sponge method

Vandevoorde, D.[1*], Cnudde, V.[2], Dewanckele, J.[2] & Verhaeven, E.[1]
[1]Artesis Hogeschool, Antwerp, Belgium
([*]vandevoordedelphine@yahoo.co.uk)
[2]Geology and Soil Science – UGCT, Ghent University, Ghent, Belgium

French porous limestones are able to absorb large quantities of water. This phenomenon will accelerate the deterioration of the material. In such cases, the material might be treated with a hydrophobic product, which creates a superficial layer that hampers the penetration of water. In order to decide if such a treatment should be applied or not, the water absorbing behaviour of the material should be measured. With the same measuring technique the efficiency of the hydrophobic barrier can be evaluated. Moreover, it allows the monitoring of such barriers as a function of time. At the same time, the water absorption of porous stone material is an indication of the degree of deterioration and its sensitivity to future deterioration. Up to now, two different measuring techniques exist, the capillary rise method and the Karsten pipe. The latter can be operated in laboratory as well as *in situ*, but is not always reliable for *in situ* analysis. This research proposes an alternative method: the contact sponge method. The contact sponge method consists of a contact-plate, containing a humid sponge. The contact plate is pressed against the stone surface and is weighted before and after contact with the surface. The difference in weight corresponds with the water absorption by the stone. Results can be expressed by the mass difference as a function of area and time. This recently developed method was tested on non-treated and treated porous stone materials in a laboratory environment by traditional techniques and highly advanced imaging techniques such as X-ray CT, in order to evaluate its performance in comparison with the two existing methods.

Mineralogical and textural patterns for fluids migration and consolidation

López-Buendía, A.M.[1*], Guillem López, C.[2], Cuevas Castell, J.M.[2] & Baeza, N.[2]
[1]AIDICO - Materials Research Unit, Paterna, Valencia, Spain.
([*]angel.lopez@aidico.es)
[2]AIDICO - Marble Technical Unit, Novelda, Alicante, Spain

The pathways of the fluids of the natural stone are a very relevant parameter with a wide range of applications. In conservation and restoration, consolidation of stone can be used applying resin injection or, eventually, with other inorganic or organic components. In damage prevention, salt-rich water migration can trigger the apparition of diverse pathologies, such as eflorescences, and crypto-eflorescences, which are related to the precipitation of salts dissolved into the fluids, on the surfaces or inside the rocks. The pathologies could decrease dramatically the mechanical properties of the materials, as well as to produce a loss of the esthetical effect of the stones.

The dynamic of fluids through the stone depends on properties related with the liquid (surface tension, viscosity) and the mineral (surface energy) as well as their interaction in the pathway media (pore size distribution) and with the environment (pressure). Contac angle measurement was applied was applied as a direct and quick method for wettability determination of the parameters controlling the fluids circulation. Liquids with different polarity and known surface tension were used for the energy surface approach of the mineral. Porosity was evaluated by petrography analysis, Hg porosimetry and capillarity. The energy surface shows significant mineral variations, following the trends, as follows:

dolomite>sparry calcite>micrite calcite>quartz >micas

The methodology was applied for consolidation of stone using resin with different surface tensions. Results were evaluated using the penetration depth into the stone and the mechanical effect of the consolidation.

On the mineralogy of β-Dicalcium silicate of hydraulic lime binders in various calcination conditions

Triantafyllou, G.[1*], Markopoulos, Th.[1] & Přikryl, R.[2]
[1]Dept. of Mineral Resources Engineering, Technical University of Crete, Chania, Greece ([*]gtriant@mred.tuc.gr)
[2]Inst. of Geochemistry, Mineralogy and Mineral Resources, Charles University, Prague, Czech Republic

Neogene limestone resources from Crete/Greece were mineralogically and chemically characterized as potential raw materials for the production of hydraulic lime binders in order to be used in restoration and conservation applications. A series of calcination experiments was undertaken in the range 850 - 950 °C for 3, 6, 9 and 12 hours respectively, followed by rapid cooling. The calcination products are characterized as eminently natural hydraulic lime binders [1].

The evaluation of the X-ray powder diffraction patterns evidences the presence of dicalcium silicate, entirely of the β-Ca_2SiO_4 monoclinic polymorph phase, space group $P2_1/n$. The amount of β-Ca_2SiO_4, which is the major hydraulic phase, increases at higher temperatures and longer residence times. Lime, gehlenite, aluminate and ferrite phases, and quartz are present in minor amounts. The range of diffraction scans from 30° to 46° 2θ (CuKα) encompass the interval of strong diffraction peak intensities. The first and the second strongest reflection of β-Ca_2SiO_4 at 32.14° and 32.57° (2θ) (d=2.77 Å-2.74 Å), overlap certain peaks of other minerals present, thus influencing their height and width. However, the reflection at 2θ=41.19° (d=2.1898 Å) is appreciable, free of any overlapping and quite intense. An estimation of the average crystallite size, by the Scherrer equation, is proposed here in, taking into account the line broadening at half maximum intensity (FWHM), of this reflection which appears in each calcination condition. The cell parameters have been calculated from the X-ray powder patterns using the Diffrac plus software (Brucker AXS). Representative results are shown in Table 1.

Table 1: Crystallographic data of the β-Dicalcium silicate phase in various calcination conditions

Cell parameters	(1)	(2)	(3)
a (Å)	5.509(5)	5.512(5)	5.514(5)
b (Å)	6.755(5)	6.756(5)	6.758(5)
c (Å)	9.306(5)	9.310(5)	9.313(5)
Angle β	93.95°	94.12°	94.28°
Average crystallite size (Å)	260	295	325

(1) 850° C, (2) 900° C, (3) 950° C and 12 hours of firing respectively

The calcination conditions directly affect the crystallinity of the β-Ca_2SiO_4 phase, since a significant increase of the average crystallite size is observed, at higher temperatures and longer residence times. The crystal size of the β-Ca_2SiO_4 mineral phase present is considered to be sufficient small and it does not transform to the γ-Ca_2SiO_4 upon cooling [2]. The precence of other elements in the raw material, such as Al, Na, K, Mg, Fe, etc., may contribute to the stability of the β-phase. There is no significant change in the values of the cell parametres, except in the case of angle β, whose values increase under intense firing conditions. These lattice parametres are quite similar with those reported by [3].

Due to this investigation, the amount of β-Ca_2SiO_4 appears to be well crystallized and of a more stable structure at higher calcination conditions, which is important since the hydration process of this phase is slow.

Mineralogical, physicochemical and mechanical characterisation of historical lime mortars from Cyprus

Theodoridou, M.[1*], Ioannou, I.[1] & Philokyprou, M.[2]
[1]Dept. of Civil and Environmental Engineering, University of Cyprus, Nicosia, Cyprus ([*]mtheodo@ucy.ac.cy)
[2]Dept. of Architecture, University of Cyprus, Nicosia, Cyprus

The use of composite construction materials, such as mortars, is evident throughout the history of mankind. Mortars with various binding materials have been used across different pre-historic and historic periods to meet several construction applications, such as jointing masonry blocks, finishing walls and isolating water bearing structures.

In the framework of an ongoing research, more than 70 samples of mud, gypsum and lime mortars from different archaeological sites and historic buildings and monuments (i.e. cisterns, water mills, churches and fortifications) in Cyprus have been collected and studied following a systematic analytical approach. Here we present macroscopic observations and experimental results on selected lime-based mortar specimens, aiming to characterize these samples and to determine their composition and properties, in order to reproduce appropriate repair mortars by reverse engineering. We focus on petrographic observations of thin sections carried out by polarizing optical microscope. Scanning electron microscope equipped with energy dispersive X-ray microanalyser (SEM-EDX) is also used to examine the microstructure and texture of the mortar samples and to determine semi-quantitatively the chemical composition and interface of their binders. X-ray diffractometry (XRD) is performed to identify the main mineral crystalline phases of the specimens, while their physical properties (i.e. open porosity and bulk density) are also determined by vacuum saturation using water as the wetting liquid. The samples also undergo mercury intrusion porosimetry (MIP) analysis in an effort to collect further information about their pore structure and volume. Last but not least, a portable drilling resistance measurement system (DRMS) is used for a micro-destructive assessment of their mechanical state.

Our macroscopic observations and experimental results confirm that the studied mortars differ in terms of colour, texture, grain size and surface roughness. Petrographic observations provide evidence that the samples mostly consist of fine to medium bioclastic aggregates and aggregates of a reef limestone nature. Traces of feldspars are also observed in some cases.

SEM photos provide occasional evidence of boundary reactions at the interface between the (calcitic) binding matrix and some small (angular, sub-angular and rounded) reddish inclusions of size 1-3 mm. These inclusions are identified by EDX as regions of silica-alumina composition. XRD analyses confirm that calcite is the main mineralogical constituent of the studied historic mortars. These analyses also confirm the occasional presence of calcium aluminosilicate compounds in some of the specimens. We presume that these compounds originated from the addition of crushed brick or ceramic powder in the original mortar mix. The latter has probably been used in the absence of natural pozzolanas on the island to enhance the performance of mortars, increase their mechanical strength, adhesion and hydraulicity and prolong their longevity.

It is anticipated that the results of this study will prove to be useful in understanding the production technology of ancient lime-based mortars in Cyprus. It is also expected to contribute towards the design of new compatible mixtures that may be used in the conservation and restoration of monuments and historic structures.

Materials of decorative stuccoes on an historic theatre of the early XXth century in Bari (Southern Italy) and study of the fire effects

Calia, A.*, Lettieri, M., Masieri, M. & Quarta, G.
CNR- Institute for Archaeological and Monumental Heritage, Lecce, Italy (*a.calia@ibam.cnr.it)

This paper sets out the study of decorative stucco elements in the Petruzzelli Theatre in Bari (Southern Italy), consisting of mouldings and decorations in greater or lesser relief present on the ceilings and walls, and on statues. The Petruzzelli Theatre is an important example of a nineteenth century "Politeama" (i.e. a venue intended for various forms of live entertainment) which was inaugurated in 1903. The stuccoes were affected by the fire which struck the Theatre in 1991, causing serious damage to the main auditorium, whose furnishings and roof were almost completely destroyed; the foyer was less badly affected, and a large part of the decorations (stucco, papier-mâché and wood) on the walls and ceilings remained intact.

Examination by naked eye detected diverse forms of damage to the decorations (Fig. 1); both, extensive blackening due to the presence of combustion deposits, and superficial "roasting", crumbling, cracks and separation of the stuccoes from the wall were observed in the areas affected by the flames. In contrast, in the areas furthest from the heart of the fire the damage appears to be basically due to the effect of high temperature fumes, with the presence of combustion deposits, underneath which the material is apparently intact.

Fig. 1: a: Stuccoes of stage box affected by the fire; **b, c:** Stuccoes of Foyer covered by a layer of combustion deposits; **d:** Piece of stucco fallen from the stage box decorations; **e:** Golden stucco in area not affected by the fire.

The present study aims at the characterization of the constituent materials and the painted surface decorations, as well as ascertaining the effects of the fire.

It was carried out on the samples from the surviving parts of the stage-box decorations, directly affected by the fire, and on those present inside the foyer, affected by the fire to varying degrees. These stuccoes were compared with samples not affected by the fire, which were taken from rooms next to the Theatre.

The composition and structure of the stuccoes were investigated by Optical microscopy in transmitted and reflected light, DRX, FT-IR, DTA-TGA, ESEM with EDS microanalyses.

The combined analyses pointed out different kinds of stuccoes in terms of mineralogical-petrograhical composition. The effects of the fire action were identified in new mineralogical phases, coming from the de-hydration of the gypsum binder, as well as from the mineral pigments used in the painted layers. Microcracks in the stucco groundmass, detachments and melting phenomena of the superficial finishings were also observed, as well as micro-blisters likely due to the burning of the oil binder.

Deterioration of the Sasov castle (Slovakia) and replacement material for the weathered building stone

Adamcova, R.[1*], Petrinec, R.[1], Valter, M.[2] & Plötze, M.[2]
[1]Dept. of Engineering Geology, Faculty of Natural Sciences, Comenius University in Bratislava, Slovakia
([*]adamcova@fns.uniba.sk)
[2]Inst. for Geotechnical Engineering, ETH Zurich, Switzerland

The Sasov castle in Middle Slovakia belongs to the cultural heritage, being one of the national monuments. The ruins of the medieval castle on a volcanic hill above the Hron River are a characteristic landmark, 4 km SE from the town Ziar nad Hronom. In 1997 the condition of the buildings was documented. In a revision after 12 years, the comparison with the previous documentation revealed the fastest deteriorating parts. Searching for the reasons, an engineering geological map of the castle hill was created, showing the relation of tectonic faults and slow slope movements (tilting) with cracks in the masonry and some collapsed walls. Most of the cavities and overhangs in the remaining masonry are due to the weathered binder. Intensive weathering of the building stone, studied within the project VEGA 1/0413/09, caused other reasonable part of the damages.

The masonry is built mainly of Neogene andesite, which is common in this area, as part of the volcanic Stiavnicke Vrchy Mts. More altered highly macro-porous stones show some yellowish-brownish coatings on the surface and fissures. The comparison of some better preserved building stones with the rock in an old local quarry showed a very good match in the properties (mineral assemblage, colour, porosity, strength) with the most altered parts in the rock mass. The accessible but more weathered rock of the upper part of the quarry was exploited as first for the castle. Exposed to environment on the castle hill without any cover, it disintegrates faster than in the rock mass. Volume changes due to smectite swelling as well as freezing-thawing processes in the effective pores probably enhance the deterioration. The most altered building stones are almost white and disintegrate into sand. But there, the X-ray diffraction indicates the possibility of other source or an epiclastic origin.

The sound quarry stone is an andesite of dark grey colour, from medium-grained to aphanitic texture, micro-porous, and extremely strong. Results of the X-ray powder diffraction showed that the mineral assemblage is dominated by andesine (62 wt%) and amorphous phases/glass (27 wt%). As minor phases, augite (8 wt%) and magnetite (3 wt%) were identified. With increasing alteration, smectite content is increasing up to 22 wt%, while augite, magnetite and amorphous phases are decreasing. A considerable part of the macro-pores is the result of selective leaching of weathering products, even when some of the macro-pores are primary voids, caused by the rapid cooling of the melt near the surface. Comparison of the sound rock with the altered one shows an increase in total porosity (from 2.4% to 21.2%) and in effective porosity (from 2.2% to 15.0%). There is a clear relation between the porosity and smectite content on one side, and the uniaxial strength (tested by the Point Load Test) on the other side. The strength dropped from 270 MPa to 51 MPa for more weathered macro-porous stone. Enlin-Neff tests on rock powders proved higher water adsorption in the weathered rock mainly due to the smectite content.

For any castle reconstruction, sound stone from deeper parts of the quarry can be taken as replacement material. It promises better durability, good mechanical properties, as well as acceptability from a historical point of view.

Incorporation of fine and coarse sepiolite in lime-metakaolin mortars

Andrejkovičová, S.[1*], Ferraz, E.[2], Velosa, A.[2] & Rocha, F.[1]
[1]Geosciences Dept., Geobiotec Unit, University of Aveiro, Portugal ([*]slavka@ua.pt)
[2]Civil Engineering Dept., Geobiotec Unit, University of Aveiro, Portugal

The aim of this research was to assess the behaviour of fine and coarse sepiolite acting as water reservoir in lime-metakaolin mortars for applications in building rehabilitation. With this purpose three sets of mortars were prepared: a) mortars with 1:3 air lime (AL): sand volumetric ratio, in which lime binder was replaced by 10% and 20% of metakaolin (MK, commercial product, Portuguese origin); b) the same mortar compositions in which air lime was substituted by 5% of i) fine sepiolite (S, average particle size 2.4 μm, commercial product, Spanish origin), ii) coarse sepiolite (CS, particle size within the range 0.3-1.2 mm). Samples were cured for 28 days according the EN 1015-11 standard.

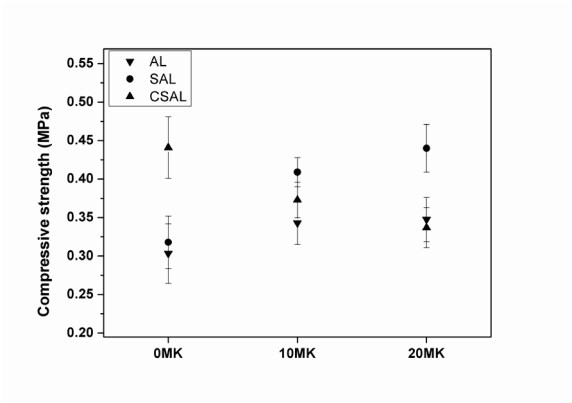

Fig. 1: Compressive strength (MPa) of mortars.

The obtained results showed the increase of mechanical properties in AL-metakaolin mortars when compared to AL-mortar, as well as the improvement of flexural and compressive strengths with the addition of metakaolin content (Fig. 1). Compared to AL mortar, flexural and compressive strengths increased 20% and 12% for AL-metakaolin mortars, respectively. New calcium-silicate and calcium-aluminium-silicate mineral phases were identified in mortars containing metakaolin, which result in higher mechanical strength in metakaolin-blended mortars.

As expected, the fibrous habit of sepiolite caused enhanced conjugation with the individual components and comprehensive compatibility in the mortar system. Considerable improvement is related to fine sepiolite-AL-metakaolin mortars, where compressive strength increased 24% in comparison with AL-metakaolin mortars, while 6% enhancement is associated with addition of sepiolite to AL mortar without metakaolin. It is a consequence of high specific surface area and absorbent properties of sepiolite. The incorporation of coarse sepiolite in AL mortar raises the compressive and flexural strength, by 47% and 52% respectively, compared to AL mortar. On the contrary, the presence of coarse sepiolite in AL-metakaolin mortars promotes a significant decrease of mechanical strengths. Phenolphthalein tests showed an improvement of carbonation rate with the addition of both fine and coarse sepiolite. In early ages, the addition of fines has a significant impact on mortar compressive strength. The fibrous structure of the fine sepiolite also has a possible positive outcome on mortar strength due to binding effect. The effect of chemical reactions, both carbonation and pozolanic reaction will be more evident at 90 days due to slow reaction rate.

Sandstones at the historical "Berlin City Palace"

Ehling, A.[1*] & Jörg Bowitz, J.[2]
[1]Federal Inst. for Geosciences and Natural Resources, Berlin, Germany ([*]angela.ehling@bgr.de)
[2]Berlin, Germany

The "Stadtschloss" or "*Berlin City Palace"* was a royal palace in the centre of Berlin, Germany, heavily damaged in WWII, its remnants being demolished by the East German (GDR) authorities in 1950. The palace bore features of the Baroque style, and its shape, finalized by the mid 18th century, is attributed to Andreas Schlüter, whose first design likely dates back to 1702, although the palace incorporated earlier parts, such as a foundation from 1443. It was the principal winter residence of the kings of Prussia from 1701-1918 (who were the German Emperors from 1871-1918), converted to a museum following the fall of the German Empire in 1918. Following the reunification of Germany, it was decided to rebuild the "Stadtschloss".

According to the present plans, there is an interesting constellation: a historical building has to be rebuilt with 3 historical facades, yet the original building is lost. There are no specific guidelines for the use of rock and plaster materials, but the architects want to restore the historical impression as best as possible, which requires the use of original materials.

The historical facades of the palace had been composed of plastered bricks with architectural elements made of sandstones. How do we know, which sandstones had been used? Around Berlin there are no outcropping sandstones. There is some literature about the use of sandstones since 1700, and some of the original sculptures were saved during the demolition. Provenance analyses have been carried out on about 40 samples of these materials by mobile, non-destructive IR-spectroscopy (Fig. 1).

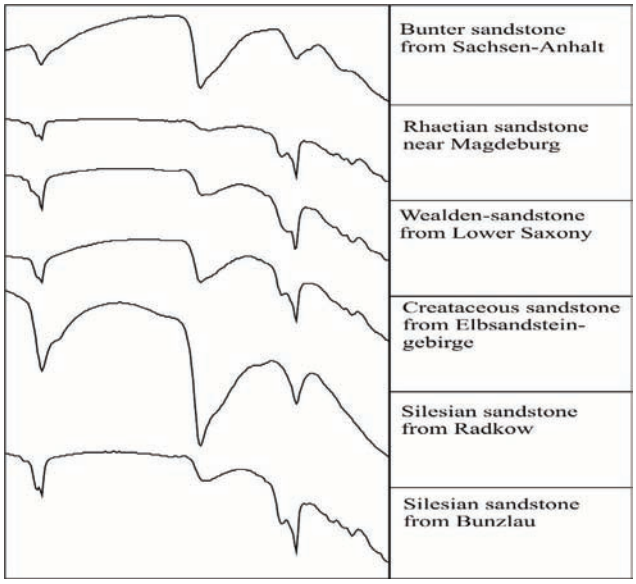

Fig. 1: IR spectra of some analyzed sandstone samples for provenance determination.

The data show that most of the sandstones came from the Elbsandsteingebirge in Saxony, south of Dresden, quarried prior to 1870. In addition, Buntsandstein from Sachsen-Anhalt (near Halle), Rhaetian sandstone from the Magdeburg region, and Wealden sandstones from Lower Saxony were used later on. From the 1870's onward the only rock material used was Cretaceous sandstones from Lower Silesia.

Historic quarries in Hungary

Gherdán, K.[1*], Biró, T.K.[2], Péterdi, B.[3],Markó, A.[2], Schaller, K.[4] & Uhlir, C.[4]
[1]Eötvös Loránd University, Budapest, Hungary ([*]gherdankata@hotmail.com)
[2]Hungarian National Museum, Budapest, Hungary
[3]Geological Institute of Hungary, Budapest, Hungary
[4]CHC-University of Salzburg, Austria

Historic Quarries is a Culture 2007-2013 project of the European Union coordinated by Salzburg University. The most important aim of the project is to present historic quarries as significant parts of European cultural heritage and to provide open access to the historic quarry heritage of Central Europe (Austria, Czech Republic, Hungary, Poland, Slovakia, Romania) through an online information system, aimed at providing geographical, historical, petrographic and touristic information. This paper summarizes the results of the research carried out on quarries situated in Hungary.

The starting point of our work was Ferenc Shafarzik's catalogue and rock collection established in the beginning of the 20th century. This important scientific and industrial enterprise was created in order to collect information on active coeval quarries and their rock types in the Kingdom of Hungary, now extending to the territory of eight countries. The catalogue lists 3162 quarries, from which 1058 are in the territory of present day Hungary: 153 gravel and 13 sand pits, and 892 quarries of other (42) rock types. Together with previously visited quarries (in the framework of previous projects by OTKA (National Science Foundation Project T-25086, Prehistoric raw material atlas...) and the Erosion and Humidity, Culture 2000 program of the European Union) this makes up 143 Schafarzik quarries in 97 villages/towns. Since the beginning of the current project 24 Schafarzik quarries have been visited, where scientific data and samples have been collected, photographs taken, geographical coordinates recorded. Besides, 10 other quarries, which do not appear in the Schafarzik catalogue, but have geological, archaeological or historical importance, have also been visited.

A sample collection of ten quarries has already been published on the internet (http://www.historic-quarries.org/quarries/showlist/46) and five entries about five quarries for quarrypedia have also been presented.

The collected information will help us to better understand lithic raw material utilisation over thousands of years and preserve and spread the knowledge of historic quarry sites and landscapes both among professionals and non-professionals.

Calcite dilatation potential and its influence in marble thermal expansion

Luque, A.*, Álvarez-Lloret, P., Cardell, C., Cultrone, G. & Sebastián, E.
Dept. of Mineralogy and Petrology, Faculty of Sciences
University of Granada, Spain (*analuque@ugr.es)

In the last decades, much research has focused on the physic decay that some marbles show when exposed to environmental thermal change (e.g. The Finland Hall in Helsinki, the Grande Arche de la Defense in Paris, the Courtyard of the Lions in the Alhambra, Spain). It has been demonstrated that this effect is a direct consequence of the anisotropy of thermal dilatation of marble rock-forming minerals (calcite and dolomite), mainly calcite [1]. According to [2,3] preferential mineralogical orientation, fabric and texture of the marble are, among others, the main parameters that influence the physical behaviour of these rocks under thermal oscillation [4].

White Macael marble is a typical ornamental stone used in the Architectural Heritage of Spain. It has been used in numerous ornamental elements as Roman inscriptions, fountains, columns, etc., including the Lions Fountain and the columns of the Lions Courtyard in the Alhambra of Granada (Spain), which are among the most valuated ornamental pieces in Spain. As reported by [5], White Macael is a marble with great thermal susceptibility. Indeed, the results obtained by [6] showed that this marble has a marked preferential crystallographic orientation, simple grain boundaries and large anisotropic thermal dilatation coefficient, all of which directly favour its decay under thermal changes.

The present research documents other two fundamental factors to be taken into account when assessing the effect of thermal dilatation of this marble: i) the dilatation degree that calcite crystals display when are confined in a compact rock and ii) the dilatation degree they show when are in powder state and, therefore, free from confinement pressures. To perform this investigation, an on site thermal experiment has been carried out by applying X-ray thermo-diffraction (XRTD) [7] in both White Macael marble slabs (2000x1000x400 μm) and on powder samples obtained after grinding the above. The preliminary results revealed that the White Macael marble has a greater dilatation coefficient when is analysed in powder state than in marble samples. We suggest that this yield to confinement pressures (strains) at the boundary grains which could triggers physical decay in the marble. Further analyses currently under way are aimed at correlating thermal differences with degree of marble decay after thermal changes by using different types of marbles.

Anisotropic behaviour of calcitic and dolomitic Spanish marbles

Luque, A.[1*], Leiss, B.[2], Cultrone, G.[1], Sebastián, E.[1] & Siegesmund, S.[2]
[1]Dept. of Mineralogy and Petrology, Faculty of Sciences, University of Granada, Spain (*analuque@ugr.es)
[2]Geowissenschaftliches Zentrum der Universität Göttingen, Germany

Marbles used as construction material have shown a great susceptibility to temperature changes and several researches have pointed at the anisotropic thermal behaviour of its constituent minerals, calcite and dolomite, as one of the main factor influencing the thermal decay of marbles [1]. These two minerals, mainly calcite, show a marked anisotropy of their physical properties with respect to the crystallographic c- and a-axes of the single crystal [2]. The anisotropy of physical properties is conditioned by the lattice preferred orientation (texture) of these minerals [3]. Numerous studies already show how the microstructural and textural characteristics influence physical parameters, clearly demonstrate that these parameters can help predicting stone durability [4-7].

Six marbles are described in our study: four calcitic and two dolomitic, showing marked differences with respect to grain sizes, grain boundaries and twinning, indicating different degrees for deformation and post-deformative recrystallisation.

Texture measurements were carried out on an X-ray texture goniometer (PANalytical X'pert System X-ray diffractometer). On the basis of at least five experimental pole-figures of each sample, a quantitative texture analysis was carried out by calculating the orientation distribution function by means of the WIMV-algorithm [8] and the iterative series-expansion method [9]. The bulk rock anisotropy of the thermal dilatation coefficient and ultrasound waves velocity were calculated by applying the VOIGT averaging method [10].

The velocity of compressional pulses was measured to define a first visual reference - coordinate system (X-, Y- and Z-). Thermal expansions were measured parallel to these directions and the thermal expansion coefficients were calculated. To relate direct and experimental measurements, the fabrics of all marbles were studied by an environmental scanning electron microscopy equipped with a heating stage in three steps of one thermal cycle (in 20º, 90º and 20º C). Different degrees of microcrack-developments were identified in all marbles depending on orientation. The results show that texture type and intensity also influence the behaviour of marbles exposed to thermal changes. We suggest that even in marbles with a strong anisotropy, i.e. a large thermal dilatation, grain size and grain boundary configuration can influence the development of preferred oriented microcracks of marbles and, as a consequence, their thermally controlled decay.

Sulphatation process in calcitic and dolomitic marbles altered by SO_2

Luque, A.[1*], Martínez de Yuso, M.V.[2], Cultrone, G.[1] & Sebastián, E.[1]
[1]Dept. Mineralogy and Petrology, University of Granada, Spain
([*]analuque@ugr.es)
[2]Central Research Services, University of Malaga, Spain

Atmospheric pollution is one of the main decay agents of monumental pieces located in industrialized urban centres. SO_2 is a permanent and abundant component of air pollution and, although it does not have an immediate visual effect, after a continuous exposition, it can end up damaging irreversibly the construction material.

Marble is an ornamental stone commonly used in monuments and it is very susceptible to deteriorate by SO_2 attack because of its mineralogical composition (calcitic and dolomitic) which favours the development of gypsum on the surface [1]. This reaction is known and the final gypsum development is via an initial formation of $CaSO_3$ which is subsequently oxidized to $CaSO_4$ by atmospheric oxygen [2]. However, if many researches described the epsomite growth ($MgSO_4$+$7H_2O$) on dolostone surfaces, this reaction seems to not show the existence of previous sulphite stage formation ($MgSO_3$) in this types of rocks, even if this salt is know as a component employed in wood pulping process and paper production processes [3].

To measure how easily marble suffers atmospheres rich in SO_2, selected calcitic and dolomitic samples were exposed during 24 h to sulphur dioxide in a climatic chamber under controlled thermohygrometric conditions (20ºC and > 90% HR). The superficial damage produced by SO_2 on marbles was studied using two non-destructive techniques: chromatic change by means colorimetry and chemical analysis using X-ray photoelectron spectroscopy (XPS). Moreover, the development of new reaction phases was observed by variable pressure scanning electron microscopy (VPSEM).

Colorimetric analysis evidenced a decrease in lightness (L*) and chromatic parameters (a* b*) showing that these changes are due to the formation of new minerals phases. XPS, generally used in the analysis of metallic pieces, is somehow novel in the field of stone deterioration. The use of this technique has allowed to demonstrate the development of sulphites and sulphates in marbles with high precision, after just 24 hours of their exposure to SO_2 and to distinguish a different decay path between calcitic and dolomitic marbles. Salts crystals show different morphologies and concentrations depending on the type of salt and the compositions of substrate where they grow.

Mapping, weathering forms and petrographic features – the western portal of Cârţa Cistercian Monastery (Sibiu County, Romania)

Mihăilă, A.
Dept. of Geology, Faculty of Biology and Geology, "Babeş-Bolyai" University, Cluj-Napoca, Romania
([*]anamaria.mihaila@ubbcluj.ro)

At the end of the XIII[th] century, one of the most imposing monastic architectural assemblies from south-eastern Europe was built in Cârţa (Sibiu County, Romania). The abbey played an important role in medieval Transylvania, as it was located at the interference of Byzantine and Occidental cultural-religious influences [1]. The style of the monastery is early gothic, but the western façade and portal must have been finalized later on (probably still before 1300), as the portal shows mature gothic features [2].

The research focuses on the western portal of the abbey, which was chosen for its architectural importance and the use of dimensional building stones. Three types of mapping were performed: a standard mapping of the sandstone blocks and of mortar types including the numbering of each block, the sound velocity mapping after clash-test and the relative humidity mapping after more than 650 measurements by using Hydromette Compact B Gann equipment.

Based on Fitzner's classification [3], the most frequent weathering forms identified after *in situ* investigations of the portal were: granular disintegration, breakout, discoloration and biological colonization prevails in the lower part; the middle part is highly affected by winds and thus typical weathering forms appear (alveolar weathering, rounding and notching), especially on the northern side; the upper part, frequently exposed to atmospheric factors, is dominated by intense biological colonization and the formation of crusts. The different weathering patterns of the portal's parts correlate with the relative humidity and sound velocity mappings, pointing to a more intense alteration of the northern side, because of its exposure and the action of the winds from the Făgăraş Mountains.

The identified source area of the raw material is located 12 km away, near Colun village. The Sarmatian sandstones from Colun were analyzed both macroscopically and microscopically in order to compare them with the sandstones used at the construction of the abbey. The optical microscopy study shows that both rocks are litharenites with carbonatic cement and bioclasts, metamorphic quartz with undulatory extinction, and altered feldspars.

Sulfation of carbonate rocks as an important factor of cultural heritage monuments deterioration in different climatic regions

Mosyagin, A.V.[*], Frank-Kamenetskaya, O.V., Vlasov, D.Yu. & Zelenskaya, M.St.
Saint Petersburg State University, Saint Petersburg, Russia
([*]al.mosyagin@gmail.com)

The paper presents the results of study and comparison of the sulphate deterioration processes of carbonate rocks (marble and limestone) that were used as building materials for cultural heritage monuments in urban environment of several cities: Saint Petersburg (Russia), Sevastopol (Crimea, Ukraine), Oslo (Norway), Orebru (Sweden). It is shown that formation of gypsum-rich patina plays one of the leading roles in deterioration (Fig. 1a) [1,2].

During the study carbonate rocks (limestone and marble) used for the construction were examined and the condition of their surface (presence of cracks, chipping etc.) were described, black crusts of gypsum-rich patina were sampled. Collected samples were studied by optical microscopy, powder X-Ray diffraction, scanning electron microscopy. Microbial species were determined by the use of different microbiotical techniques.

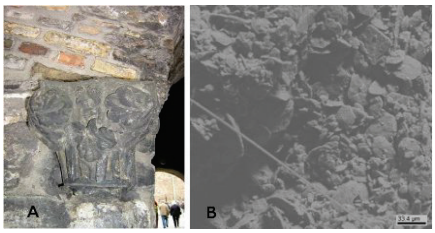

Fig. 1: a. Limestone column volute totally covered with black crust of gypsum-rich patina, Akershus caslte,Oslo (Norway).**b.** SEM image of flattened gypsum crystals from the black crust, Akershus caslte,Oslo (Norway).

Our study shows that sulfation processes take place in all studied climatic regions due to the presence of SO_2 in atmosphere. The gypsum crystals morphology is quite similar and the most often habit is lamellar, strongly flattened after the second pinacoid (Fig. 1b). Prismatic elongated crystals were observed much more rarely. It was shown that the range of deterioration was closely connected with the shape and the material of the monument. The largest diversity of crystal habits was investigated in Saint Petersburg due to the wide diversity of substrate rocks. The largest gypsum crystal was found in Tauric Chersonesos on the porous limestone wall and reached 240 μm. Three stages of the gypsum-rich patina formation were noticed: the initial, when tiny gypsum crystalls occur beneath the biofilm; the intermediate stage, with multiple large gypsum crystals and microorganisms among them; the intensive stage with microbial community under the gypsum layer [2].

The presence of microorganism communities was shown in every investigated specimen by microbiological studies. Six species of micromicetes from genera Cladosporium, Alternaria, Epicoccum, Scytalidium, common for all specimens were picked out. It seems that they take part in the gypsum-rich patina formation, while the way of this process is not clear yet. The simulation experiments are still in progress.

Enhanced weathering of stone by salts: physical, chemical and remediation strategies

Schiro, M.[1*], Ruiz-Agudo, E.[2] & Rodriguez-Navarro, C.[1]
[1]Dept. of Mineralogy and Petrology, University of Granada, Spain ([*]mschiro@gmail.com)
[2]Dept. of Mineralogy, University of Münster, Germany

In the presence of salt and water, stone monuments suffer from both physical and chemical weathering. An effective remediation strategy should inhibit both weathering processes [1[. In order to develop this type of conservation treatment, a full understanding of salt-enhanced physical and chemical weathering must first be achieved. For this we have chosen to study sodium sulphate, as one of the most damaging salts known [2]. As model substrates we have selected a non-porous glass slide and a sintered porous glass of controlled porosity.

Using these salt and model substrates, we have started examining physical weathering due to crystallization pressure generation. First we have studied the crystallization of a single drop of saturated sodium sulfate solution evaporating on the surface of a non-porous glass slide. Evaporation at 21°C and 35% relative humidity resulted in precipitation of the single phase thenardite (anhydrous $NaSO_4$), as determined by polarized optical microscopy, environmental scanning electron microscopy (ESEM) and X-ray diffraction (XRD).

Next, we used the porous glass to understand crystallization in a porous system. The evaporation rate was recorded using thermal gravimetry (TG) and results were used to calculate the concentration of sodium sulfate in solution at every point during evaporation. The heat of crystallization was measured in parallel by differential scanning calorimetry (DSC), which determined crystallization events and the timing of phase transitions [3]. Results from DSC in combination with TG enabled calculation of supersaturation with respect to each phase. However, it is not possible to determine which phases precipitate using these methods. In order to overcome this limitation, we needed a tool that allowed us to probe below the surface. Two-dimensional X-ray diffraction (2D-XRD) is an innovative and powerful tool which performs synchrotron-like experiments in a normal lab, by using a Molybdenum X-ray source (more than 5 times more penetrative than conventional Copper source). The first phase to form is the metastable heptahydrate ($NaSO_4 \cdot 7H_2O$) [4], followed by a phase transition to mirabilite ($NaSO_4 \cdot 10H_2O$), with the final phase transition forming thenardite (anhydrous $NaSO_4$). In combination with the results from TG/DSC, critical supersaturation at the onset of crystallization within the porous system was calculated, as well as the associated crystallization pressure.

The combination of instruments used in this work provides the basis for understanding the process by which crystallization of salt phases occurs by evaporation (i.e., the most common situation leading to salt damage in building stones and natural environments). By examining different salts and different substrates, we will have a clear background against which we can measure how effective a specific remediation treatment is at reducing crystallization pressure and inhibiting damage.

Provenance study of marbles based on qualitative and quantitative petrography (Moldanubian Zone, Czech Republic)

Šťastná, A. & Přikryl, R.*
Inst. of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University in Prague, Czech Republic (*prikryl@natur.cuni.cz)

The present provenance study was carried out on calcite and dolomite marbles of the Moldanubian Zone (south part of the Bohemian Massif, Czech Republic). Local marbles have been quarried and used as dimension stones in the 19th and 20th centuries [1].

The complex geological situation here is reflected partly in the petrographic variability of marble properties (e.g. presence of non-carbonate phases and various fabric). The mineralogical composition of petrographic types varies significantly, marbles verge into calc-silicate rocks in some localities. The fact that Czech marbles differ from white Mediterranean marbles also means that there are special requirements on the selection of provenancing techniques. Previously successfully used conventional analytical procedures such as X-ray powder diffractometry or stable isotope geochemistry may not usually provide a stringent criterion for a provenance determination [2,3].

Provenance methodology was based on detailed optical microscopy (OM) of the whole rock in combination with cathodoluminescence (CL) of microfacies, petrographic image analysis (PIA) of carbonate grains and electron backscatter diffraction (EBSD) of carbonate grains. The studied marbles were distinguished on the basis of the mineral assemblage, the colour type of cathodomicrofacies and fabric parameters (carbonate grain size and grain shapes, index of grain size homogeneity, presence of shape or crystallographic preferred orientation).

Substrate effects on stone bioconsolidation by bacterial carbonatogenesis

Jroundi, F.[1], Rodríguez-Navarro, C.[2], Vicente Navarro, J.[3] & Gonzalez-Muñoz, M.T.[1*]
[1]Dept. of Microbiology; Sciences Faculty, University of Granada, Spain (*mgonzale@ugr.es)
[2]Dept. of Mineralogy and Petrology; Sciences Faculty, University of Granada, Spain
[3]Instituto del Patrimonio Histórico Español, Madrid, Spain

Carbonate and silicate stones (e.g., limestones and sandstones) have been widely used as sculptural and construction materials since ancient times, thus constituting a significant part of mankind's Cultural Heritage [1]. They are, however, highly sensitive to weathering. Consequently, the study of stone decay and conservation has become an important research field. Among the newly developed conservation treatments, those based on the use of bacterial carbonatogenesis are gaining interest. In this context, we developed an efficient consolidation method based on the activation of the carbonatogenic microbial community that inhabits building stone (calcarenite) by the application of a suitable nutritional solution [2]. For the effective use of this novel conservation treatment, it is pivotal to shed light on how deep the new bacterial carbonate precipitates within porous stones. However, we have found some difficulties in identifying the newly formed carbonate cement because these treatments were carried out on calcarenite stone [1,3], and the bacterial carbonate was typically calcite (i.e., the same mineral existing in the original stone). In order to by pass this problem, a treatment was applied on a sandstone sample (from Prague, Czech Republic) which typically shows extensive damage (e.g., Prague´s Charles Bridge [4]) and presents similar porosity and pore size distribution than the previously treated calcarenite [1,3;5]. The treatment was applied by spraying a nutritional solution M-3P [5] on one of the larger surface of sandstone slabs (150x30x15 mm). XRD analyses of depth profiles in the treated sandstone show that calcium carbonate precipitated as vaterite down to a depth of 8-9 mm. SEM observations revealed that quartz grains in the sandstone were fully covered with mineralized bacterial EPS and numerous micrometer-sized espherulites of vaterite in contact with mineralised bacterial cell down to a depth of 15 mm (that is, the full thickness of the treated stone slabs).

These results indicate that: (i) the activation of carbonatogenic bacteria inhabiting the sandstone results in the production of consolidating $CaCO_3$ cement, and (ii) the nature of the substrate (carbonate or silicate) strongly influences polymorph selection of the carbonate biomineral phase (stable calcite or metaestable vaterite). These results may have important implications in bacterial conservation of ornamental stones others than carbonate stones, and demonstrate that the crystallographic affinity between the substrate and the bacterial biomineral (i.e., possible existence of epitaxy or its absence) controls which calcium carbonate phase is formed.

Reasons of variations of the mineral compositions of the mantle rocks beneath the Yakutian kimberlite province

Ashchepkov, I.[1*], Afanasiev, V.[1], Vladykin, N.[2], Pokhienko, L.[1], Ntaflos, T.[3], Travin, S.[2], Ionov, D.[4], Palessky, V.[1], Logvinova, A.[1], Kuligin, S.[1] & Mityukhin, S.[5]

[5]ALROSA Company, Russia

Minerals from the deep seated xenoliths concentrates (>20000 EPMA and >9000 LAM ICP MS) form seven regions of Yakutian kimberlite conference reveal a significant difference in the major and trace elements [1,2] which is mostly seen on the clinopyroxene compositions [2]. It result in the difference of the mantle layering in separate tectonic units [3-5] and due to the reactions with the plum (PM) and subducted related melts (SRM) during [6,7] the evolution of the SCLM beneath each part of Yakutia. Cpx from Central (M.Botuobinsky) reveal relatively fertile mantle source due to high scale hybridization and fertilization with carbonatitic and protokimberlitic melts. Alakite mantle subjected to SRM essentially K-(Na) metasomatism (800-600 ma) with richterites and K-Cpx in deep SCLM reveal more La/Yb_n rations for Cpx increasing with the pressure in opposite to those from M.Botuobinsky field. Daldyn field SCLM reveal more depleted SCLM with the silica enrichment due to SRM reactions [6,7]. In Kuoyka and Anabar regions dunites dominte, SRM fertilization starts <40kbar [2,3,8] due to shallow subduction producing Cr- pargasite metasomatism. The most upper levels on SCLM mantle show the high scale Na- metasomatism probably fluid related. Mantle sections beneath the periphery of Siberian SCLM in Mesozoic show the enrichment due to basaltic PM reactions detected in Cpx TRE spidergrams. Layering determined by monomineral thermobarometry [3] for Gar, Opx, Cpx, Chr and Ilm is in a good agreement with OPx –Gar barometry showing the 10-12 contrast units. Pervasive metasomatism passed through the general layering. Monomineral thermobarometry allows to construct the mantle transects through the fields and kimberlite regions. The thermobarometry for the ilmenites allow to reconstruct the layers subjected to the metasomatuism by the protokimberlites. Precise data for the Ol obtained using 20 min measurements at 20KV on CAMECA 50 SX allow to obtain preliminary Ol geotherms using methods [9-10] are coinciding in general with those produced by pyroxene methods.

Detectability of the post-perovskite transition in mantle-related multi-phase systems

Grocholski, B.[1*], Shim, S.-H.[1] & Prakapenka, V.[2]
[1]Massachusetts Institute of Technology, Cambridge, Massachusetts, USA ([*]brent_g@mit.edu)
[2]University of Chicago, Illinois, USA

Seismic observations of the D" discontinuity, especially in regions of high velocity where it is more readily observed [1], have been attributed to the thermal response of the perovskite to post-perovskite (PPv) transition. This interpretation is dependent on the assumption of a narrow depth interval for the transition combined with a large and positive Clapeyron slope. However, our recent study on binary and ternary systems [2] showed that 10% Fe and 10% Al increase the thickness of the two-phase region to 400-600 km, making seismic detection of the PPv transition difficult.

We have made new measurements on pyrolitic and San Carlos olivine compositions up to 170 GPa and 3000 K in laser-heated diamond cell at the GSECARS sector of Advanced Photon Source. Gold was used as the internal pressure standard and argon was used as a pressure medium. Both compositions include ferropericlase (Fp), for which the effect on the transition has only been modelled in our previous study [2]. Pyrolite contains 10% Al, while San Carlos olivine is aluminium-free.

The effect of aluminium on the Pv to PPv transition is profound even in the multi-phase systems, with our measurements on a pyrolitic composition indicating a PPv transition begins at a depths 100±100 km below the core-mantle boundary (CMB) and has a wide two-phase region of 800±200 km. In contrast, the PPv transition in a San Carlos olivine composition occurs at a depth 100±100 km above the CMB with a two-phase region thinner than 100±100 km.

These are in good agreement with our predictions in [2] in that Al increases both depth and thickness of the PPv transition (as measured in pyrolite) while Fp (or high Mg/Si) decreases the thickness through buffering effect (as measured in San Carlos olivine). Harzburgite, existing in the subducting lithosphere, has much smaller amount of Al and higher Mg/Si ratio, making an ideal candidate rock for a sharp PPv transition. Therefore, the PPv transition may exist in harzburgite subducted into the deep mantle, while it does not exist in pyrolitic mantle.

Phase transitions, densities, and sound velocities of mantle and slab materials down to the upper part of the lower mantle

Irifune, T.[1*], Nishiyama, N.[1], Tange, Y.[1], Kono, Y.[1], Shinmei, T.[1], Kinoshita, Y.[1], Negishi, R.[1], Kato, T.[1], Higo, Y.[2] & Funakoshi, K.[2]
[1]Geodynamic Research Center, Ehime University, Matsuyama, Japan ([*]irifune@dpc.ehime-u.ac.jp)
[2]Japan Synchrotron Radiation Research Institute, Hyogo, Japan

Phase transitions, densities, and elastic wave velocities have been accurately measured on mantle and subducting slab lithologies by a combination of multianvil and ultrasonic techniques, coupled with synchrotron in situ X-ray observations, under the P, T conditions of the whole mantle transition region. Moreover, use of sintered diamond as the second-stage anvils has dramatically extended the P, T conditions for in situ X-ray diffraction studies toward those of the middle part of the lower mantle.

We have performed such experiments on rocks such as pyrolite, MORB, and harzburgite, which are supposed to be the major consituents in the mantle and the slabs, at pressures to the upper part of the lower mantle. The resultant density and elastic wave velocity data are compared with those obtained seismologically, and we found that pyrolite is a reasonable model composition for the mantle transition region and the upper part of the lower mantle, except for the bottom part of the mantle transition region, where the sound velocities, particularlly Vs, are significantly higher than those of the typical seismologica models.

One possible senerio for this discrepancy is the presence of a layer of harzburgite, the main body of the subducted slabs, which may globally exist near the 660km seismic discontinuity. The feasibility of this idea will be discussed on the basis of our recent experimental data on phase relations, densities, and sound velocities of pyrolite and harzburgite under the P, T conditions of this region of the mantle.

Pressure-induced phase transitions in transition-metal sesquioxides: effect of d electrons

Umemoto, K.
Dept. of Geology and Geophysics, University of Minnesota, Minneapolis, USA (umemoto@cems.umn.edu)

After discoveries of the $CaIrO_3$-type post-perovskite (PPV) phase in $MgSiO_3$ and Al_2O_3, sesquioxides (M_2O_3) have been investigated in search of low-pressure analogs of these minerals. Here we investigate three 4d-transition-metal sesquioxides: Y_2O_3, Rh_2O_3, and In_2O_3. Y_2O_3 and In_2O_3 undergo pressure-induced transitions accompanied by increase in cation coordination number from 6 to 7. However, in Rh_2O_3, such transition does not occur up to ~350 GPa. This cannot be explained by simple arguments based on ionic radii ratio. By calculating electronic density of states and spatial distributions of the 4d states, it is clarified that effects of 4d electrons are crucial for stability of crystal structures. Extraordinary stability of Rh_2O_3(II)-type Rh_2O_3 against other phases is naturally explained. This study indicates that the complexity of phase sequences in 3d/4d-transition-metal sesquioxides is caused not only by the ionic radii ratio but also by electronic occupancy and spatial distribution of the d states.

The post-spinel transition in Si- and Cr-bearing Fe_3O_4 solid solutions

Schollenbruch, K.[1], Woodland, A.B.[1*], Frost, D.J.[2], Langenhorst, F.[2] & Boffa Ballaran, T.[2]
[1]Institut für Geowissenschaften, Universität Frankfurt, Germany
([*]woodland@em.uni-frankfurt.de)
[2]Bayerisches Geoinstitut, Universität Bayreuth, Germany

Spinel-structured phases occur in many different geological environments and play an important role in the Earth´s upper mantle and transition zone. At high P, some spinels like magnetite (Fe_3O_4) and chromite ($FeCr_2O_4$) transform to denser post-spinel phases (magnetite at ~10 GPa, [1]; chromite at ≥12.5 GPa, [2]), while others break down into their constituent oxides (e.g. $FeAl_2O_4$, [3]). The high-P phase, h-Fe_3O_4, is not quenchable, hampering study of this transition. On the other hand, two high-P polymorphs of chromite were found in a meteorite [2] indicating a stabilizing effect of Cr for the post-spinel structures. Following on our results for Fe_3O_4 [4] we are experimentally studying Si and Cr-bearing Fe_3O_4 solid solutions in an attempt to 1) recover the post-spinel phase for structural investigation, and 2) determine the effects of these cations on phase stabilities at transition zone pressures.

Multi-anvil experiments were performed between 8 and 13 GPa and 1000-1300°C using pre-synthesized spinels with Si-bearing compositions 0.85 Fe_3O_4 – 0.15 Fe_2SiO_4 and 0.7 Fe_3O_4 – 0.3 Fe_2SiO_4 and Cr-bearing solid solutions $Fe(Cr_{0.2},Fe_{0.8})_2O_4$ and $Fe(Cr_{0.5},Fe_{0.5})_2O_4$. In the Si-bearing experiments, a new phase appears at 8 GPa that coexists with a spinel-structured phase. This phase is Si-poor and drives the spinel to higher Si contents than the original bulk composition. At ≥ 10 GPa, the new Si-poor phase becomes dominant and coexists with stishovite. Observed reflections in X-ray and electron diffraction patterns are inconsistent with magnetite or either structure reported for h-Fe_3O_4 (e.g. $CaMn_2O_4$-type, [5], $CaTi_2O_4$-type [6,7]). The new phase is magnetic under ambient conditions and its Mössbauer spectrum is distinct from magnetite. Interestingly, the diffraction peaks are essentially the same as those reported by [8] for an unknown phase found in the system Fe_3O_4-Fe_2SiO_4-Mg_2SiO_4, which they referred to as a "mystery phase". The same structure also occurs in Cr-bearing samples at ≥10 GPa along with either a spinel or an eskolaite - hematite solid solution. In this case, significant amounts of Cr can apparently be incorporated in this new phase.

Structural determination of the "mystery phase" is in progress, but made difficult by its apparent rather low symmetry. Our study points to the stability of another type of high-P post-spinel phase in addition to the reported $CaTi_2O_4$- or $CaMn_2O_4$-type structures found at yet higher pressures.

Ab initio calculation of seismic velocities of phase AnhB ($Mg_{14}Si_5O_{24}$) and implication for the 300 km discontinuity in the Earth's mantle

Belmonte, D.[1*], Civalleri, B.[2], Ganguly, J.[3], Ottonello, G.[1] & Vetuschi Zuccolini, M.[1]
[1]DIPTERIS, Università di Genova, Genoa, Italy
([*]donato.belmonte@unige.it)
[2]Dipto. di Chimica IFM and NIS Centre of Excellence, Università di Torino, Turin, Italy
[3]Dept. of Geosciences, University of Arizona, Tucson, USA

We have carried out *ab-initio* calculations of the longitudinal and transverse seismic velocities, along with the effect of pressure, of the phase Anhydrous B ($Mg_{14}Si_5O_{24}$) (AnhB), using a developed version of the CRYSTAL06 code [1] and the hybrid B3LYP density functional method [2].

The unit cell previously invetigated by us at zero pressure [3] was brought at several compressional states corresponding to different static pressures, carrying out a full optimization of internal coordinates. The calculated second-order elastic constants (*stiffnesses*) were corrected for P through the general equation of Barron & Klein [4,5] expressed in terms of eulerian strain. Fig. 1 shows the single crystal seismic anisotropy obtained at P = 3 GPa using the program CAREWARE [6].

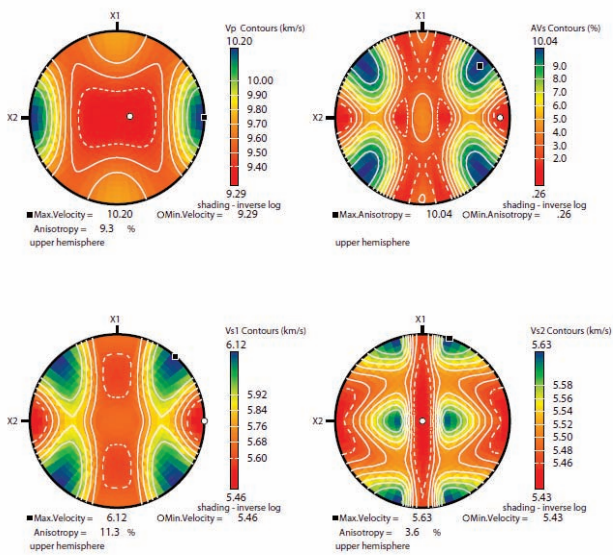

Fig. 1: Single-crystal seismic anisotropy of phase AnhB at P = 3 GPa. Projections are upper hemisphere. X1, X2, X3 are the reference axes for the elastic constants, X1≡[100], X2≡[010], X3≡[001]. Contours in Km/s for Vp, Vs1, Vs2, and in % anisotropy for dVs (top right of the figure).

Single crystal values were then adopted to determine the aggregate seismic velocities using a Voigt-Reuss-Hill averaging procedure. The shear wave impedance change associated with the reaction 5 Forsterite + 4 Periclase = AnhB, which takes place at P-T condition corresponding to the 300 km discontinuity in the Earth's mantle [7], seems to be compatible with that observed for this discontinuity [8].

Elasticity of antigorite and seismic anisotropy of subduction zone

Bezacier, L.[1], Reynard, B.[1], Bass, J.D.[2*], Sanchez-Valle, C.[3] & Van de Moortèle, B.[1]
[1]ENS Lyon, CNRS, Lyon, France
[2]Dept. of Geology, University of Illinois, Urbana, USA
([*]jaybass@illinois.edu)
[3]Institute for Mineralogy and Petrology, ETH, Zürich, Switzerland

Serpentinization of the mantle wedge is an important process that influences the seismic and mechanical properties in subduction zones. Seismic detection of serpentines relies on the knowledge of elastic properties of serpentinites, which thus far has not been possible in the absence of single-crystal elastic properties of antigorite. The elastic constants of antigorite, the dominant serpentine at high pressure in subduction zones, were measured using Brillouin spectroscopy under ambient conditions. In addition, antigorite lattice preferred orientations (LPO) were determined using an electron back-scattering diffraction (EBSD) technique. Isotropic aggregate velocities are significantly lower than those of peridotites to allow seismic detection of serpentinites from tomography. The isotropic V_P/V_S is 1.76 in the Voigt-Reuss-Hill average, not very different from that of 1.73 of peridotite, but may vary between 1.70 and 1.86 between the Voigt and Reuss bonds. Antigorite and deformed serpentinites have a very high seismic anisotropy and remarkably low velocities along particular directions. V_P varies between 8.9 and 5.6 (46% anisotropy), and 8.3 and 5.8 (37%), and V_S between 5.1 and 2.5 (66%), and 4.7 and 2.9 $km.s^{-1}$ (50%) for the single-crystal and aggregate, respectively. The V_P/V_S ratio and shear-wave splitting also vary with orientation between 1.2 and 3.4, and 1.3 and 2.8 for the single-crystal and aggregate, respectively. Thus deformed serpentinites can present seismic velocities similar to peridotites for wave propagation parallel to the foliation or lower than crustal rocks for wave propagation perpendicular to the foliation. These properties can be used to detect serpentinite, quantify the amount of serpentinization, and to discuss relationships between seismic anisotropy and deformation in the mantle wedge. Regions of high V_P/V_S ratios and extremely low velocities in the mantle wedge of subduction zones (down to about 6 and 3 $km.s^{-1}$ for V_P and V_S in pure serpentinite, respectively) are difficult to explain without strong preferred orientation of serpentine. Local variations of anisotropy may result from kilometer-scale folding of serpentinites. Shear wave splittings up to 1-1.5s can be explained with moderately thick (10-20 km) serpentinite bodies.

Metallic alloys and zoned spinels in interstitial glasses from mantle lherzolites

Ryabchikov, I.D.[1*], Ntaflos, Th.[2], Kogarko, L.N.[3] & Kurat, G.[2]
[1]Institute for Geology of Ore Deposits, Russian Academy of Sciences, Moscow, Russia ([*]iryab@igem.ru)
[2]Dept. of Geological Sciences, University of Vienna, Austria
[3]V.I. Vernadsky Institute of Geochemistry, Russian Academy of Sciences, Moscow, Russia

We report evidence that suboceanic lithospheric mantle under island of Sal, Cape Verde archipelago was infiltrated by the highly reduced magma at some time prior to the eruption of host melanephelenites, which brought fragments of these mantle material to the surface. These melts are now represented by interstitial glasses in peridotites which contain sulphide grains, among them troilite, with the inclusions of Fe-Ni alloys and separate metallic phases [1]. Outer part of zoned spinel grains which have grown from such melts show abrupt drop in Fe^{3+} contents, which indicates drastic decrease in f_{O_2} values (Fig. 1). On the other hand, $Fe^{3+}/\Sigma Fe$ values for inner zones are close to 0.27 which is normal for spinels from mantle lherzolites.

In order to assess oxidation state of iron in spinels we performed analyses on electron microprope with separate determination of metals and oxygen. This permitted to calculate Fe^{2+} and Fe^{3+} contents using balance of charges principle.

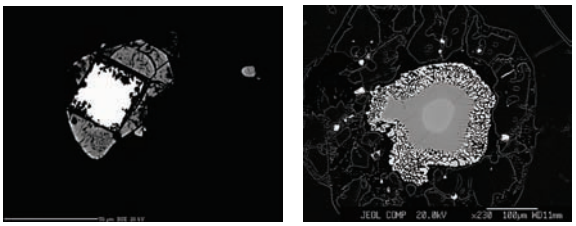

Fig. 1: Ni-Fe alloy surrounded by pentlandite in glass (left) and zoned spinel with Fe^{3+}-free rim surrounded by glass with small grains of Cr-rich spinel (right).

Analysed spinels are very close to ideal stoichiometry: number of cations per 4 oxygens does not differ from 3 by more than 0.002. Therefore, ferric and ferrous iron contents in spinels from spinel lherzolites may be calculated from usual microprobe analyses under the assumption of ideal stoichiometry.

Oxygen fugacity calculated for the equilibrium of intergranular melt and microphenocrysts of olivine and clinopyroxene with Fe-Ni alloys present in Sal mantle xenoliths using equilibrium constants of the following reactions

$Fe_2SiO_4 + CaMgSi_2O_6 = 2Fe + CaMgSiO_4 + O_2$ and

$Ni_2SiO_4 + CaMgSi_2O_6 = 2Ni + CaMgSiO_4 + O_2$, is approximately 4÷5 log units below QMF buffer. At such low f_{O_2} values spinels should contain almost no ferric iron, which is observed in the rims of zoned spinels surrounded by glass.

Very narrow widths of transitional zones between Fe^{3+}-bearing cores and Fe^{3+}-free rims of spinels imply that parts of Cape Verde mantle were invaded shortly before the eruption by highly reduced melt carrying sulphur deficient sulphides and Fe-Ni alloys. Extreme redox differentiation in the mantle may be caused by the disproportionation of Fe^{2+} into Fe^{3+} and Fe^0, which may occur in the lower part of subcontinental lithosphere, in transition zone, in lower mantle or in D" layer near the core-mantle boundary. Fe^0 will be dissolved in interstitial sulphide melts present in the mantle. Migration of such S-deficient sulphide melts would create relatively oxidised and reduced domains in the mantle.

Thermal expansivity and dehydrogenation process in gedrite

Oberti, R.[1*], Welch, M.D.[2] & Zema, M.[3]
[1]CNR-IGG, UOS Pavia, Italy ([*]oberti@crystal.unipv.it)
[2]Dept. Mineralogy, The Natural History Museum, London, UK
[3]Dept. Earth Sciences, University of Pavia, Italy

The crystal chemistry of gedrite-group amphiboles has been recently discussed by [1,2], who also clarified relations among bond topology, bond valence and site preference and identified similarities and differences between monoclinic and orthorhombic amphiboles. The present work is aimed at providing information on the behaviour of gedrite at high-T conditions, in terms of thermal expansivity and cation order and dehydrogenation processes. The only data available on thermal expansivity of orthorhombic amphiboles concern anthophyllite [3], and no dehydrogenation occurs due to the lack of Fe^{2+}. Sample A(26) in [1] (code AMNH136484), with reported composition $^{A}Na_{0.46}$ $^{B}(Mg_{1.11}Fe^{2+}_{0.83}Mn_{0.02}Ca_{0.04})$ $^{C}(Mg_{3.44}$ $Fe^{2+}_{0.33}$ $Al_{1.18}Ti_{0.05})$ $^{T}(Si_{6.26}$ $Al_{1.74})$ $O_{22}OH_2$, was annealed up to 1273 K at intervals of 25 K using a micro furnace. Unit-cell parameters were measured *in situ* at each step, and structure refinement was done from single-crystal diffraction data collected at 533, 723 and 973 K during both annealing and reversal (thus on the partially dehydrogenated phase).

The almost linear increase in the unit-cell parameters (α_V = 3.15 $\times 10^{-5}$ K^{-1}, α_a = 1.10 $\times 10^{-5}$ K^{-1}, α_b = 0.94 $\times 10^{-5}$ K^{-1}, α_c = 1.19 $\times 10^{-5}$ K^{-1}) ends around 973 K, where an abrupt contraction in all the edges (much stronger in *a*) indicates the start of the dehydrogenation process, which proceeds by migration and oxidation of all Fe from the *M*4 to the *M*1 and *M*3 sites and significant changes in site geometry. When dehydrogenation stops (as monitored through unit-cell variations), reversal experiments down to R*T* allowed calculation of thermal expansion coefficients of the partially dehydrogenated phase: α_V = 3.51 $\times 10^{-5}$ K^{-1}, α_a = 1.15 $\times 10^{-5}$ K^{-1}, α_b = 1.09 $\times 10^{-5}$ K^{-1}, α_c = 1.26 $\times 10^{-5}$ K^{-1}. The crystal was then heated at 1273 K and finally cooled to room *T* to check for the completeness (as far as allowed by the Fe^{2+} content) of the dehydrogenation process.

A significant difference in thermal expansivity with respect to anthophyllite is observed only for the much greater stiffness of the *a* edge (α_a = 1.49 $\times 10^{-5}$ K^{-1} in [3]), and is related to the presence of a half-filled A site in gedrite. Na disorders into two different positions within the A cavity in the dehydrogenated sample, the second of which is closer to the A chain and particularly to the O3A oxygen atom. Hence, the dehydrogenated samples have a different bond valence arrangement. The behaviour of the different cation polyhedra and structure moduli during annealing and dehydrogenation, and differences with respect to anthophyllite and monoclinic amphiboles will be discussed.

Single-crystal elasticity of superhydrous phase B, $Mg_{10}Si_3O_{18}H_4$, by Brillouin scattering spectroscopy

Rosa, A.D.[*], Sanchez-Valle, C., Wang, J. & Saikia, A.
Inst. for Geochemistry and Petrology, ETH Zurich, Switzerland
([*]angelika.rosa@erdw.ethz.ch)

Superhydrous phase B, $Mg_{10}Si_3O_{18}H_4$ (here referred to ShyB), belongs to the group of dense hydrous magnesium silicate phases (DHMS) that have been identified as the major water reservoirs in deep subducted slabs. Experimental studies in peridotitic compositions have shown that ShyB can be stable up to 30 GPa and 850°C and thus play an important role in the recycling of water at depth. In order to formulate accurate mineralogical and compositional models of subducted slabs and to interpret seismic observations in these areas, precise elasticity data at relevant P-T conditions are needed for this phase. The bulk modulus of ShyB has been measured by X-ray diffraction in both multi-anvil apparatus and diamond anvil cells in single-crystals and polycrystalline samples [1-3] as well as by Brillouin scattering spectroscopy [4]. However, existing results show large discrepancies.

In this contribution we present results of Brillouin scattering measurements of sound velocities and single-crystal elastic properties of ShyB at ambient conditions. Single-crystals used in this study were synthesised in a multi-anvil press at ETH Zurich at 20 GPa and 1200°C. The samples were confirmed to be ShyB by single-crystal x-ray diffraction and chemical composition determined by EMPA is $Mg_{10.4}Si_{3.1}O_{18}H_{2.7}$. Brillouin scattering measurements were conducted in platelet scattering geometry in three different samples at ambient conditions. A total of 82 mode velocities were used to invert the 9 independent components of the C_{ij} elastic tensor.

The Voigt-Reuss-Hill averages of the adiabatic bulk and shear moduli are K_S = 150(3) GPa and μ = 98(2) GPa, respectively. These results are in good agreement with the previous Brillouin scattering study by [4]. The results show that the aggregate compressional and shear wave velocities, V_P = 9.17(9) and V_S = 5.43(4) km/s, are the lowest among coexisting phases in subducted peridotites, including Mg-Perovskite, hydrous Ringwoodite or Ferropericlase. The velocity distribution calculated from the best-fit elastic model of ShyB reveals nearly isotropic seismic behaviour of ShyB at room conditions. The compressional anisotropy (A_P) amounts only 6.6% whereas the shear anisotropy (A_S) has a slightly higher value of 1.6%. If the moderate anisotropy of ShyB is maintained at high P-T, the strong seismic anisotropy observed in subducted slabs below the transition zone may be difficult to explain without strong preferential orientation (LPO) in this phase. In view of the structure of ShyB we will further discuss the effects of various possible LPO types on the single-crystal anisotropy of ShyB in the slab.

Geoelectric abnormity in earthquake and thermoelectricity of magnetite

Shen, Junfeng[1*], Shen, Xuhui[2] & Liu, Qian[1]
[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China ([*]shenjf@cugb.edu.cn)
[2]Institute of Earthquake Science, China Earthquake Administration, Beijing, China

Geothermal and geoelectric fields are often changed in the course of the earthquake's gestating and occurring periods. According to the theory on thermo-electricity conversion, geoelectricity can be impacted by gradient thermal field which formed on the room around the earthquake focus. By understanding accurately on the discipline of geoelectric variety, some important information which related with earthquake occurrence in deep crust can be obtained.

Because the magnetite is existed far and wide in crust, and also often form a large aggregate. So that magnetite is maybe better medium for thermoelectric conversion.

BHTE-06 thermoelectric instrument was used for the thermoelectricity test on magnetite by under 10-80°C. temperature difference (also called active-temperature). The results showed that approximative 0.3mm magnetite grain can generate -2.175mv voltage in average, and max. value is -4.5mv. Which means natural magnetite belongs to N type semiconductor minerals. Thermoelectric coefficient (thermal voltage increment above temperature difference) was computed, and showed it is a constant nearly, and is approximatively -0.05mv/°C. Also, it is a remarkable linear between thermal voltage and temperature difference, and its correlation coefficient is 0.985. Other more, the thermoelectricity is independent of the genesis and crystal direction of magnetite.

Based on the results mentioned above, authors consider that thermoelectric mode in earthquake is a possible mechanism on geoelectric abnormity. So, a new idea on geoelectric abnormity in earthquake was proposed, that is thermoelectric mode.

The following viewpoints were emphasized in the thermoelectric mode. Namely, more magnetite mineral aggregates are existed in the crust, and once excitated by pulsed gradient thermal field caused by earthquake, it will be turned into dipole voltaic source in underground due to dipole effect, and the dipole voltaic source will produce an accessional dipole pulsed electric field. Moreover, this electric field leads to a pulsed electric field abnormity while it was added to telluric electricity field and natural electric field. Therefore, based on related physical geography theory, a calculation formula on intensity for additional thermoelectric field caused by thermoelectricity can be written as:

$$E = -0.159\frac{\sigma \times \Delta T \times \Phi \times \rho_c \times [(h^2 - 2x^2)Cos\alpha + 3hxSin\alpha]}{\rho_m (h^2 + x^2)^{5/2}}$$

The formula showed that thermoelectric fields E are impacted by several factors, such as thermoelectric coefficient of semi-conductive mineral σ, resistivity ρ_m, embedded depth h, vertical section area to thermo current Φ and angle of connective line to two pole with horizontal plane α, also temperature difference ΔT, crust resistivity ρ_c, and the distance from observation point to semi-conductive mineral aggregate projective point on earth face x. In terms of simulated calculation followed the formula, the additional thermoelectric field E may reach to n mV/km to $n\times10^2$ mV/km, and the max. value is more than $n\times10^3$ mV/km. Such electric field intensity is strong enough to cause geoelectric abnormity on earth face, so that thermoelectricity is one of criterions for deep crust information in earthquake.

High-pressure behavior of $FeTiO_3$: decomposition into $(Fe_{1-x},Ti_{0.5x})O$ and $FeTi_3O_7$

Yagi, T.[1*], Nishio-Hamane, D.[1], Ohshiro, M.[1], Niwa, K.[2], Okada, T.[1] & Seto, Y.[3]
[1]Inst. for Solid State Physics, University of Tokyo, Kashiwa, Japan ([*]yagi@issp.u-tokyo.ac.jp)
[2]Dept. of Materials Science and Engineering, Nagoya University, Nagoya, Japan
[3] Dept. of Earth and Planetary Science, Kobe University, Kobe, Japan

Divalent transition metals do not favor perovskite structure and most of the ABO_3-type compounds with divalent transition metal decompose into simple oxides under pressure. Among them, $FeTiO_3$ is a unique compound which crystallizes into a single phase of perovskite above about 16 GPa. In order to clarify the stability of this perovskite phase, we have studied the phase relation of $FeTiO_3$ up to a pressure of about 67 GPa by synchrotron X-ray diffraction and analytical transmission electron microscopy.

We have found that $FeTiO_3$ perovskite decomposes into $(Fe_{1-x},Ti_{0.5x})O$ wüstite and $FeTi_3O_7$ phase, at above 40 GPa and 2000 K. The $FeTi_3O_7$ phase has the orthorhombic unite cell, although the detail of the crystal structure is still unclear. Figure 1 shows the representative X-ray diffraction patterns and TRP is the $FeTi_3O_7$ phase while WP is the wüstite phase. Although the recent study on $FeTiO_3$ [1] reported almost the identical X-ray diffraction pattern, their explanation on decomposed products was clearly in error, because they did not do any direct chemical analysis.

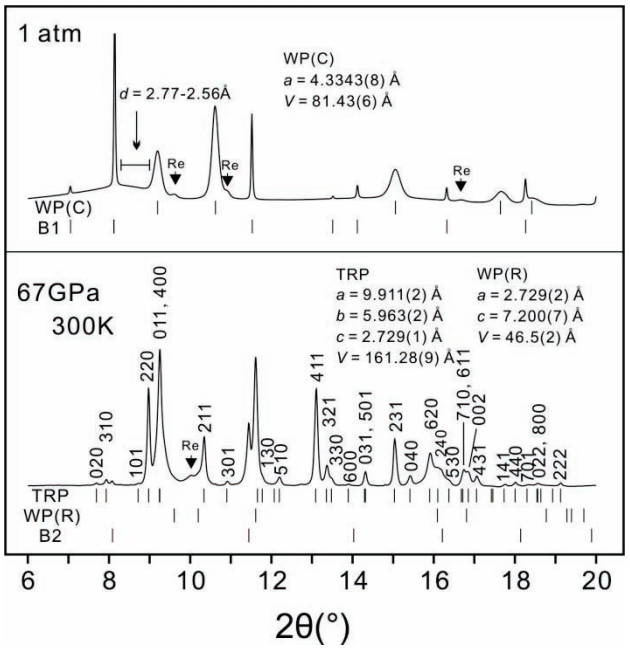

Fig. 1: Representative X-ray diffraction pattern of $FeTiO_3$ after heating at 67GPa (bottom) and after recovering to ambient condition (top).

Our study also demonstrates that the phase assemblage of $(Fe_{1-x}, Ti_{0.5x})O$ and $FeTi_3O_7$ is the densest in the $FeTiO_3$ system, implicating a new fate for ABO_3-type compounds under high pressure condition such as the deep interior of the terrestrial planets.

Effect of hydrogen and aluminum on the elastic properties of orthopyroxene: implications for mantle discontinuities

Wang, J.Y.[1*], Sanchez-Valle, C.[1] & Stalder, R.[2]
[1]Institute for Geochemistry and Petrology, ETH Zurich, Switzerland ([*]jingyun.wang@erdw.ethz.ch)
[2]Inst. für Mineralogie und Petrographie, Universität Innsbruck, Austria

Olivine, orthopyroxenes, garnets, and clinopyroxenes are major minerals in the upper mantle. Studies on the elastic properties of the minerals have provided essential understanding of geochemical and seismic observations for the upper mantle. While the elastic properties of Mg- and Fe-end-members have been relatively well-studied, there is still a lack of knowledge for the effect of minor element on the elastic properties of opx.

Aluminum and hydrogen are two important minor elements observed in natural opx. Here we investigate the effect of these elements on the single-crystal elastic properties of orthopyroxees using Brillouin scattering spectroscopy. Hydrous aluminum-free opx (HyOpx) and hydrous aluminum-bearing opx (AlOpx) samples were synthesized at 2.5 GPa and 1150°C in piston-cylinder apparatus. HyOpx contains 280 ppm H_2O, while AlOpx has Al_2O_3 content of 6.3 wt% similar to natural opx with 1500 ppm H_2O and 0.26 wt% FeO. The aggregate bulk (K_S) and shear (μ) elastic moduli of HyOpx, K_S = 108.5(9) GPa and μ = 77.0(4) GPa, are indistinguishable from those of anhydrous opx. This comparison suggests that incorporation of H_2O up to 280 ppm does not significantly affect the elastic properties of $MgSiO_3$-orthoenstatite. The aggregate elastic moduli of AlOpx, K_S = 126.2(1.2) GPa and μ = 81.3(8) GPa, are however higher than those of pure $MgSiO_3$-orthoenstatite by 14.7 and 6%, respectively. These results indicate that substitution of Al^{3+} for smaller Si^{4+} in tetrahedral sites in natural opx increases the bulk modulus relative to Mg-end-members. This conclusion is supported by the strong increase in the C_{33} elastic constant upon Al substitution showing the stiffening of the tetrahedral chains along c-axis. Consequently, the aggregate velocities of AlOpx, V_P = 8.50(9) km/s and V_S = 5.01(6) km/s, are 7% and 4% higher than those of the magnesian end-member. Aluminum has thus the strongest effect on the seismic velocities of opx among all minor elements.

Results of elasticity of AlOpx at high pressure conditions will be presented to explore the influence of Al^{3+} on the phase transition from orthopyroxene to clinopyroxene and discuss its relation to the seismic X discontinuity (~300 km depth) observed in the upper mantle. We will also discuss the effect of Al^{3+} on the aggregate velocities and elastic anisotropy of opx at high pressures to provide better constrains on the composition and mineralogy of the upper mantle.

High-pressure behaviour of $SrAl_2Si_2O_8$ feldspar

Pandolfo, F.[1*], Boffa Ballaran, T.[2], Nestola, F.[3], Koch-Müller, M.[4], Mrosko, M.[4] & Bruno, E.[5]
[1]Dept. Scienze della Terra, University of Pavia, Italy ([*]fra.pandolfo@gmail.com)
[2]Bayerisches Geoinstitut, Universität Bayreuth, Germany
[3]Dept. of Geoscience, University of Padova, Italy
[4]Dept. Chem. Earth, GeoForschungsZentrum, Potsdam, Germany
[5]Dept. Scienze Mineralogiche e Petrologiche, University of Torino, Turin, Italy

A single crystal of Sr-feldspar with end-member composition $SrAl_2Si_2O_8$ (space group *I*2/*c* at room pressure) and 1100 ppm of structural OH was investigated by X-ray diffraction at high-pressure *in situ* using a diamond anvil cell up to 7.8 GPa and compared with a sample of the same composition totally anhydrous investigated up to 5 GPa. Between 6.57 and 6.61 GPa the hydrous sample shows a thermodynamically first order phase transition from *I*2/c to $P2_1/c$ (a previous phase transformation reported from *I*2/c to a triclinic phase is not confirmed here for the same end-member composition [1]). The compressibility of the *I*2/*c* phase is clearly lower than that of $P2_1/c$ one. Moreover, the *I*2/*c* phase showed an anomalous unit-cell volume behaviour between 3.67 and 6.57 GPa, which cannot be ascribed to a further symmetry change (based on the systematic absence analysis) and neither an isosymmetric phase transformation can be evoked (e.g. no discontinuous change in the volume typical of a isosymmetric transition is found). Due to such anomaly (volume softening) it was impossible to fit the pressure – volume data using a single equation of state. Comparing these data up to 5 GPa with those of anhydrous sample we did not find any observable difference indicating that an amount of only 1100 ppm of water does not influence the compressional behaviour of $SrAl_2Si_2O_8$ feldspar. With respect to a previous work on a composition $(Ca_{0.20}Sr_{0.80})Al_2Si_2O_8$ (showing a sequence of transitions from $I\bar{1}$ to *I*2/*c* to $P2_1/c$ with pressure [2]) our data show that the same *I*2/*c* to $P2_1/c$ transformation occurs at a pressure 0.6 GPa higher due to entrance of Ca.

Our new results supply further information on the stability field diagram along the $CaAl_2Si_2O_8$ - $SrAl_2Si_2O_8$ join as function of pressure and provide new insights relative to the high-pressure behaviour of anorthite, which remains still to be investigated for pressures above 7-8 GPa and that could show the same transformation sequence showed in the Sr-richer side of the diagram.

Formation of a perovskite solid solution between $MgSiO_3$ and $MnSiO_3$ at the lower mantle condition

Nagai, T.[1*], Ishido, T.[1] & Fujino, K.[2]
[1]Dept. of Natural History Sciences, Hokkaido University, Sapporo, Japan ([*]nagai@mail.sci.hokudai.ac.jp)
[2]Geodynamics Research Center, Ehime University, Matsuyama, Ehime, Japan

Silicate perovskites are important constituent minerals in the lower mantle. We recently found that $MnSiO_3$ perovskite with orthorhombic symmetry is stable at the lower mantle condition [1]. Now it is greatly interesting how much $MnSiO_3$ component can incorporate into $MgSiO_3$ perovskite.

We prepared gel compounds with chemical compositions of $MgSiO_3$:$MnSiO_3$ = 9:1, 3:1, 1:1 and 1:3 (mol ratios) as the starting materials. High pressure and high temperature experiments were performed using a laser-heated diamond anvil cell combined with synchrotron X-ray diffraction (PF-AR and Spring8, Japan) at the pressures between 30 and 60 GPa, and at the temperatures between 1300 and 2000 K.

From the diffraction patterns obtained at high pressure, we confirmed the existence of $(Mg,Mn)SiO_3$ perovskites with all the compositions prepared. All the perovskites have orthorhombic symmetry and variations of lattice parameters at about 50 GPa shows almost linear correlation with the chemical composition. Only $(Mg_{0.9},Mn_{0.1})SiO_3$ perovskite is quenchable at an atmospheric pressure, but the others become amorphous during decompression. We conclude that the system of $MgSiO_3$-$MnSiO_3$ forms a complete perovskite solid solution at the lower mantle condition.

Sodium-bearing majoritic garnet: natural and experimental aspects

Bobrov, A.[1*], Dymshits, A.[1], Litvin, Yu.[2], Litasov, K.[3], Shatskiy, A.[3] & Ohtani, E.[3]
[1]Geological Faculty, Moscow State University, Moscow, Russia ([*]archi673@yandex.ru)
[2]Institute of Experimental Mineralogy, Chernogolovka, Russia
[3]Tohoku University, Sendai, Japan

Majoritic garnets were found as inclusions in diamonds from several localities worldwide, including South Africa, Guinea, Canada, Brazil, Russia, and China (see [1] for review). They belong to both the peridotitic and eclogitic suites. However majoritic garnets with Si atoms pfu >3.07 are almost exclusively eclogitic. These majorites show high Na with Na_2O wt% ranging up to ~1.4. Recently Harte and Cayzer [2] have documented evidence of exsolution textures involving clinopyroxene and majoritic garnet which indicate original majoritic garnets with up to 2.16 wt% Na_2O. Most of the Na present in majoritic garnet is accommodated via the pressure dependent exchange reaction $Na^+ + Si^{4+} = Mg^{2+} + Al^{3+}$ (Na for Mg in the X site and Si for Al in the Y site). Such mechanism of sodium incorporation in majoritic garnet supports the idea of a presence of the $Na_2MgSi_5O_{12}$ end-member in garnet solid solution [3].

As is evident from the experimental study of the model systems pyrope ($Mg_3Al_2Si_3O_{12}$)-Na-majorite ($Na_2MgSi_5O_{12}$), pyrope-jadeite ($NaAlSi_2O_6$), and pyrope-Na_2CO_3 at P = 7.0 and 8.5 GPa and T = 1100-1900°C [4], magmatic crystallization of Na-bearing majoritic garnet and its composition are controlled by several factors, among which are melt composition, pressure, and temperature. Experiments confirmed the compatibility of Na-bearing majoritic garnet with sodium-rich silicate and carbonate-silicate melts. In all systems, an increase of pressure leads to the growth of sodium content in garnet. In addition, in all studied systems, a decrease of temperature relatively to liquidus values resulted in the successive increase of sodium content, so that the highest sodium concentrations were observed at the solidus of the systems.

Multianvil experimental study of the pyrope-$Na_2MgSi_5O_{12}$ system at 11–20 GPa and 1900–2300°C demonstrated further increase of both Na and Si in liquidus garnet. Maximal concentration of $Na_2MgSi_5O_{12}$ end-member (3.785 pfu Si and 0.739 pfu Na or 5.7 wt% Na_2O) was obtained at 20 GPa. Our experiments provide evidence for complete miscibility in this system at least up to 40 mol% of Na-component. We synthesized pure $Na_2MgSi_5O_{12}$ garnet and established P-T conditions of the pyroxene/garnet transition for the first time. The results obtained allow us to assume that Na-majorite is a possible concentrator of sodium under the conditions of deep upper mantle and transition zone, where the stability of pyroxene phase is limited.

A new hydrated high pressure phase in the MASH system

Gemmi, M.[1], Merlini, M.[1*], Fischer, J.[1], Poli, S.[1], Mugnaioli, E.[2] & Kolb, U.[2]
[1]Dipto. di Scienze della Terra, Università degli Studi di Milano, Italy ([*]marco.merlini@unimi.it)
[2]Institute of Physical Chemistry, Johannes Gutenberg-University, Mainz, Germany

The MgO-Al_2O_3-SiO_2-H_2O (MASH) system is well known to be a simplified model system for the study of water transport and recycling into Earth's mantle via subduction processes. Therefore any new water bearing phase arising in P, T conditions compatible with the subducted slab is highly interesting for the comprehension of the complex geological processes determining the dynamical evolution of subducting zones. A new phase with these characteristic have been discovered in experimental runs having clinochlore bulk composition, in the P,T range of 5.2-5.5 GPa and 680-720 °C. It is monoclinic with space group C2/c and unit cell parameters a=9.882(1), b=11.623(1), c=5.081(1), β=111.1(1)°. The new phase has been identified with conventional electron diffraction. Its structure has been solved using the automated electron diffraction technique (ADT) [1-3]. This new technique allows a single crystal electron diffraction experiment on crystals of less than 1μm. The obtained intensities are quasi kinematical and therefore suitable for a conventional direct methods structure solution attempt. To our knowledge this is the first high pressure phase solved in this way. It has chemical composition of $Mg_{2.1}Al_{1.8}Si_{1.1}O_6(OH)_2$, and has a pyroxene like structure with 3 cations instead of 2 in the octahedral layer, which force the tetrahedral chains to be more separate. The two anion sites of the extra octahedral cation, that are not shared with any tetrahedra are occupied by an hydroxyl. Thanks to the structure solution obtained by ADT it has been possible to synthesise an almost pure sample suitable for powder x-ray diffraction analysis. Rietveld refinement on this data and image simulation of high resolution electron microscopy images further confirm this structural model.

First crystal-structure determination of an olivine inclusion still trapped in a diamond: composition and implications for diamond source pressure

Nestola, F.[1*], Nimis, P.[1], Ziberna, P.[1], Longo, M.[1], Marzoli, A.[1], Harris, J.W.[2], Manghnani, M.H.[3] & Fedortchouk, Y.[4]
[1]Dipt.o di Geoscienze, Università di Padova, Italy ([*]fabrizio.nestola@unipd.it)
[2]Dept. of Geographical and Earth Sciences, University of Glasgow, UK
[3]Hawaii Institute of Geophysics and Planetology, University of Hawaii, Honolulu, USA
[4]Dept. of Earth Sciences, Dalhousie University, Halifax NS, Canada

A novel experimental approach using single-crystal X-ray diffraction has been applied to the study of an olivine inclusion still trapped in a Siberian diamond. The experimental procedure, typically used for in situ high-pressure studies (i.e. diamond-anvil cell), allowed us (i) to determine with high precision the internal pressure at the inclusion, and (ii) to refine for the first time the crystal structure of the olivine without extracting it from the host diamond. The crystallographic data allowed us to refine the mean number of electrons on the M2 and M1 crystallographic sites of the olivine and to obtain a composition Fo93Fa7. Knowing the P-V equation of state for such composition, we determined an internal pressure of 0.40(2) GPa. This pressure value is used to estimate the pressure of formation of the host diamond, taking into account elastic relaxation and using the most up-to-date compressibility and thermal expansion parameters for olivine and diamond.

High-pressure phase relations in $FeCr_2O_4$ and in the system $NaAl_3Si_3O_{11}$-$CaAl_4Si_2O_{11}$ with implications to post-spinel phases and Na-rich CAS phase in shocked meteorites

Akaogi, M.*, Tsukamoto, S., Kojitani, H. & Haraguchi, M.
Dept. of Chemistry, Gakushuin University, Tokyo, Japan
(*masaki.akaogi@gakushuin.ac.jp)

Studies on natural high-pressure minerals in shocked meteorites provide valuable information on mineralogy and properties of the Earth's deep mantle, as well as the shock processes. Recently, two high-pressure polymorphs of $FeCr_2O_4$-rich chromite were found in a shocked meteorite by [1,2]. The two phases have calcium-ferrite ($CaFe_2O_4$) type and calcium-titanate ($CaTi_2O_4$) type structures. These were the first report on natural occurrences of post-spinel polymorphs of $A^{2+}B^{3+}{}_2O_4$. Although high-pressure stability relations in $FeCr_2O_4$ can be used to constrain the P,T conditions of the shock events, they have not yet been fully examined. In several shocked Martian meteorites, [3] found a high-pressure calcium aluminosilicate (CAS) phase with 75mol% $NaAl_3Si_3O_{11}$-25mol%$CaAl_4Si_2O_{11}$ composition. Although $CaAl_4Si_2O_{11}$-rich CAS phase with the hexagonal Ba-ferrite structure has been synthesized in HP phase assemblages of continental crust, sediments and basalt, no stability relations in the system $NaAl_3Si_3O_{11}$-$CaAl_4Si_2O_{11}$ have been examined.

In this study, we have determined the phase relations in $FeCr_2O_4$ and in the $NaAl_3Si_3O_{11}$-$CaAl_4Si_2O_{11}$ system, in order to apply the results to evaluate P,T conditions of the formation processes of the natural high-pressure minerals in the shocked meteorites. The high-pressure experiments were carried out up to 27 GPa and 1900°C, using a multianvil apparatus. The quenched samples were analyzed by means of microfocus and powder X-ray diffractometers and a scanning electron microscope with an energy-dispersive detector. Above about 14 GPa, $FeCr_2O_4$ chromite with spinel structure first dissociates into a new $Fe_2Cr_2O_5$ phase and Cr_2O_3 with corundum structure. The new $Fe_2Cr_2O_5$ phase has the same structure as a high-pressure form of $Mg_2Al_2O_5$ found by our recent high-pressure experiments in $MgAl_2O_4$ [4]. At 16-19 GPa, the two phases further combine into $FeCr_2O_4$ polymorph with calcium-ferrite structure below about 1300°C, while the other polymorph with calcium-titanate structure becomes stable above about 1300°C. Both of the calcium-ferrite and calcium-titanate phases are stable up to at least 27 GPa. These results suggest that the natural $FeCr_2O_4$-rich calcium-ferrite and calcium-titanate were formed at pressure above 19 GPa at temperature below and above 1300°C, respectively, during the shock event.

The CAS phase with $CaAl_4Si_2O_{11}$ composition is stable above about 13 GPa at 1600°C [5]. In the system $NaAl_3Si_3O_{11}$-$CaAl_4Si_2O_{11}$, the CAS phase dissolving $NaAl_3Si_3O_{11}$ component coexists with jadeite, corundum and stishovite below 22 GPa, above which the CAS phase coexists with Na-rich calcium ferrite, corundum and stishovite. At 1600°C, the maximum solubility of $NaAl_3Si_3O_{11}$ component in the CAS solid solution is about 50 mol% at 22 GPa, and it increases to about 70 mol % at 1900°C. The dissociation of $NaAlSi_2O_6$ jadeite to $NaAlSiO_4$ calcium ferrite plus stishovite occurs at about 22 GPa at 800-2000°C. When we adopt the Na:Ca ratio of 75:25 of the natural Na-rich CAS-phase in the shocked Martian meteorite [3], our results suggest that the natural CAS-phase crystallized at pressure around 22 GPa and temperature of about 2000-2200°C. The inferred P,T conditions are consistent with those estimated using other high-pressure minerals in the shocked meteorite.

Sound velocities of Earth's deep materials

Murakami, M.
Tohoku Univesity, Aramaki Aoba-ku, Sendai, Japan
(motohiko@m.tains.tohoku.ac.jp)

Average composition and structure of the Earth's deep interior can be approached by comparing observed seismic velocities to appropriate laboratory data collected for candidate materials under relevant conditions. Precise knowledge of the elastic properties of Earth's deep materials under high-pressure condition is crucial for constructing the accurate mineralogical model of the Earth's deep interior. However, only few experimental acoustic measurements exist under relevant high-pressure conditions. Recent technical advances in high-pressure Brillouin spectroscopic measurements combined with diamond anvil cell apparatus extended significantly the upper pressure limit for acoustic measurements [1,2] and also enable us to explore the sound velocities under high-pressure and high-temperature conditions using infrared laser heating technique [3]. Here we present the recent progress of elastic wave velocity measurements on Earth's deep materials by Brillouin spectroscopy in a diamond anvil cell (DAC) in conjunction with synchrotron X-ray diffraction technique under ultrahigh-pressures. Based on the results we have recently obtained on mantle minerals [4] and glass materials [5] (Fig. 1), the mineralogy of deep mantle and the structure of the silicate melt in the deep magma ocean will be discussed.

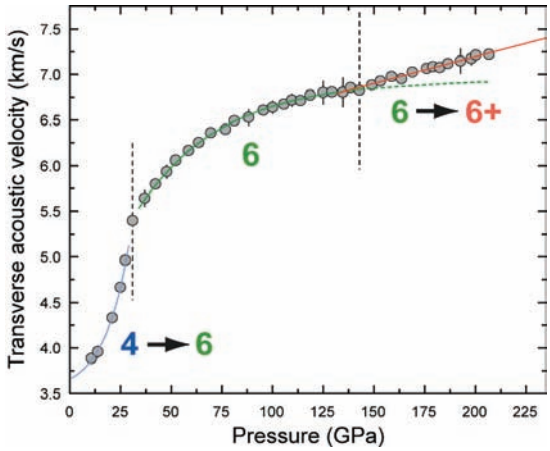

Fig. 1: Transverse acoustic wave velocities of SiO_2 glass as a function of pressure up to 207 GPa [5]. The velocity trajectories for three distinct high-pressure regimes are shown as blue, green and orange lines, respectively. Numbers indicate the potential Si-O coordination number within each pressure regime. Approximate pressure boundaries for each Si-O coordinated structure are shown as the vertical dotted lines.

Pressure-induced high spin - low spin transitions of iron in the lower mantle minerals are very important to understand the mineral behaviours such as structural change and iron partitioning, and to understand the dynamics of the lower mantle. However, the spin transition of iron in Mg-perovskite, the most abundant lower mantle mineral, has been the issue of a great deal of controversy. There have been large discrepancies among previous experimental studies and also between the results of theoretical and experimental studies. We think that these discrepancies largely originate from the poor quality and/or poor characterization of the experimental samples. This time, we could obtain the data on the spin state of Fe^{3+} in Mg-perovskite up to 200 GPa (the highest pressure ever reported) by the X-ray emission spectroscopy (XES) using well qualified samples. These results are fairly consistent with the theoretical reports and explain the diversity among the experimental reports to a certain extent.

We measured the XES data of Fe^{3+} in Mg-perovskite of the composition $Mg_{0.85}Fe^{3+}_{0.15}Al_{0.15}Si_{0.85}O_3$ loaded in a diamond anvil cell at BL-12 of SPring-8. The obtained XES patterns show high spin at pressures up to around 120 GPa and then the k_β' peaks gradually decrease at higher pressures. However, even at 200 GPa, the XES pattern is still intermediate between the high spin and low spin patterns. These XES patterns at various pressures are well fitted by the linear combination of the high spin and low spin patterns of the reference material Fe_2O_3, and the fitted ratio of the low spin pattern increases gradually, not stepwise, with pressure. These results indicate that Fe^{3+} at the A-site of Mg-perovskite is high spin up to 200 GPa, while Fe^{3+} at the B-site becomes low spin at relatively low pressure. In addition, the gradual increase of the fitted ratio of the low spin pattern suggests that Fe^{3+} at the A-site replaces Al at the B-site by the cation exchange reaction caused by the annealing (around 1000 K - 1400 K) of the samples during the XES measurements. This means that the spin state of iron in the experimental samples is not only a function of pressure and temperature during measurement but also affected by the heat treatment of the samples during the experiments. From the present results, most Fe^{3+} in $FeAlO_3$-bearing Mg-perovskite in the deep lower mantle is expected to be in the low spin state at the B-site.

Garnet of the pyrope-majorite series

Bryanchaninova, N.I. & Makeev, A.B.*
Dept. of Petrography, Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry RAS, Moscow, Russia (*abmakeev@mail.ru)

Majorite discovered in Coorara meteorite is very rare in the terrestrial rocks. The pyrope with high content majorite component $Mg_3Fe_2[SiO_4]_3$ (26–42%), similar that described only from meteorites and as small inclusions in superdeep diamonds and was found in the kersantite-spessartite dikes in the Middle Timan. Majorite pyrope to variable degree is associated with diamond. On the one hand, it occurs as inclusions in diamond crystals, on the other hand, in rocks, where such garnet is found, microcrystalline diamond is established. According to modern systematics of garnets, ideal formula of majorite is expressed as $Mg_3Fe_2[SiO_4]_3$. Majorite end-member is not found in nature. Recalculated microprobe data of majorite grains found in Australian meteorite, give 66% of of majorite component and the remainder of pyrope. Pyropes with 26–42% of majorite component from the Middle Timan lamprophyre and pyrope inclusions with 24–26% of majorite in diamonds from the Juin Field, Brazil are the closest to majorite from the the Coorara meteorite. These garnets and majorite from the Coorara meteorite are Cr- and Ca-free.

Inclusions of pyrope-majorite in diamonds associated with ferripericlase, perovskite and manganese ilmenite indicate ultrahigh pressure of formation of the garnet. Mantle xenoliths with the pyrope-majorite garnet in volcanic rocks can be served as indicator of deep origin of such rocks. Formation conditions of mineral assemblage *Ca,Mg-perovskite+"majorite"+diamond* were estimated by through empiric barometer using formula coefficient of Si in garnet formula, which is resulted in very high pressure of 22 GPa and consequently, depth of crystallization of this mineral assemblage of 400–670 km. These calculated data are consistent with experiments for Al-free iron-magnesium garnets. According to [1], majorite is stable at 2000±200°C and 20 GPa. The notion «majorite» in scientific literature has double meaning. In some papers, majorite is considered as garnet, in which according to microprobe data SiO_2 is in excess, i.e., there are non-stoichiometry between cations and Si excess at tetrahedral site. No special X-ray structural study was carried out to support incorporation of Si at octahedral sites of trivalent cations in garnets. Non-stoichiometry and excess of silica in composition of real garnets of minute inclusions (which size rarely exceeds 1–20 microns), most likely could be caused by technical problems of electron microprobe measurements or inhomogeneous sample resulted from microingrowths of pyroxene in garnet. Currently, the latter is received fact. In natural pyrope from garnet-bearing xenoliths of diamond-bearing kimberlites, [2,3] described omphacite, diopside-jadeite solid solution, and showed, that with the clinopyroxene content in garnet of 20 and 30%, SiO_2 was 44–45.5 wt.% and crystallo-chemical coefficients of Si^{4+} calculated on the basis of 12 O, were 3.14–3.24. Oriented inclusions of pyroxenes in garnets, which in turn are enclosed in diamond crystals from Brazil and South Africa, are described by many researchers. Experimental study suggests that oriented pyroxene inclusions found in natural garnets are resulted from exsolution of hypothetical mantle Fe-Mg-silicate. However, it does not follow that homogeneous phase enriched in pyroxene component should be mineral with the cubic garnet structure. Findings of tetragonal almandine-pyrope phase (TAPP) included in diamonds from the San-Luis placers, Juin district, Brazil support this conclusion.

Synchrotron spectroscopy of Fe-bearing $MgSiO_3$ perovskite and post-perovskite to over 1 Mbar

Catalli, K.[1*], Shim, S.-H.[1] & Sturhahn, W.[2]
[1]Massachusetts Institute of Technology, Cambridge, MA, USA (*krystle@mit.edu)
[2]Argonne National Laboratory, Argonne, IL, USA

Iron- and aluminium-bearing Mg-silicates are the dominant minerals in the lower mantle of the Earth. Iron may exist in multiple valence (2+ and 3+) and spin states (high, low, and intermediate), which may change with pressure and profoundly affect the properties of minerals in the Earth. We have investigated the electronic state of ferric iron in $MgSiO_3$ perovskite and post-perovskite using synchrotron Mössbauer spectroscopy (SMS) and X-ray emission spectroscopy (XES).

Fe^{3+} and Al^{3+} are thought to enter perovskite and post-perovskite by charge-coupled substitution. Previous studies of perovskite with Fe^{2+} starting materials reveal the charge disproportionation of iron at high pressure, transforming up to 60% of Fe^{2+} to Fe^{3+}, and the amount of Fe^{3+} in the sample is further increased by the presence of Al [1,2].

Perovskite was synthesized in the diamond anvil cell above 45 GPa with all iron as Fe^{3+}. Two Fe^{3+}-bearing compositions were investigated, 18% Fe^{3+} (Fe^{3+}-Pv) and 10% Fe^{3+} + 10% Al (Fe^{3+},Al-Pv). Fe^{3+}-bearing post-perovskite (Fe^{3+}-PPv) was synthesized at 120 GPa.

Both the $K\beta_{1,3}$ line position and the $K\beta'$ line intensity of Fe^{3+}-Pv in XES suggest a decrease in average spin to ~50 GPa. SMS data reveal that there are two distinct iron environments in the sample. One is low quadrupole splitting and suggestive of high spin Fe^{3+} which we assign to the dodecahedral site. The second site has very high quadrupole splitting, which is consistent with low spin Fe^{3+} in the octahedral site. The SMS results also support the XES results of a gradual spin transition, but reveal that it only occurs in one cation site (likely octahedral site) in the structure [3].

XES data of Fe^{3+},Al-Pv also reveal a gradual reduction in spin with pressure, however between 63 and 84 GPa there is discontinuous drop in the intensity of $K\beta'$ and shift in the $K\beta_{1,3}$ line. SMS reveals that low spin Fe^{3+} exists in the octahedral site from 26 GPa, but above 70 GPa a third iron site appears in the spectra, that we also assign to low spin Fe^{3+}. This third site has a quadrupole splitting value consistent with low spin Fe^{3+}. The different behaviour observed for Fe^{3+},Al-Pv relative to Fe^{3+}-Pv suggests Al is likely the cause. The sharp increase in the low spin component at high pressure may be due to an increased amount of Fe^{3+} entering the octahedral site at the expense of Al, a consequence of the combined substitution of Fe^{3+} and Al in perovskite.

SMS of Fe^{3+}-PPv at 120 GPa reveal that approximately half of the Fe^{3+} exists in the octahedral site in low spin and half exists in the 8-fold coordinated site as high spin, revealing that Fe^{3+} does not change spin states across the Pv-PPv phase transition.

Our study suggests that Fe^{3+} in the octahedral sites of mantle silicates likely undergoes a spin transition in the lower mantle and Al has greatly affects the spin transition.

Equation-of-state of Fe^{3+}-bearing phase-X

Comodi, P.[1*], Nazzareni, S.[1], Bindi, L.[2] & Bobrov, A.[3]
[1]Dipt.o di Scienze della Terra, University of Perugia, Italy
([*]comodip@unipg.it)
[2]Museo di Storia Naturale, University of Florence, Italy
[3]Geological Faculty, Moscow State University, Moscow, Russia

Phase X is a synthetic phase with general formula $A_{2-x}M_2Si_2O_7H_x$ where A= K, Na, Ca, [], and M= Mg, Fe, Al, Cr^{3+} (with H_2O contents from 1.8 to 4.2 wt.%) [1]. Experimental petrology showed that it coexists with a typical mantle assemblage (olivine/wadsleyite, clinopyroxene and garnet) in a pressure range of 14 - 20 GPa and temperature up to 1600°C. Besides, phase X represents a potential host for incompatible and large elements (Na, K, Rb, Cs, Ba) in metasomatized upper mantle and transition zone. In subduction slabs settings, it was found from the breakdown of phlogopite and K-rich amphibole ([2] and the reference therein), thus it might be one of the possible candidates for carrying water and K deep into the Earth's mantle.

The structure of phase X, sp.gr. $P6_3cm$, consists of di-octahedral sheets of MO_6 octahedron stacked along the *c* axis and linked together by Si_2O_7 group, which form pillars between the layer where A atoms are contained. Two different OH environments were found by Raman spectroscopy.

The H*P* behaviour of hydrous and anhydrous end-members $K_2Mg_2Si_2O_7$ were studied by synchrotron X-ray diffraction and IR spectroscopy [3]. Only limited variation on the EoS of the two compositions was found with a K_0 ~ 74 GPa for both, and the structures remain stable up to 30 GPa. The hydrous sample showed a softening and broadening of the OH stretching modes by increasing pressure up to 20 GPa when they become very weak. However, density functional based computations [4] showed bulk moduli about twice than that measured by Liu et al. [3] for the Na (K_0 = 128 GPa, K' = 4.0) and K (K_0 = 132 GPa, K' = 4.4) anhydrous end-members. So up to now the baric behaviour of phase-X it not well constrained. To better define the EoS of phase-X, and how the Fe^{3+} -> Mg substitution may influence the elastic constants, we investigate the sample studied by Bindi et al. [5] with chemical composition $(K_{1.307}Na_{0.015})(Mg_{1.504}Fe^{3+}_{0.373}Al_{0.053}Ti^{4+}_{0.004})Si_2O_7H_{0.36}$, [sp. gr. $P6_3cm$, lattice constants a = 5.005(1) Å, c = 13.148(2) Å; V = 285.23(9)Å^3]. The sample was synthesized with the high-pressure toroidal "anvil-with-hole" apparatus at 7 GPa and 1650°C in the model peridotite system with 70 wt% of chemical K_2CO_3. Peridotite was prepared from a mixture of stoichiometric gels (60 wt% olivine, 16 wt% orthopyroxene, 12 wt% clinopyroxene, and 12 wt% garnet), and had the composition of garnet lherzolite (wt%) similar to pyrolite. H*P* single-crystal X-ray diffraction data from in house apparatus (Perugia University) and synchrotron source (ID-27 beamline ESRF, Grenoble) were collected by using diamond anvil cell loaded with different pressure media (methanol-ethanol-water mixture, neon) and pressure calibrant (ruby, quartz, Sm^{2+}:BaFCl).

Preliminary compressibility data at low pressure (<5 GPa) give a bulk modulus K_0 = 135(10) GPa with K' fixed to 4, more similar to the calculated than measured values for the potassium end-member. Details on the compressibility pattern and the stability over a large pressure range will be presented.

Experimental HP-HT study of the incorporation of Pb in two important Ca-bearing silicates of the Earth's mantle

Dubrail, J.[1,2*], Gautron, L.[2], Gréaux, S.[3] & Wilke, M.[1]
[1]GFZ German Research Centre for Geosciences, Potsdam, Germany ([*]julien@gfz-potsdam.de)
[2]Laboratoire Géomatériaux et Environnement, Université Paris-Est, Paris, France
[3]Geodynamics Research Center, Ehime University, Matsuyama Japan

Pb isotopes are geochemical tracers of primary importance. Three isotopes of Pb are the ultimate radioactive decays products of the actinides ^{238}U, ^{235}U and ^{232}Th (respectively ^{206}Pb, ^{207}Pb and ^{208}Pb – ^{204}Pb being the stable non-radiogenic form). The U-Th-Pb decay system constitutes the richest families of radionuclides in geochemistry (43 isotopes from 12 different elements). The three half-lives of this system span the age of the Earth, and make it the most used for dating the early Earth processes. Moreover, Pb presents an anomalous geochemical behaviour, called the Pb paradox, observed in almost all oceanic basalts: MORB and OIB basalts have more radiogenic Pb than expected for the primordial mantle [1]. To explain this isotopic imbalance, one of the solutions is the existence of non-radiogenic reservoirs in the deep Earth. The core and the lower continental crust have been proposed as reservoirs but neither of them contains sufficient non-radiogenic Pb to resolve the paradox [2-4]. Therefore, complementary reservoirs in the mantle need to be considered [4].

We explored here the possible existence of hidden Pb reservoirs in the mantle by studying the incorporation of Pb in two Ca-rich silicates of the Earth's mantle: the $CaSiO_3$ perovskite (Ca-pv) and the CAS phase. The Ca-pv is the third major mineral phase of the Earth's lower mantle, host of U and Th [5] and proposed source of radiogenic Pb for HIMU basalts [6,7]. The second phase explored is the CAS phase of composition $CaAl_4Si_2O_{11}$, which is formed in the mantle transition zone from subducted slabs [8], and is expected to be present as a solid residue in partially molten slabs subducted to the deep mantle [9].

High-pressure and high-temperature reactions between grossular garnet $Ca_3Al_2Si_3O_{12}$ (which gives Ca-pv and CAS at HP-HT) and PbO_2 along with parent actinides oxides UO_2 and ThO_2 have been performed up to 18 GPa and 2200 K using a multi-anvil press apparatus. The chemical compositions were characterized by electron probe microanalysis and analytical scanning microscopy. X-ray micro-diffraction analyses were also carried out to study the effects of the incorporation of heavy elements on the host structures. The principal results show significant Pb incorporation without major structural changes in both Ca-pv and CAS with up to 2 wt% of PbO in Ca-pv and 12 wt% of PbO in CAS. The results also show that the Ca-pv incorporates together U, Th and Pb. While the CAS phase does not incorporate U and Th alongside Pb. This suggests that the CAS phase could constitute a major host of non-radiogenic Pb in a long-lived garnetite mantle reservoir that is proposed in the portion of the transition zone that harbours subducted slabs [4].

The deep carbon observatory: unanswered questions in deep carbon science

Hazen, R.M.*, Hemley, R.J. & Bertka, C.M.
Geophysical Laboratory, Carnegie Institution, Washington DC, USA (*rhazen@ciw.edu)

In spite of carbon's importance, many unanswered questions remain regarding the physical, chemical, and biological behavior of carbon-bearing systems at depths greater than a few hundred meters. Recent results from field, experimental and theoretical studies point to the need for a new broadly interdisciplinary effort to understand deep carbon reservoirs and fluxes, the extent of possible deep abiotic organic synthesis, and the nature and extent of the deep biosphere. The Deep Carbon Observatory is a new international organization devoted to the study of these unanswered questions [1].

Recent findings underscore the need for a focus on deep carbon science. In particular, experimental discoveries of high-P-T organic synthesis from inorganic precursors [2], observations of complex interactions between organic molecules and minerals [3], field evidence for significant outgassing of C-O-H-N volatiles [4], recognition of extensive deep microbial ecosystems [5], and new experimental measurements and theoretical models of carbon sources and sinks [6] demand a careful reappraisal of deep carbon.

Postspinel transition boundaries in pyrolite and Mg_2SiO_4: comparison by high-pressure experiments with multicell technique

Ishii, T.*, Kojitani, H. & Akaogi, M.
Dept. of Chemistry, Gakushuin University, Tokyo, Japan
(*puchan_cat@yahoo.co.jp)

The 660 km discontinuity which separates mantle transition zone and lower mantle is considered to be due to decomposition from spinel phase to the assemblage of perovskite phase and rocksalt phase (postspinel transition). Precise postspinel phase relations in Mg_2SiO_4 and pyrolite have been frequently examined with quench and in situ X-ray diffraction experiments in previous studies. But it is still discussed whether this transition really corresponds to the 660 km discontinuity, based on uncertainty of pressure in various pressure scales, and so on. To compare precisely the postspinel transition in pyrolite and Mg_2SiO_4, we examined the transition at P, T conditions of the 660 km discontinuity with a multicell sample chamber technique. We also compared phase boundaries of formation of perovskite in Mg_2SiO_4 and $MgSiO_3$.

Mg_2SiO_4 forsterite was synthesized from a mixture of MgO and SiO_2 with a 2:1 mole ratio by heating for 75 hours at 1500°C. $MgSiO_3$ enstatite was synthesized as follows. A mixture of MgO and SiO_2 with a 1:1 mole ratio was heated for 1 hour at 1670°C and quenched to form $MgSiO_3$ glass. The glass was crystallized into enstatite by heating for 63 hour at 1300°C. Pyrolite was prepared by mixing SiO_2(44.98), TiO_2(0.20), Al_2O_3(4.45), Cr_2O_3(0.38), FeO(8.05), NiO(0.25), MgO(37.78), CaO(3.55) and Na_2O(0.36), where numbers in parentheses are contents in wt%. High-pressure experiments were made at 21-25 GPa and 1400-1800°C with a 6-8 type multianvil apparatus. Three samples (pyrolite, Mg_2SiO_4, and $MgSiO_3$) were packed in three holes in a single Re capsule, kept simultaneously at desired pressure-temperature conditions for 2-6 hours, quenched and recovered after the run. Phase identification of each sample was made with a microfocus X-ray diffraction apparatus, and compositional analyses of them were made with a SEM-EDS (scanning electron microscope with energy dispersive X-ray spectrometer).

The postspinel transition boundaries in Mg_2SiO_4 and pyrolite are placed at about 22.5-23.5 GPa and 1400-1800°C. The postspinel transition in pyrolite occurs at lower pressure than that of Mg_2SiO_4 by about 0.5 GPa. The reason why pyrolite and Mg_2SiO_4 have the different phase relations and different transition pressures is that pyrolite contains minor components such as Fe, Al, and Ca. The postspinel transition boundary in pyrolite has a less negative slope than that in Mg_2SiO_4. The experimental results indicate that a part of garnet in pyrolite first transforms to ilmenite, and subsequently spinel and ilmenite transform to the perovskite assemblage at temperatures lower than 1500°C. A part of spinel in pyrolite is dissociated into garnet and magnesiowustite, and then the rest of spinel transforms to perovskite and magnesiowustite at temperatures higher than 1700°C. When we also compare phase boundaries of formation of perovskite in Mg_2SiO_4 and $MgSiO_3$, the two boundaries have almost the same slopes, and the former boundary is placed at higher pressure by about 0.7 GPa than the latter.

Thermal expansion of $CaIrO_3$

Katerinopoulou, A.[1*], Balic-Zunic, T.[1], Krüger, H.[2], Kahlenberg, V.[2] & Trønnes, R.G.[3]
[1]Dept. of Geography and Geology, University of Copenhagen, Denmark ([*]aka@geo.ku.dk)
[2]Inst. of Mineralogy and Petrography, University of Innsbruck, Austria
[3]Dept. of Geology and Mineral Reseources Engineering, NTNU, Trondheim, Norway

Deep Earth dynamics are greatly affected by the $MgSiO_3$ perovskite (pv) to post-perovskite (ppv) transition. The transition conditions correspond to the D"-zone, which has long been an enigmatic region in the boundary between the Earth's mantle and core. The thermodynamic properties of the transition would give important constraints on the phase stability relations. However, such a study can only be performed on an analogue material, because the post-perovskite phase of $MgSiO_3$ is not stable at ambient conditions. $CaIrO_3$ is the only known material where both pv and ppv phases are quenchable at 1 atm. It is stable at 1 atm as ppv (*Cmcm*) and also crystallizes as metastable orthorhombic pv phase (*Pbnm*) [1].

The thermal expansion of $CaIrO_3$ in both *Cmcm* and *Pbnm* phases has been determined by single crystal X-Ray diffraction (SXRD). In the case of the post-perovskite structure, an anisotropic linear expansion is observed. The *b*-axis, which is normal to the edge-linked octahedra, shows the largest expansion. Data can be fitted with a second-order Grüneisen approximation [2]. The *Pbnm* perovskite is a more open and flexible crystal structure, where the octahedra are corner linked. An even larger anisotropy is observed in this case, the expansion curve of the *b*-axis has a negative slope. The *a*-axis expands with temperature while the *b*-axis contracts. This suggests that the [IrO_6] octahedra in the structure rotate in the sense that diminishes the discrepancy to the ideal cubic archetype. The results shed new light on the thermodynamic processes in the D´´ region of the lower mantle.

An unusual mantle mineral grouping in the Luobusha ophiolite chromitites, Tibet, China

Li Guowu[1*], Shi Nicheng[1], Xiong Ming[1], Bai Wenji[2], Fang Qingsong[2] & Ma Zhesheng[1]
[1]China University of Geosciences, Beijing, China ([*]liguowu@126.com)
[2]Institute of Geology, Chinese Academy of Geological Sciences, Beijing, China

After the discovery in 1980 of diamonds in ophiolite rocks from Luobusha and Dongqiao, Tibet, China, a mineralogical study of the Luobusha area was proposed. Within the Luobusha ophiolite chromitites, an unusual mineralogical grouping was discovered as inclusions in chromite. This includes silicates, oxides, sulphides and very large variety of metallic and intermetallic compounds. Apart from the natural occurrence of diamond, moissanite, wüstite, coesite, *etc*., the presence of UHP minerals was confirmed. Together with this discovery, native metallic elements (Si, Fe, Zn, Pb, Al, Cr, Ni, Os, Ir, Ru, Rh, Pd, Au, Ag, W, Cu and Ti), alloy minerals (Fe-Si, Fe-Ti-Si, Ni-Fe-Cr, Ni-C, Fe-C, Cr-C, Ti-C, W-C, SiC, Fe-Co, Al-Fe-La, W-C, Fe-Mn, Au-Ag, Ag-Sn Ti-W, Cu-Zn, Si-Ca, Ti-N, Fe-Si Si-Ca-Cu as well as PGE minerals (Ni-Fe-Ir, Rt-Fe, Pt-Fe-Pd, Fe-Ru) were found. Although most crystal sizes of the inclusions are very small (about 15-60 μm for the most grains), XRD work was carried out on a diffractometer equipped with a CCD detector (SMART APEX, Bruker AXS Inc.) In every particular element group a certain amount of mineral species have been discovered, for example in Fe-Ni-Cr and Fe-Co, taenite, awaruite, iron and wairauite were have been identified by XRD. In the Fe-Si, Fe-C and W-C systems, luobusaite, qusongite, yarlongite and zangboite were discovered as new mineral species. Of these, single crystals of yarlongite and zangboite were obtained for the crystal structure determination. However, for most crystal samples, including luobusaite and qusongite, only a powder XRD pattern could be obtained and therefore the crystal structures were refined using the Reitveld method. In the above-mentioned metal and alloy minerals, XRD data was successfully obtained for only 30% of the minerals.

Metal and intermetallic compounds were presumably formed under reducing conditions. Therefore, they cannot coexist with chromites. An SEM image showed the PGE minerals were enclosed in the chromites. Interestingly, other native metals and alloys were also discovered as inclusions in the PGE minerals. The species enclosed in the PGE minerals are diamond and coesite. Native silicon can also be found as an inclusion in moissanite. "Ferdisilicite", "fersilicite" and native silicon were observed as inclusions in luobusaite. This kind of complex enclosed relationship indicates that the minerals had to undergo a long process of migration.

These metal and intermetallic compounds are believed to have been transported from deep within the mantle by a plume and incorporated in the ophiolite during seafloor spreading. Blocks of the mantle containing the minerals were presumably picked up by later boninitic melts from which the chromitites precipitated, transported to shallow depth and incorporated into the chromitite.

Morphogenetic evidence of the mantle fluid activity

Posukhova, T.V.
Dept. of Mineralogy, Moscow State University, Moscow, Russia (tposukhova@mail.ru)

Diamonds and accompanying minerals from the Arkhangelsk kimberlites and different placers (Ural, Timan, North Yakutiya, Sierra-Leone, Chikapa) were investigated. Morphology, physical properties, and interior structure of the diamonds have been examined by different methods: SEM, IR-spectroscopy, X-ray tomography, Raman-spectroscopy, cathodoluminesence. Chemical composition of the accompanying minerals has been examined with EDS and WDS- micro-beam spectroscopy.

It was established that diamonds in all objects have a specific peculiarities. The round dodecahedron forms prevail, among colored polyhedra grey crystals are the most abundant, crystals have a lot of black inclusions. Usually the degree of resorption is high. Knob-like asperities, ribbing, frosting corrosion sculptures, fetch channels and lamination lines are well developed on the surface of diamond crystals from these sources. Comparison with experimental data shows that such morphological peculiarities were formed during the solution of the octahedron crystal in carbonate-silicate systems in presence of H_20-CH_4 fluids with C=O, -OH, -HOH, CO_3, CH_2, CH_3 groups at T=1300-1450^{o}C and P=0,1-2,5 GPa. The presence of H_2O in diamonds was established previously and was confirmed with our IR-spectroscopic data. In addition, spectroscopic data show that in diamonds from Arkhangelsk province and investigated placers on average slightly higher nitrogen, CO_2 and H_2O contents are present. Results of IR-spectroscopy and Raman-spectroscopy permitted us to propose a presence of carbon-hydrogen inclusions. Such inclusions in diamonds were investigated in North Yakutian placers. CH_4, C_3H_8, C_4H_{10}, and C_5H_{12} were established by Raman-spectroscopy and gas-chromatography methods. We investigated such inclusions in garnets from the Mir pipe.

Another evidence of the fluid activity gives us peculiarities of the minerals which accompany diamonds in these objects. We found flogopite and millerite as inclusions in investigated diamonds. Specific coronary structure of garnets and clinopyroxenes (keliphitic rims, higher Mg and lower Fe in outer zone) and wide extent of garnet-pyroxene-flogopite association in the Grib pipe were established. All mineral grains of garnets, pyroxenes and ilmenites in Arkhangelsk kimberlites have round form. A higher proportion of them are heavily frosted and contain etch channels. Such mineralogical peculiarities are typical for the potassium metasomatic processes.

Thus, our data permit us to propose an important role of potassium carbonatic melts and mantle fluid in the origin of the investigated diamonds and accompanying minerals.

Phase and melting relations of a residual eclogite within an upwelling heterogeneous upper mantle

Rosenthal, A[1*], Yaxley, G.M.[1], Green, D.H.[1,2], Hermann, J.[1], Spandler, C.S.[1,3], Kovács, I.[1,4] & Mernagh, T.P.[5]

The existence, creation and modification of compositional heterogeneities within the Earth's upper mantle and their influences on the petrogenesis of primitive magmas have been highly debated for decades. The possible origins of mantle heterogeneities within the Earth's peridotite-dominated mantle are numerous and complex.

One major mechanism invokes an important role for recycling of oceanic crust at subduction zones, and the storage of these recycled mafic (and sedimentary) materials in the deep mantle, before it is thought to be incorporated in the adiabatically upwelling upper mantle sources of some primitive magmas.

To assess the influence of recycled oceanic crust on the creation of mantle heterogeneities and on the petrogenesis of primitive magmas in homogeneous, buoyant, upwelling peridotite-dominated mantle, high pressure experimental investigations of the melting behaviour of subducted oceanic crust and its residues will be presented.

We track a sequential process in which melts are redistributed from the (initially) low temperature melting of average oceanic crust [1], and then from the residue (nominally anhydrous eclogitic compositions) of such subducted oceanic crust (Res2, this study). This study establishes the phase and melting relations of a reasonable melting residue, which is itself derived directly from subducted oceanic crust at high pressures and temperatures (GA2; [1]). In particular, this study has systematically determined the solidus temperatures, phase relations, and partial melt compositions during upwelling of a residual rutile-bearing quartz/coesite eclogite (Res2) from 5 to 3 GPa and 1500-1200°C.

This data is then combined with the results of earlier experimental investigations to constrain the complex melting behaviours of (residual) eclogite bodies in upwelling mantle, the nature of the interactions of their partial melts with ambient peridotitic mantle, and the nature of re-melting of such metasomatised mantle assemblages, with a brief evaluation of the contributions of these processes to the genesis of some primitive magmas.

Characterization of the pressure induced Ringwoodite → Mg-perovskite + Mg-wüstite phase transition by Catastrophe Theory

Sciascia, L.[1*], Parisi, F.[2], Princivalle, F.[2] & Merli, M.[1]
[1]Dipto. di Chimica e Fisica della Terra e Applicazione alle Georisorse ed ai Rischi Naturali, Università degli Studi di Palermo, Italy ([*]lucianasciascia@gmail.com)
[2]Dipto. di Geoscienze, Università di Trieste, Italy

Seismic discontinuities in the terrestrial mantle have significant impact on geodynamics and several experimental and theoretical works aimed at understanding their physical and chemical origin have been performed in the last decades. It had long been accepted that seismic discontinuities at about 520, and 660 km depth are related to phase changes involving olivine and its polymorphs. In particular, the less pronounced 520-km discontinuity [1] has been attributed to a phase change from wadsleyite (β-olivine) to ringwoodite (γ-olivine) [2], while the origin of discontinuity in the lower mantle is still not fully understood [2,3]. According to recent phase equilibria studies, it seems that it is mainly due to the breakdown of ringwoodite to Mg-perovskite + Mg-wüstite [4,5].

In order to shed light on this issue, the evolution of the electron arrangement in the crystal-structure across the pressure induced phase transition has been investigated in terms of topology of the electron density.

Calculations of the electron densities have been performed by means of the ab initio CRYSTAL computer program [7] at the HF/DFT level, using an Hamiltonian based on the B3LYP scheme [8]. The local functions to construct the crystalline orbitals were chosen as a Gaussian-type. The topological characteristics of the electron density have been obtained following the Bader's 'Atoms In Molecules' approach. All the calculation have been performed for pressures ranging from a nominally negative pressure of ~-10 GPa (corresponding to a virtual expanded state) to ~60 GPa. To address the compression mechanism, calculations have been performed at different unit cell volumes and the energies obtained as function of the volumes have been fitted by means of the Murnaghan equation.

Aiming at explaining the observed breaking of some chemical bonds with increasing the pressure, a topological mechanism based on the Catastrophe Theory [6] applied to the framework of the Bader's theory [7] has been proposed for the first time.

One of the most interesting results observed was the progressive approach of a bond critical point (BCP) and a ring critical point (RCP) near the transition point, until the coalescence is reached at the transition point. It has been also found that the angle between the stable manifold of the BCP and the unstable manifold associated to the RCP approximate 0° at the transition point, which means that the couple of coalescent critical point are candidates to represent a catastrophe scene in the theory of catastrophes [6,7].

The present analysis, characterizing the electron arrangement in the polymorphs, allowed us to determine the real coordination environments as a function of pressure and therefore its relationship with the high-pressure transition.

Crystal chemistry and mineralogy in Earth's interior and a special mineralogical grouping from Luobusha ophiolite

Shi Niheng[1*], Li Guowu[1], Bai Wenji[2], Xiong Ming[1], Fang Qingsong[2] & Ma Zhesheng[1]
[1]China University of Geosciences, Beijing, China ([*]shinicheng@vip.sina.com)
[2]Institute of Geology, Chinese Academy of Geological Sciences, Beijing, China

Under the conditions in mantle oxides and silicate minerals occur a series of phase transitions as the pressure increases. They lead to a unit volume decrease, a density increase which in turn leads to decrease of the oxygen ion radius. However, for the cation radius of silicon, it not only failed to decrease, on the contrary, an trend to increasing was found. For example, the radius of oxygen in stishovite is smaller than the radius of oxygen in quartz, but Si-O bond length is 1.75 Å in stishovite, and Si-O bond length is 1.60 Å in quratz. Obviously, the cation radius of silicon in stishovite is larger than the cation radius of silicon in quartz. Along with pressure increases and the occurrence of the phase transition, the cationic radii of silicon continue to increase. For corresponding polymorphs, every cationic radius for silicon has been calculated from crystal structure data as follows (Table1):

Table 1: The cation radius of silicon (Å) in SiO_2 polymorphs

phase	quartz	coesite	stishovite	SiO_2 as α PbO_2 type	SiO_2 as pyrite type
$R_{(Si)}$ (Å)	0.296	0.293	0.512	0.533	0.530
Pressure (GPa)	normal	4-8	8-50	90-200	200-260

The Earth's core material phase and its crystal structure have been clarified by experimental mineralogy. Their crystal chemistry features can be concluded as following: 1. A simple metallic substance or intermetallic compounds (Fe-Ni metallic compounds); 2. The crystal structure displays an equal-sphere closest packing model; 3. Strong reducing environment; 4. High melting point and a high chemical stability.

This kind of crystal structure will preserve invariableness in different layers of the earth. In this case the phase transition and crystal structure can not be used to indicate pressure and depth. In fact, the four crystal chemistry characteristics mentioned above are important indicators for mineral species formation.

A mass of inclusion minerals has been discovered in the Luobusha ophiolite chromitites, Tibet, China. They include silicates, oxides, sulphides and very abundant metal and intermetallic compounds. The occurrence of diamond and coesite indicated that the formation depth of the minerals must be below 120 km and the pressure must be at 4-8 GPa. Spinel with silicon-oxygen octahedra coordination and high silicon rutile may be from the transition zone. In the metallic and intermetallic compounds luobusaite, qusongite, yarlongite and zangboite have been discovered as new minerals. These species of metallic carbides and silicides may be derived from the core-mantle boundary region. In this area, taenite, awaruite, iron and wairauite were discovered as Fe-group elements. According to chemical composition, crystal structure, reducing environment, it is possible that this four mineral species may be derived from the Earth's core.

Stability field and thermodynamic properties of $Mg_{14}Si_5O_{24}$ anhydrous phase B determined by high-pressure experiments and calorimetry

Terata, S.*, Kojitani, H. & Akaogi, M.
Dept. of Chemistry, Gakushuin University, Tokyo, Japan
(*sakilily@ca3.so-net.ne.jp)

Anhydrous phase B (Anh-B:$Mg_{14}Si_5O_{24}$) is a high-pressure magnesium silicate possibly stable in magnesium-rich regions in the upper mantle [1]. Finger et al. (1991) [2] analysed the crystal structure of Anh-B. Ganguly and Frost (2006) [3] examined the equilibrium boundary of the reaction, 5forsterite (Fo) + 4periclase(Per) = Anh-B, at 9.0-12.5 GPa and 1173-1873 K. However, the upper stability limit of Anh-B has not yet been examined. In this study, we determined stability relations of Anh-B by high pressure experiments and calorimetry, and inferred possible stability of Anh-B in the deep mantle.

High-pressure high-temperature experiments to determine the phase relations on Anh-B were performed with a Kawai-type 6-8 multianvil high pressure apparatus. The starting material was a mixture of Per and Fo with 4:5 molor ratio. The experimental conditions were 12-23GPa and 1673 -2073 K for 3 hour. Samples recovered after quenching were analyzed with powder X-ray diffraction method and SEM-EDS. Calorimetry was performed with a Calvet-type calorimeter which was kept at temperature of 978 K. Drop-solution enthalpy of Anh-B was measured with Ar bubbling technique, using lead borate as the solvent. For calorimetric measurements, Anh-B was synthesized from 14:5 mixture of Per and quartz by keeping at 15 GPa and 1723 K for 3 hours, and was recovered after quenching.

Results by the high-pressure and high-temperature phase equilibrium experiments indicated that the equilibrium boundaries of 5 Fo + 4 Per = Anh-B and of Anh-B = 5 Wadsleyite(Wads)+ 4 Per are located at 12-13.5 GPa and at 18-21 GPa, respectively at 1673-2073 K. From these boundaries, enthalpies and entropies for the two relations were constrained. The measured drop-solution enthalpy of Anh-B was 867.5(233) kJ/mol. The drop-solution enthalpy of Fo was 168.2(9) kJ/mol, and that of Per was 33.7(10) kJ/mol (H. Kojitani, unpublished data), and that of Wads was 142.2(27) kJ/mol [3]. Therefore, the enthalpy for the reaction 5 Fo+ 4 Per = Anh-B was obtained as 108.5(241) kJ/mol, and Anh-B = 5 Wads + 4 Per as 21.7(235) kJ/mol by calorimetry. From both of the results of high-pressure high-temperature experiments and calorimetry, best values of enthalpy and entropy for the two reactions were determined. For the reaction of 5Fo+4Per=Anh-B, enthalpy was 110.9 kJ/mol, and entropy was -17 J/(mol·K). For the reaction of Anh-B= 5Wads+4Per, and enthalpy was 37.8 kJ/mol, entropy was -24 J/(mol·K). The two equilibrium boundaries were calculated with these values. The boundary of 5 Fo + 4 Per = Anh-B is expressed as P(GPa)=0.0015 T(K)+9.87, and that of Anh-B= 5 Wads + 4Per as P(GPa)=0.0056 T(K)+9.00. This study shows that Anh-B decomposes into Wads and Per, and Anh-B is stable in magnesium-rich upper mantle and transition zone in the depth range of about 370 - 550 km.

Single-crystal diffractometer with an ultrahigh intensity rotating anode X-ray source

Trots, D.M.*, Kurnosov, A., Boffa Ballaran, T. & Frost, D.J.
Bavarian Research Institute of Experimental Geochemistry and Geophysics, University of Bayreuth, Germany
(*dmytro.trots@uni-bayreuth.de)

The layout and first test measurements of single crystal diffractometer with an ultrahigh intensity rotating anode source is described. We intend to employ this diffractometer system in combination with Brillouin spectroscopy for simultaneous acquisition of precise lattice parameters and acoustic velocities in minerals under extreme conditions.

The diffractometer is installed within an interlocked experimental hutch. A rotating anode FR-E+ SuperBright X-ray source from Rigaku is implemented. MoKα radiation is selected from the rotating anode spectrum using VaryMax^{TM} focusing optics. The optics employs two focusing parabolic-curved mirrors in a "side-by-side" Kirkpatrick-Baez scheme. The beam intensity is monitored by PIN diode. The flux at the detector position (~1400 mm from optics) at an operating power of 2.475 kW is approximately 10^8 photons/sec^{-1}. The beamsize at the sample position is approximately 200 microns. The diffractometer itself is an Eulerian four-circle diffractometer from Huber. It controlled via the code Single [1], which allows 8-position centring for accurate determination of lattice parameters. An X-ray counting system is based on a YAP:Ce scintillator and placed onto a counter arm. The layout of diffractometer leaves sufficient space for the focusing and collecting lenses of a Brillouin spectrometer to access the sample.

Initial test measurements in air on ruby, quartz, phase-D, periclase, diomignite as well as test measurements of quartz (~35 microns maximal dimension) and diomignite at high pressures in a diamond anvil cell have been performed. Performance of the diffractometer system is well demonstrated by diagnostic $(d_{obs}-d_{calc})/d_{calc}$-plots in figure 1. Δd/d values show a maximum scatter of ~0.00014 (low-angle reflections are ignored because $K\alpha_1$ and $K\alpha_2$ doublets are not resolved). Comparison between the intensity of weak (424) reflections measured with a diffractometer system based on a conventional X-ray tube and the rotating anode combined with multilayer optics, shows a significant increase in intensity and signal-to-noise ratio (see figure 1), while preserving the line width.

Acknowledgements: Support from European research Council Advanced Grant "Deep Earth Elastic Properties and a Universal Pressure Scale".

Elastic properties of natural orthoenstatite to 12 GPa: implications for mantle velocity structure

Zhang, J.[1] & Bass, J.D.[1,2*]
[1]Dept. of Geology, University of Illinois, Urbana, USA
[2]COMPRES (Consortium for Materials Properties Research in Earth Sciences), Urbana, USA ([*]jaybass@illinois.edu)

Orthopyroxene, $(Mg,Fe)SiO_3$, is one of the primary minerals in Earth's upper mantle. Knowledge of the elastic properties of pyroxene is essential for understanding the seismic properties of the upper mantle, including the nature of seismic anisotropy and the origin of the low velocity zone. However, previous single crystal measurements are limited up to 3Gpa while polycrystal measurements could not give us enough information about anisotropy. In this study, we have measured the sound velocities of a natural single crystal of orthoenstatite up to 12 GPa by Brillouin spectroscopy with a diamond anvil cell. The orthoenstatite samples were extracted from a peridotite from San Carlos, Arizona. The chemical composition determined by EPMA analysis is $(Mg_{1.77}Fe_{0.17}Ca_{0.04}Cr_{0.02})(Si_{1.95}Al_{0.05})O_6$. Measurements have been made on three different crystal planes, including (100) (010) and (0-11), allowing us to constrain all of the elastic moduli for this phase. Density at ambient conditions is calculated to be 3.200 g/cc based on X-Ray Diffraction average on both three samples, bulk and shear modulus are determined as 109.581 GPa and 73.882 GPa. High pressure density profiles as well as bulk and shear modulus are determined by both fourth order and third order finite strain equation of state. For third order finite strain EOS, pressure derivative are calculated as Ks'= 7.832 G'=1.947, while for fourth order finite strain EOS, Ks'= 7.832 G'=1.947 Ks''= -0.889 GPa-1 G''=-0.324GPa-1 .These results are generally in good agreement with previous studies, orthoenstatite maintain the very unusual high value of the pressure derivative [comparing with all the other mantle minerals] of the elastic modulus through the whole pressure range of its existence. Besides, a significant change in the velocities and acoustic anisotropy has been observed between 10.5-12 Gpa, which we infer to be caused by a phase transition from a low-pressure orthorhombic structure, to a high-pressure monoclinic structure (OEN-HPCEN transition). The transition pressure is higher than previously reported number for pure $MgSiO_3$. This discrepancy may be due to the presence of some other elements in our natural samples. So in a word, both the unusual value of the pressure derivatives of elastic modulus of orthoenstatite and the significant change of sound velocities as well as elastic anisotropy across the OEN-HPCEN transition has to be accounted for in interpretations of discontinuities in the upper mantle, and the cause of seismic anisotropy in this region.

HCP iron at the center of the Earth: a diamond-anvil cell study

Tateno, S.[1*], Hirose, K.[1,2], Sata, N.[2] & Ohishi, Y.[3]

The Earth's core is mainly composed of iron. Thus the crystal structure of iron is of prime importance for understanding the nature of solid inner core. Despite many efforts on the phase relations of iron have been extensively studied by shock wave, static compression, and theoretical calculation, consensus on the stable phase at the inner core condition has never been achieved. Ab initio calculation repeatedly suggests the body-centered-cubic (bcc) iron is stable at very high temperature to the inner core pressure above the stability field of hexagonal close-packed (hcp) phase, thus being the strong candidate for inner core material [1]. On the other hand, because accessible pressure and temperature (PT) range in static experiment by a diamond-anvil cell (DAC) is limited particularly on high temperature, high PT generation simultaneously inside the inner core has never been achieved. So far, it is confirmed that hcp structure is stable up to 300 GPa and 2000 K by DAC experiment [2].

Here we examined the phase relations of iron at the extreme conditions on the basis of synchrotron X-ray diffraction measurement in situ at high P-T in a laser-heated DAC. Pure iron powder was used as a starting material, which was embedded between SiO_2 for thermal insulation. The sample was heated by the newly developed flat top double-sided laser heating system using fiber lasers installed at BL10XU of SPring-8. With this technique, the accessible PT conditions in a DAC were significantly extended, reaching 350 GPa and 5700 K. The results show that iron is stable with hcp structure in the entire experimental PT range of 130-350 GPa and 2500-5700 K. We observed no evidence for phase transition in these conditions. We also found that very small temperature dependence of c/a ratio above 300 GPa, contrary to the theoretical studies, which report rapid increase of c/a with temperature [3]. The elastic property of hcp iron at the inner core should be reconsidered to explain seismic anisotropy observed in the inner core.

Melting of iron-rich alloys at high pressures and implications for planetary cores

Campbell, A.J.[*], Fischer, R.A. & Miller, N.A.
Dept of Geology, University of Maryland, USA
([*]ajc@umd.edu)

Many planetary bodies are thought to have metallic, iron rich cores, with a significant component of some 'light' alloying element(s). The identity of this light alloying component has a profound effect on the chemical properties of the core, including its melting/crystallization behavior, partitioning of minor and trace elements during core/mantle segregation and core crystallization, and other phase relations. Despite this importance, the light element component(s) of planetary bodies generally remain unknown, apart from those of a few iron meteorite parent bodies. Experimentally determined physical and chemical properties of iron-rich systems can be compared to observations and models of planetary interiors to constrain compositions of planetary cores. Here we summarize our recent high pressure, high temperature experiments on the phase diagrams of iron+light element (Fe-X) binaries. We focus mostly on melting curves in the iron-silicide and iron-oxide systems, because Si and O are leading candidates for the light element component in Earth's core.

Melting curves for FeO and Fe-Si alloys were determined in the laser heated diamond anvil cell. Temperature distributions were measured by imaging radiometry [1]. Melting transitions were identified using multiple methods: discontinuities in the temperature-emissivity relationships across the laser heated spot; discontinuities in laser power-temperature curves; and visual observation combined with the 2D temperature measurement. All three methods gave consistent results. In addition, synchrotron X-ray diffraction was used to establish the solidus and subsolidus phase relations in these Fe-alloy systems. Synchrotron methods provide more complete structural information, but optical methods can establish the phase boundaries with finer precision.

We find that both Fe-9Si and Fe-16Si alloys produce only a small (~100 K) melting point depression relative to pure Fe. X-ray diffraction reveals that at high pressures (>40-50 GPa), the solidus phase for these compositions is in the B2 structure, implying a eutectic between these alloy compositions and hcp-iron. Our melting curve of FeO, combined with recent work on the eutectic melting of Fe-FeO [2], likewise indicates a modest (300-400 K) eutectic melting depression relative to Fe. Therefore, both silicon and oxygen produce lower melting point depressions then sulfur [3] at high pressures, and the minimum temperature of an oxygen and/or silicon bearing core is necessarily greater than an iron-sulfide core.

Despite important gaps and discrepancies that remain in the available data, these and other experimental results can be compared to thermal and chemical models of terrestrial planet interiors (including Earth's). Because of the differences in melting point depressions, an iron-silicon or iron-oxygen core will crystallize more rapidly during cooling than an iron-sulfur core under equivalent conditions. This is especially so in smaller planets such as Mercury, because the pressure range spanned in a smaller planet's core is smaller, hence the eutectic depression plays a more important role in the phase relations.

Effect of carbon and hydrogen on phase relations in Fe-Ni system at high pressures and temperatures

Dubrovinsky, L.*, Narygina, O., McCammon, C. & Dubrovinskaia, N.
Bayerisches Geoinstitut, University of Bayreuth, Germany
(*Leonid.Dubrovinsky@uni-bayreuth.de)

The phase diagram of iron-enriched Fe-Ni alloy at elevated pressures and temperatures comparable to those in the Earth's core as well as the effect of the potential light element in the core (H, C, Si, S, O, etc.) on the system remains under debate. The reason is very simple: the necessary pressure-temperature range (300-350 GPa and 5,000-7,000 K) is hardly achieved in the laboratory. Conditions close to those in the core can be created in LH-DAC experiments; however the main disadvantage of the technique is a lack of control on the system under study. In contrast, the large-volume press (LVP) provides rather equilibrated and controllable experimental conditions, although at significantly lower pressures. Therefore we carried out a "cross-checking" study of phase relations in $Fe_{1-x}Ni_x$ ($0.10 < x < 0.22$) and $Fe_{0.90}Ni_{(0.10-x)}C_x$ ($0.01 < x < 0.05$) systems at pressures to 100 GPa and temperatures to 3000 K, using LH-DAC and LVP high pressure techniques. *In situ* and *ex situ* sample analyses were done by means of XRD, Mössbauer spectroscopy, and scanning and transmission electron microscopies.

We showed that laser heating in the DAC can promote undesired reactions between the sample (Fe-Ni alloy in our case) and carbon, which upon laser heating diffuses from the diamond anvils through the pressure-transmitting layers. Therefore we suggest that results obtained in LH-DAC experiments should be interpreted very carefully in general.

We investigated the mechanism of carbon and hydrogen incorporation into the structure of Fe-Ni alloy at high pressures and temperatures. We found, particularly, that rapid cooling of *fcc*-structured carbon-bearing Fe-Ni alloy to room temperature (either in the case of LH-DAC or LVP quenched experiments) results in the formation of the metastable solid solution of *bcc*-FeNi, *bct*-Fe-Ni-C (known in metallurgy as martensite) and a certain amount of preserved *fcc* Fe-Ni-C. We also showed that carbon solubility in the Fe-Ni system at high temperatures decreases with pressure.

Experimental investigation of the Fe-Si-O system at high pressures

Seagle, C.T.[1,2*], Cottrell, E.[1] & Fei, Y.[2]
[1]Dept. of Mineral Sciences, National Museum of Natural History, Smithsonian Institution, Washington, DC, USA
[2]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA (*seaglec@si.edu)

Our only direct information regarding Earth's core results from seismological observations. Acoustic waves propagate through Earth at velocities dependent on the density and elastic properties of the medium. Interpretations of these measurements are dependent on our understanding of the material properties at the environmental conditions that exist within Earth's deep interior. It is believed that Earth's outer core is composed of an iron rich alloy plus ~10 wt. % light elements while the inner core consists of ~3-6 wt. % light elements; possible light elements are O, S, Si, and others [1].

We have investigated the iron rich portion of the Fe-Si-O system at pressures between 40 and 90 GPa using the laser heated diamond anvil cell in conjunction with synchrotron x-ray diffraction (XRD) at the Advanced Photon Source, Argonne National Laboratory. The XRD data indicates that at sub-solidus temperatures, solid iron coexists with wüstite and stishovite, in general agreement with previous data obtained at lower pressures [2]. However, as temperature is further increased (or decreased in reversal experiments) Bragg reflections associated with stishovite disappear (appear) around 1800 K at 40 GPa. This temperature is too low to be associated with melting and implies two phase coexistence at high temperatures (Fe-Si alloy and wüstite). This may suggest oxygen exclusion from the solid during inner core crystallization.

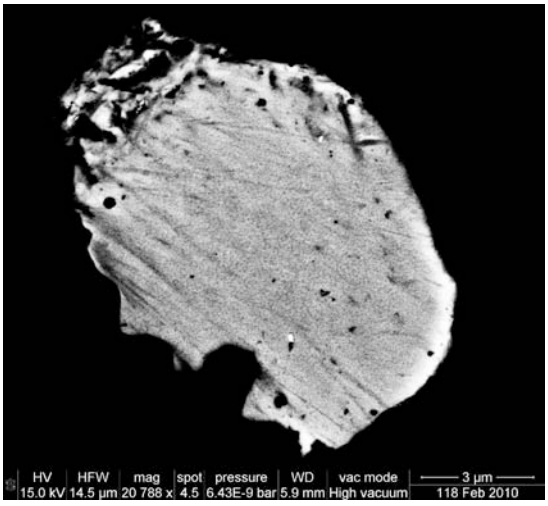

Fig. 1: Backscattered electron image of a laser heated spot in an Fe-Si-O sample recovered from 40 GPa and 3500 K. Small chemical variations are apparent in the wispy texture. X-ray diffraction data indicates that at these conditions the sample was completely molten.

The samples were recovered after the XRD experiments and polished for analysis using a scanning electron microscope and electron microprobe. Very small (~50 nm) circular features in the heated areas quenched from liquid are thought to indicate the exsolution of wüstite during rapid quenching. The bulk compositions of the quenched liquids were determined at several pressures and temperatures. The in-situ XRD measurements and ex-situ characterization will help us to better understand the melting relations in the system at high pressure.

[3]SPring8, JASRI, Hyogo, Japan

It has been suggested that the core has a density lower than that of pure iron (Fe). Si is a major candidate for the light element in the core because it is one of the most abundant elements in the Earth. The solubility of Si in metallic iron increases with increasing pressure [1,2]. Here, we will discuss the possible existence of Si in the core based on our recent results on phase and melting relations and the equation of state of the Fe-Si and Fe-Ni-Si systems at high pressure.

The melting temperature of $Fe_{0.7}Si_{0.3}$ （Fe-18 wt.% Si）alloy was determined up to 119 GPa based on a change of laser heating efficiency and the texture of the recovered samples in the laser heated diamond anvil cell experiments. The melting curve of the alloy was fitted by the Simon's equation as $P(GPa)/3.5=(T_m(K)/1473)^{4.5}$. The measured melting curve is slightly lower than that of pure Fe in the pressure range of the present experiment. The melting temperature of $Fe_{0.7}Si_{0.3}$ alloy is estimated to be 3300-3500 K at 135 GPa, and 4000-4200 K at around 330 GPa, which may provide the lower bound of the temperatures at the core-mantle boundary and the inner core-outer core boundary if the light element in the core is silicon.

We studied the melting and phase relations of the Fe-Si system under the conditions of the Earth's core [3] by using in situ X-ray diffraction study at BL10XU of Spring-8. We confirmed that a single hcp phase is stable up to 3600 K at 242 GPa and to 2400 K at 257 GPa in $Fe_{0.93}Si_{0.07}$ (Fe 3.4 wt. % Si) alloy. These results suggest that the inner core is likely to be composed of the hcp-phase of FeSi alloy. We made static compression of the $Fe_{0.93}Si_{0.07}$ alloy up to 252 GPa and the $Fe_{0.83}Ni_{0.09}Si_{0.08}$ (Fe-9.8 wt% Ni-4.0 wt% Si) alloy up to 374 GPa at 300 K, applying the NaCl-B2 pressure scale [4] with a correction at above 100 GPa made by a pressure scale based on the pressure shift of the Raman mode of diamond [5] calibrated by the Pt pressure scale [6].

We compared the densities of the present FeSi and FeNiSi hcp-alloys with the pure hcp iron and hcp iron-nickel ($Fe_{0.8}Ni_{0.2}$) alloys [7] at 330 GPa and 300 K by extrapolation of the previous data, and found that the density difference among these alloys is comparable with the uncertainty of the density of the alloys due to the uncertainty of the pressure scales. It is essential to establish the pressure scale at high pressure and temperature in order to make quantitative assessments of the Ni and Si contents in the core.

It is considered that the Earth's core is composed of Fe-Ni alloy with small amounts of light elements based on comparison between the density of Fe-Ni alloy and that of the Earth's core [1,2]. Sulfur is one of the major candidates of the light element due to its high solar abundance, formation of iron-sulfur compounds easily, and existence in iron meteorites as troilite, FeS. Metallic iron can contain small amount of sulfur at high pressure conditions. Kamada et al. [3] reported that the sulfur content in metallic iron was 7.6 at.% (4.5 wt.%) at 85.6 GPa and 2200 K. Theoretical studies on the electronic band structure [4,5] predicted that Fe-FeS system becomes solid solution at the core pressure. Therefore, it is important to clarify the compressibility of Fe-Ni-S alloy in order to discuss the density of the inner core. Here we report the result of compression study of Fe-Ni-S alloy up to 360 GPa.

Fe-Ni-S alloy was synthesized at 21 GPa and 1173 K using a multi-anvil apparatus. The composition of Fe-Ni-S alloy was $Fe_{0.881}Ni_{0.091}S_{0.0028}$ (Fe-9.6wt.%Ni-1.6wt.%S) determined by an electron probe microanalyzer. Diamond anvil cell was used for high pressure experiments. Samples were placed in the sample chamber with sodium chloride pressure medium. We calibrated the NaCl-B2 scale against the diamond Raman scale [6,7] up to 272 GPa in the additional experiment. The pressure was determined by the calibrated NaCl-B2 scale. We performed *in situ* powder X-ray diffraction experiments at BL10XU in SPring-8. $Fe_{0.881}Ni_{0.091}S_{0.0028}$ alloy has a bcc structure at ambient pressure and the unit cell parameters were a=2.951 Å and V=25.71 $Å^3$. The bcc phase transforms to the hcp structure at above 19 GPa. $Fe_{0.881}Ni_{0.091}S_{0.0028}$ alloy has been compressed up to 360 GPa successfully, and the hcp structure was stable at the maximum pressure. The fit yielded a bulk modulus K_0 = 153(30) GPa and its pressure derivative K_0' = 5.2(4) and V_0 = 22.8(6) $Å^3$. The density of $Fe_{0.881}Ni_{0.091}S_{0.0028}$ alloy at the inner core boundary (ICB) pressure (330 GPa) and 300 K is 13.75 g/cm^3. The density of the inner core material at 330 GPa and 300 K was calculated to be 13.35 g/cm^3 using the thermal expansion at 330 GPa and 5000K reported by Stacey and Davis [8]. 9 at.% of nickel and 5.3-12.0 at.% (3.1-7.2 wt.%) of sulfur can account for the density of the inner core using the present results together with the previous results [2]. The uncertainty of the sulfur content is derived from the uncertainty of the pressure scale [7]. Since metallic iron contains 7.6 at.% (4.5 wt.%) of sulfur at 85.6 GPa and 2200 K [3], hcp Fe-Ni alloy is likely to contain 5.3-12.0 at.% (3.1-7.2 wt.%) of sulfur at the ICB pressure and temperature conditions.

Equation of state and B1/B8 phase transition in FeO

Fischer, R.A.* & Campbell, A.J.
Dept. of Geology, University of Maryland, College Park, Maryland, USA (*raf815@umd.edu)

Wüstite, $Fe_{1-x}O$, is an important endmember of (Mg,Fe)O in the Earth's lower mantle. The Earth's core contains several weight percent of an unknown light element; if this element is oxygen, then wüstite may also be a significant component of the core. Therefore the high pressure, high temperature behavior of FeO, including its phase diagram and equation of state, is essential knowledge for understanding the properties and evolution of Earth's deep interior.

We performed X-ray diffraction measurements on wüstite+iron mixtures at beamline 13-ID-D of the GSECARS sector of the Advanced Photon Source, using a laser-heated diamond anvil cell to achieve simultaneous high pressures and temperatures (90 to 155 GPa and up to 3100 K). Pressures were determined from the lattice parameters of hcp iron and of NaCl, the insulator and pressure medium. Temperatures were determined by spectroradiometry. To confirm the accuracy of our temperature measurements, we verified the location of the hcp-fcc transition in Fe [1]. The wüstite in our experiments was mixed with metallic iron to produce stoichiometric FeO at high pressures and temperatures [2].

We have determined the thermal equation of state of FeO to 155 GPa, combining our new P-V-T data with earlier data [2, 3]. We find a bulk modulus K_0 = 147 GPa, and whereas prior studies assumed a value of four for the pressure derivative of the bulk modulus, K_0' [2], our higher pressure data require a lower value, K_0' = 3.72. The updated equation of state produces a high pressure Fe-FeO oxygen fugacity buffer curve that is only slightly different than that previously reported [2], over the range of overlapping conditions (<0.2 log units at 100 GPa), but with more significant differences at higher pressures such as those achieved in the present study.

The location and slope of the subsolidus phase boundary between the B1 and B8 structures in FeO at high pressures has been controversial. Our data are broadly consistent with a recent study performed above 180 GPa [3], showing a similar positive slope for the transition but temperatures that are systematically ~300 K lower.

Our results for the equation of state for FeO can be compared to the equation of state of hcp-Fe [4] to match the seismologically determined density of the outer core. Assuming a core-mantle boundary temperature of 4000 ± 500 K and a 1-2% density decrease upon melting, the amount of oxygen in the outer core required to match PREM at the core-mantle boundary is 8.0 ± 1.1 weight percent, under the simplifying assumption of a purely Fe-O outer core.

Electrical conductivity measurement of iron at high static pressure

Gomi, H.*, Ohta, K. & Hirose, K.
Dept. of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan (*gomi.h.aa@m.titech.ac.jp)

The knowledge of the thermal conductivity of the core constrains the heat flow and the amount of radiogenic elements in the core [1]. The electrical conductivity of iron has been measured by shock compression experiments. The thermal conductivity can be then calculated using the Wiedemann-Franz law. Stacey and Loper [2] estimated the thermal conductivity of outer core liquid and suggested the absence of radiogenic heat source. However, no conductivity measurement has been carried out under core pressures by static experiments. In this study, we have conducted the electrical conductivity measurements of pure iron under high static pressure at room temperature in a diamond-anvil cell. The sample resistance was obtained by the four-terminal method. The results demonstrated that the conductivity increased with increasing pressure and dropped at ~15 GPa across phase transition from bcc to hcp structure. It then increased again with pressure up to 65 GPa. The electrical conductivity was determined to be about 1×10^7 S/m at 65 GPa. We estimated the electrical conductivity of iron under the CMB pressure and temperature condition to be ~ 1×10^6 S/m, which is comparable to the previous estimate by Stacey and Anderson [3]. The details of the experiments will be reported at the presentation.

Prediction of turbostratic iron from first-principles

Ishikawa, T.[1*], Tsuchiya, T.[1] & Tsuchiya, J.[2]
[1]Geodynamics Research Center, Ehime University, Matsuyama, Ehime, Japan ([*]ishikawa@sci.ehime-u.ac.jp)
[2]Senior Research Fellow Center, Ehime University, Matsuyama, Ehime, Japan

Determining the crystal structure of iron in the Earth's inner core has been a long standing challenge for mineral physics. The hexagonal close-packed (hcp) structure has been predicted to be a dominant candidate structure [1,2]. However, the double hcp structure [3], the face-centered cubic (fcc) structure [4], the body-centered cubic structure [5] have also been suggested and it is still controversial.

Here we propose another model for the structure of iron at the extreme conditions. The model was predicted by structural exploration methods based on first-principles calculations, which are free energy surface trekking (FEST) and multiple-configuration sampling method (MCS) [6]. Exploring the metastable structures at 400 GPa by FEST, we found that the hcp iron transforms to a structure with complex stacking sequence by shear deformation and it is much more easily obtained from hcp than fcc. Based on the results of FEST, we inferred a stacking disorder structure stabilizing with a temperature-dependent stacking fault concentration, which we call turbostratic iron. Then, we determined the thermally-equilibrated stacking fault concentration at each temperature by the MCS method. We found that iron has the stacking fault concentration of about 6% at around 1000 K but it increases to about 38% at the inner core conditions. Then, we analyzed elastic properties of turbostratic iron and found that the stacking fault enhances elastic anisotropy. We anticipate that the model of the turbostratic iron gives some new aspects for the inner core structure.

Stability of body-centred-cubic and hexagonal closed-packed iron-magnesium alloys in the Earth's inner core

Kádas, K.[1,2*], Vitos, L.[1,2,3], Johansson, B.[1,3] & Ahuja, R.[1,3]
[1]Dept. of Materials Science and Engineering, Royal Institute of Technology, Stockholm, Sweden
([*]Krisztina.Kadas@fysik.uu.se)
[2]Research Institute for Solid State Physics and Optics, Budapest, Hungary
[3]Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden

The composition and the structure of the Earth's solid inner core are still unknown. Iron is accepted to be the main component of the core. Lately, the body-centred cubic (bcc) phase of iron was suggested to be present in the inner core, although its stability at core conditions is still in discussion. The higher density of pure iron compared to that of the Earth's core indicates the presence of light element(s) in this region, which could be responsible for the stability of the bcc phase. However, so far none of the proposed composition models were in full agreement with seismic observations. The solubility of magnesium in hexagonal Fe has been found to increase significantly with increasing pressure, suggesting that Mg can also be an important element in the core. Here, we report a first principles density functional study of bcc and hcp Fe-Mg alloys at core pressures and temperatures [1,2]. We show that at core conditions 5-10 atomic percent Mg stabilizes the bcc Fe both dynamically and thermodynamically. Our calculated density, elastic moduli and sound velocities of bcc Fe-Mg alloys are consistent with those obtained from seismology, indicating that the bcc-structured Fe-Mg alloy is a possible model for the Earth's inner core.

Phase relations of iron-sulphur alloys above 2 Mbar

Ozawa, H.[1*], Hirose, K.[1,2], Tateno, S.[1], Sata, N.[2] & Ohishi, Y.[3]
[1]Dept. of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan ([*]ozawa.h.aa@m.titech.ac.jp)
[2]Japan Agency for Marine-Earth Science and Technology, Institute for Research on Earth Evolution, Kanagawa, Japan
[3]Japan Synchrotron Radiation Research Institute, Hyogo, Japan

In 1952, Birch first proposed that the Earth's core is made of alloys of iron and lighter elements. The core is thought to contain considerable amount of light element(s) such as S, O, Si, C, and/or H. The identification of light element(s) in the core, however, still remains uncertain, although the density and seismic velocity profiles and the physical properties of iron and iron-alloys have been much more precisely determined in these fifty years. Since the solid inner core has been growing by crystallization of the liquid outer core with Earth's cooling, the phase diagram of iron-light element system at inner-core/outer-core boundary (ICB) pressure should be known to identify the light elements in the core. Sulphur is thought to be a plausible light element because of its high solar abundance and the easy alloying with iron. Ab initio calculations predict the formation of Fe-FeS solid solution at least in iron-rich part at the ICB condition (e.g., [1]). On the other hand, experimental studies suggest that the Fe-Fe_3S system exhibits a eutectic to 65 GPa (e.g., [2]).

Here we have determined the phase relationships of iron-sulphur alloys up to 250 GPa and 3000 K on the basis of synchrotron X-ray diffraction (XRD) measurements *in situ* at high pressure and temperature using a laser-heated diamond-anvil cell. Starting material was mixed fine powder of Fe and FeS with 20 at.% S composition. We observed coexistence of hexagonal close-packed iron and Fe_3S as subsolidus phases over the entire present experimental conditions. In addition to the XRD measurements, chemical analyses were carried out on the sample recovered from 198 GPa and 3500 K with the field-emission-type electron probe microanalyzer. The direct analyses of the recovered sample demonstrated that solid iron coexisting with Fe_3S contained small amount of sulphur (about 2 at.%) which is less than required to account for the density deficit of the solid inner core. The present results imply that the system Fe-Fe_3S exhibits a eutectic system at least to 250 GPa. Because the solubility of sulphur in the solid iron is still quite limited at such high pressure, other light elements might be necessary to account for the core density deficit.

Thermodynamics of iron melting up to 100 GPa

Steinle-Neumann, G.[1*] & Dolejš, D.[2]
[1]Bayerisches Geoinstitut, University of Bayreuth, Germany ([*]g.steinle-neumann@uni-bayreuth.de)
[2]Institute of Petrology & Structural Geology, Charles University, Prague, Czech Republic

The division of the Earth's core into a solid interior and its liquid envelope has been established by seismological constraints decades ago. The crystallization of the inner core from the outer liquid plays an essential role in the generation of the Earth's magnetic field. In addition, the exclusion of the light elements during freezing contributes buoyancy to convection in the outer core, and the latent heat released contributes to the energy budget of the planetary interior. While experiments are difficult to perform at conditions of the inner core boundary (~330 GPa, 5000-7000 K) ab-initio computations considering both the hcp and liquid iron phases have placed important constraints on these values (e.g. [1,2]).

While the division of the core for other terrestrial planets is not established, models for origin of their magnetic fields can only be advanced if thermodynamic parameters of the liquid and relevant solid phases of iron are well characterized, especially along the melting curve.

Here we have adopted recently published internally consistent equations of state for solid and liquid iron [3] in order to explore its relevant thermodynamic properties up to 100 GPa. The model closely reproduces the experimentally determined phase equilibria. We further explore the thermodynamics by investigating the density contrast and the latent heat difference between the solid and liquid phase during transformations from the bcc (δ) to the fcc (γ) at ~6 GPa and from the fcc to the hcp (ε) phase at ~55 GPa along the melting curve. Along the univariant solid-liquid curve, the density difference between the two states decreases with pressure, and the latent heat released by cooling shows significant differences, increasing from bcc (~14 kJ/mol) through fcc (~17 kJ/mol) to the hcp phase (~25 kJ/mol).

With central pressures of ~10 GPa for the Moon, ~45 GPa for Mercury, and ~60 GPa for Mars and lower pressures for their respective core-mantle boundary different amounts of heat will have been released in the solidification of their respective inner cores.

Structural and elastic properties of Fe_4P at high pressure

Wu Xiang[1*], Qin Shan[1] & Steinle-Neumann, G.[2]
[1]School of Earth and Space Sciences, Peking University, Beijing, China ([*]xiang.wu@pku.edu.cn)
[2]Bayerisches Geoinstitut, Universität Bayreuth, Germany

The earth's core is composed mainly of iron, nickel and several light elements. Recently many Fe-Ni-P meteorites have been discovered, which implies that phosphorus is a candidate light elements in the Earth's core. Melliniite (Fe_4P) with 12.2 wt% phosphor is the most iron-rich Fe-phosphide. It provides a basis for exploring the effect of phosphorus in the Earth's core. However, natural Melliniite grains are very small (<100 μm)[1], and it has not been synthesized in the laboratory, which puts considerable limits on its structural and elastic characterization at high pressure. Here our study aims to answer this issue using *ab initio* calculations based on the density function theory with LSDA+U, implemented in VASP code.

At ambient condition, Melliniite is cubic with space group $P2_13$ and Z=4. Phosphorus atoms occupy the 4a site and iron atoms are at the 4a (labeled Fe1) and 12b sites (Fe2) [1]. From the computations the equation of state of Melliniite is deterimned with V_0 = 214.2 $Å^3$, K_0 = 203 GPa and K_0' = 3.6. The zero pressure volume is 2% smaller than that obtained in experiments (218.76 $Å^3$) [1]. The magnetic moment of Fe1 is larger than that of Fe2. A magnetic collapse occurs for Fe1 at ~80 GPa and completely loses at ~110 GPa. Magnetic moment of Fe2 gradually decreases on compression and disappears at ~110 Gpa. The elastic constants C_{11} and C_{22} show softening at high pressure, associated with the loss of magnetization. The static *P*-wave and *S*-wave velocities also show the same softening behavior in the corresponding pressure range. At 0 K the density of Fe_4P is 3% smaller than that of pure Fe at outer core condition [2]. The temperature effect is estimated, and the results show that phosphorus can play a modest role in reducing the density of an iron-nickel alloy at conditions of the Earth's core.

Combined SIMS and FTIR studies of "water" in nominally anhydrous minerals

Mosenfelder, J.L.*, Rossman, G.R. & Guan, Y.
Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, USA (*jed@gps.caltech.edu)

The accurate analysis of trace concentrations in nominally anhydrous minerals (NAMs) is a long-standing problem [1], with implications for a wide variety of geophysical and petrologic problems in the Earth and other planetary bodies. SIMS and IR are powerful, complementary analytical tools capable of measuring concentrations down to levels of less than 1 ppm H_2O. Each technique has its advantages and disadvantages. Importantly, however, neither is an absolute method, relying on other techniques such as manometry or nuclear reaction analysis (NRA) for full quantification.

We have conducted calibrations comparing FTIR and SIMS data for a wide variety of NAMs: olivine, orthopyroxene, clinopyroxene, pyrope and grossular garnet, rutile, zircon, kyanite, andalusite, and sillimanite. We employ both primary standards, whose H concentrations were determined independently using manometry or NRA, and "secondary standards", whose H concentrations were determined using polarized IR spectroscopy (or unpolarized, for garnets) referenced back to calibrations developed using primary standards. Our most extensive work has been on olivine, for which we collected repeated calibration data in order to bracket measurements of H diffusion profiles in experimentally annealed crystals at levels of ~25-100 ppm H_2O. A representative calibration is shown in Figure 1.

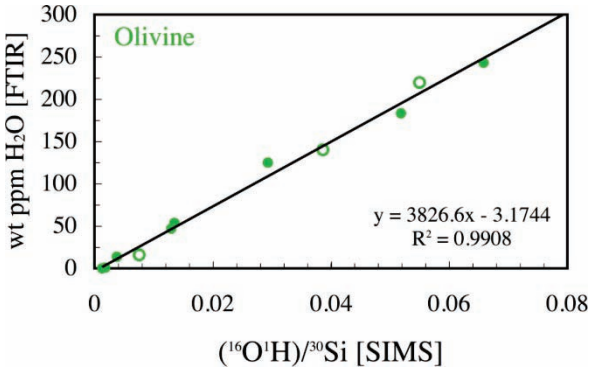

Fig. 1: $^{16}O^{1}H/^{30}Si$ (SIMS) vs. H_2O (FTIR) for 11 olivines. Primary and secondary standards shown with open and closed symbols, respectively. "Near blank" standards include synthetic forsterite (0 ppm H_2O) and San Carlos olivine (0.5 ppm H_2O).

Some of the issues to which we paid careful attention and will address in this presentation include: 1) sample cleaning and assessment of contaminated surfaces, as reflected by relative C, F, Cl, and S counts; 2) "contamination" of measurements by nm-scale hydrous inclusions (e.g. titano-clinohumite in olivine; amphibole in orthopyroxene; muscovite in kyanite), reflected by sudden and extreme changes in $^{16}O^{1}H$ (and/or ^{19}F) counts during crater sputtering; 3) assessment of reproducibility through multiple measurements on each sample (typically ≥5); 4) measurement of matrix effects both for minerals of different composition, and polymorphs (in the case of Al_2SiO_5); and 5) assessment of the potential of SIMS for determining site-specific IR absorption coefficients in minerals [2].

Towards a protocol for quantitative micro-FTIR measurements of water in the nominally anhydrous minerals of the upper mantle

[5]Research School of Earth Sciences, The Australian National University, Canberra, Australia

"Water" in the nominally anhydrous minerals (NAMs) of the upper mantle is considered to play a significant role in determining the rheological, seismic, electrical conductivity and melting properties. Both the concentration and the way how water is incorporated is important to understand and formulate the effect of water on these properties. There are several different analytical techniques (i.e., SIMS, NRA, ERDA, manometry and proton-proton scattering) which are able to give accurate quantitative information, but only Fourier-transform infrared (FTIR) spectroscopy is capable of providing qualitative and quantitative information simultaneously. The qualitative information appears to be better constrained than the quantitative as the assignment of infrared bands to particular substitution mechanisms is relatively well constrained for olivine [1] and also has some preliminary results on pyroxenes [2]. The quantitative aspects of micro-FTIR seem to be less determined because there are several different ways for undertaking quantitative analysis and data processing. Our goal is two-fold: 1) To give an overview of analytical setups and data evaluation routines that have been used so far and demonstrate that the non-uniform analytical conditions and data evaluation prevent any direct quantitative comparison among different studies; 2) To outline a protocol for future studies. The most problematic part of quantitative infrared spectroscopy is the use of both polarized [3] and unpolarized [4] radiations, and the application of mineral- [5], substitution mechanism-[6] and wavenumber-dependant calibrations [7] for determining absolute concentrations. It has been demonstrated that there is a systematic relationship over a wide range of absorption properties between polarized and unpolarized light [4] which would make it possible to re-evaluate and, thus, make comparable previous results. It was also shown that wavenumber-dependant calibrations give only a rough first-order approximation on water concentrations, but for more accurate results mineral- and substitution mechanism calibration should be used [6]. The protocol would give instructions on both the analytical setup (i.e., sample preparation, microscope settings) and data evaluation (i.e., background substraction, integration and calibration factors) which may facilitate the achievement of more accurate quantitative measurements and direct comparison of quantitative FTIR results in the future.

"Water" in nominally anhydrous minerals and its influence on some physical properties

Koch-Müller, M.
Deutsches GeoForschungsZentrum, Potsdam, Germany
(mkoch@gfz-potsdam.de)

Hydroxyl incorporation in nominally anhydrous minerals called NAMs is an important research field in geosciences with many implications in analytics, geochemistry, mineral physics and thermodynamics. Since the first studies on NAMs of the Earth's crust in the early 60ties our knowledge and understanding in this field has grown exponential. In this contribution I will summarize the latest developments. The paper is divided in three part: in part one recent analytical developments and/or improvements for "water" quantification in NAMs will be presented, compared and discussed; part two deals with important incorporation mechanisms of hydrogen and how to access it, e.g. for wadsleyite; in part three some data on the influence of "water" incorporation in NAMs on physical properties such as kinetics of phase transitions, phase stabilities and mineral reactions will be presented.

Spatial OH-defect distribution in single crystals of synthetic enstatite

Prechtel, F.* & Stalder, R.
Institute of Mineralogy and Petrography, University of Innsbruck, Austria (*felix.prechtel@uibk.ac.at)

Single crystals of pure enstatite ($Mg_2Si_2O_6$) up to 800x600 µm were synthesized under water-saturated conditions at 6 GPa and 1250°C with variable silica activity. Run products were investigated using a novel technology, a FT-IR-spectrometer equipped with a focal plane array detector enabling IR-imaging with a spatial pixel resolution of 2.7 µm.

IR spectra within the OH-absorption region show strong pleochroic behaviour: absorption bands (1) at 3687 cm^{-1} and 3592 cm^{-1} show strongest absorptions for $E||n_\beta$, whereas absorption bands (2) at 3362 cm^{-1} and 3067 cm^{-1} show strongest absorptions for $E||n_\gamma$. The intensity ratio of the bands within one group is always constant within a narrow range but absorption bands are sensitive to the silica activity (Fig. 1). The most probable interpretation is an assignment of the high-energy absorption bands (1) to tetrahedral (T-site) defects (i.e., V_T) caused by a lower availability of Si and the low-energy absorption bands (2) to octahedral (M-site) defects (i.e., V_M) caused by a lower availability of Mg.

All crystals show an internal zonation pattern with an increasing T-site to M-site defect ratio from core to rim which is interpreted to be caused by changing silica-activity during the experiments. The defect ratio and the zonation pattern are applied as monitor for crystal growth conditions. Furthermore, our observations can be used for the estimation of high-pressure diffusivities of metal cations and metal vacancies. Diffusion models have been developed to strengthen this theory (Fig. 2).

Continuative experiments at 4 GPa and 8 GPa are currently object of investigation.

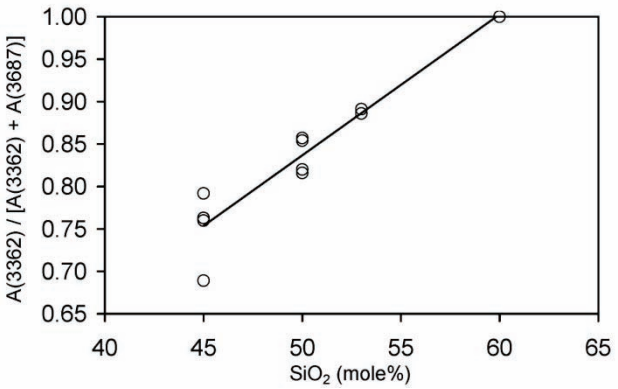

Fig. 1: Influence of silica activity on the dominance of the band around 3362 cm^{-1} expressed as A(3362)/[A(3362) + A(3687)].

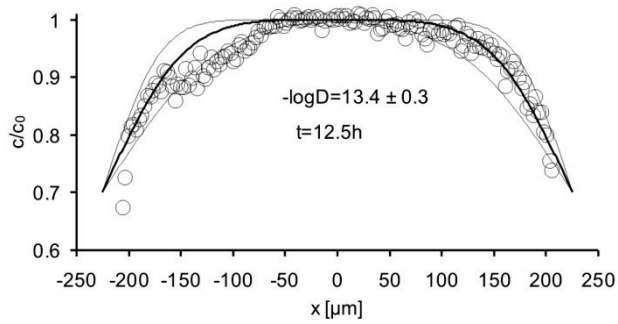

Fig. 2: Concentration profile of Mg-vacancies charge balanced by protons derived from the absorption band at 3362 cm^{-1} with apparent diffusion coefficients of $D_{Mg(M)}$ for a realistic defect equilibration time.

Water content of pyroxenes from Italian volcanoes: implications for the hazard of Etna and Aeolian volcanoes

Nazzareni, S.[1*], Skogby, H.[2], Pompilio, M.[3] & Zanazzi, P.F.[1]
[1]Dept. of Earth Sciences, University of Perugia, Italy ([*]sabrina.nazzareni@unipg.it)
[2]Dept. of Mineralogy, Natural History Museum, Stockholm, Sweden
[3]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Pisa, Italy

Volcanic clinopyroxenes NAMs may be used to evaluate volatiles evolution during magma crystallization and ascent, especially when glass and melt inclusions are not available or appear totally crystallized. Southern Italy (Aeolian arc and Etna) is one of the most active volcanic areas of Europe and being densely populated has a high level of volcanic hazard.

We performed polarized FTIR, SC-XRD, LA-ICP-MS and EPM analysis on the same clinopyroxene (Cpx) phenocrystals from Etna (3930 BP picritic eruption, Cono del piano - 2001 and 2002 eruptions) and from different volcanic stages of Vulcano, Salina and Alicudi (Aeolian arc), and Mössbauer on selected samples to account for possible H loss by Fe oxidation. We calculated the water contents of Cpxs from the FTIR spectra using the Libowitzky & Rossman [1] calibration.

The H_2O contents of Cpx:s from the Aeolian volcanoes reach up to 390 ppm H_2O by weight in Salina, up to 345 ppm H_2O by weight in Vulcano and up to 270 ppm H_2O by weight in Alicudi. Vulcano cpxs showed a large variation in water content, within the same volcanic stage: primordial Vulcano 23-236 ppm H_2O; Lentia complex 22-345 ppm H_2O; Vulcanello 40-101 ppm H_2O. To evaluate if this variation might be ascribed to H loss during the late stage of eruption or due to variation in the reservoir, we carried out which Mössbauer analyses and re-hydrogenation experiments on 5 selected samples. Two heat treatments were performed under hydrogen gas flow at 700°C for 6 hours each, and after each experiment the IR spectra were collected again. The most "dry" samples take up H (i.e. Pl7 from 23 to 136 ppm H_2O, Lt2 from 36 to 187 ppm H_2O), while the most H_2O rich remains almost unchanged suggesting H loss for the former while the latter may be representative of original crystallisation conditions.

The water content of the Etna cpx:s is quite high suggesting a water rich magmatic system and showed only minor variations from the different eruptions: 254 ppm H_2O for 3930 BP picritic eruption; 214 ppm H_2O for 2001 eruption; 161-254 ppm H_2O for 2002 eruption. Zoned Cpx's from 2001 and 2002 eruptions showed, in general, a more water and trace elements (Y, Zr, Yb, Ce, La) rich core and a more "dry" and trace elements depleted rim possibly grown during a late volcanic stage. In general we found that the H_2O contents of our Cpx's correlate inversely with Ce, La between REE and Y, Yb between HREE, while no correlation is found with elements like Sr. Although Fe oxidation could have been responsible for partial water loss, different physico-chemical magma conditions during the rim growth is a more likely explanation. Wade et al [2] proposed a partition coefficient $D_{H2O}^{cpx/liq}$ as function of Al^{IV}. For the present samples we observe a partition coefficient slightly higher than 0.005, as based on the water contents measured in cpx and olivine-hosted melt inclusions. The above data are the first measured on etnean minerals and since pyroxene is one of the early phases on the liquidus, they are useful, together with melt inclusions, for estimate the total budget of volatiles in the ascending magma.

[1] Libowitzky, E. & Rossman, G. (1997) *Amer. Mineral.*, **82**, 111-121. [2] Wade, B. et al. (2008) *Geology*, **36**, 799-802.

Water contents of majorite garnet, Al-bearing perovskite and Al-bearing stishovite generated in pyrolite-H_2O systems

Inoue, T.[1*], Katsuda, M.[1] & Yurimoto, H.[2]
[1]Geodynamics Research Center, Ehime University, Matsuyama, Japan ([*]inoue@sci.ehime-u.ac.jp)
[2]Dept. of Earth Sciences, Hokkaido University, Sapporo, Japan

Water is the most abundant volatile component in the Earth, and the presence of H_2O in mantle minerals affects elastic and rheological properties. It is well known that wadsleyite and ringwoodite, which are the most abundant minerals in the mantle transition zone, can accommodate a significant amount (up to ~3 wt %) of H_2O in their crystal structures (e.g. [1,2]). Recently, we have reported the partitioning of H_2O between high pressure polymorphs of olivine (wadsleyite, ringwoodite, and perovskite) [3] in the system $(Mg,Fe)_2SiO_4$-H_2O, and knowledge of the water content in these minerals has been clarified well. On the other hand, majorite garnet is the second abundant mineral in the mantle transition zone, but there are few reports for the H_2O content except for [4]. In addition, there are few reports for the H_2O content of Al-bearing perovskite and Al-bearing stishovite, except for [5-7]. We have conducted high pressure experiments to determine the water content of majorite garnet, Al-bearing perovskite, and Albearing stishovite.

High-pressure experiments were conducted by an MA-8 type (Kawai-type) high-pressure apparatus at Ehime University. We used a pyrolite composition which was approximated with respect to five major components, CaO, MgO, FeO, Al_2O_3, and SiO_2. Two starting H_2O contents, 2.9 and 8.3 wt% were selected. The experimental P-T conditions were 22-23 GPa and 1300-1700°C. The recovered samples were polished and then the chemical compositions were determined by EPMA at Ehime University and the H_2O contents of the minerals were measured by SIMS at Hokkaido University.

The recovered run products at 22 GPa and in the H_2O 2.9 wt% system were basically majorite garnet + ringwoodite + liquid, and ringwoodite was transformed to perovskite at 23 GPa. On the other hand, those at 22 GPa and in the H_2O 8.3 wt% system were basically majorite garnet + stishovite + liquid, because the extra MgO-rich liquids were generated under hydrous and highpressure conditions and stishovite became liquidus under those conditions. The H_2O content of ringwoodite decreased with increasing temperature from ~1.8 wt% at 1400°C to ~0.5 wt% at 1700°C, which is consistent with Ohtani et al. (2000). However, the H_2O content of majorite did not change so much with increasing temperature from ~0.3 wt% at 1400°C to ~0.2 wt% at 1700°C. In addition, the coupling phenomena between H^+ and Al^{3+} were observed in both Al-bearing perovskite and Al-bearing stishovite. Further details will be presented.

Hydrogen defects and diffusion in alkali feldspars

Behrens, H.
Institut für Mineralogie, Leibniz Universität Hannover, Germany (h.behrens@mineralogie.uni-hannvoer.de)

Hydrogen defects in Eifel sanidines and an adularia from unknown locality were studied combining IR spectroscopy with heating and diffusion experiments under well controlled conditions. Near infrared spectra show that OH groups are predominant hydrous species in Eifel sanidine but presence of minor amounts of molecular H_2O cannot be excluded. Short term annealing at 400°C produces a small but significant irreversible change in the OH stretching vibration band. The portion of hydrous species with low H-bonding (adsorbing at wavenumbers around 3450 cm^{-1}) is increased on expense of species with low hydrogen bonding (adsorbing at 3200 cm^{-1}).

Polarized mid-infrared spectra of sanidine and adularia plagioclase recorded *in situ* at temperatures up to 600°C show shifts of maxima towards higher wavenumber and an overall decrease in integrated intensities. However, no evidence was found for further rearrangement in local environment of hydrogen upon heating. The dichroic scheme of OH vibration bands remains basically unchanged with predominant orientation of OH dipoles along the crystallographic *a*-axis. In Eifel sanidine a second type of OH dipoles oriented parallel to *b** is observed also in the high temperature spectra.

At 900 – 1000°C Eifel sanidines rapidly lost about one third of hydrogen which is very mobile in the feldspar structure. The remaining hydrogen is more strongly bonded and can be removed only by long term annealing at high temperatures under extremely dry conditions (i.e. in air dried by phosphorus pentoxide). Annealing experiments under controlled water pressures show constant hydrogen contents in the sanidine below 1 bar (except for extremely low water fugacity) and a continuous increase in hydrogen concentration with water fugacity above 1 bar. These findings support that the Eifel sanidines contain two OH species, a mobile one and a strongly localized one.

Diffusion of hydrogen in sanidine and adularia was investigated by D/H isotope exchange in the T range 600 – 1050°C at ambient pressure and at elevated pressures up to 400 MPa. Runs at 1 atm were performed in a fused silica tube connected to a liquid D_2O reservoir at room temperature. In the high pressure experiments samples were sealed with D_2O in gold capsules and processed in externally heated pressure vessels using Ar/D_2O as the pressure medium. Diffusion coefficients were determined either by measuring concentration-distance profiles of OH and OD with an IR microscope or by measuring the total exchange of oriented plates after various run durations using a macroscopic IR technique. Both methods gave consistent data. D/H interdiffusion in sanidine is independent on the crystallographic orientation and can be described at ambient pressure by

$$D = 9.6^{+4.6}_{-2.8} \cdot 10^{6} \frac{m^2}{s} \exp\left(\frac{-162 \pm 3\, kJ / mol}{RT}\right).$$

Diffusion rates are almost identical for adularia and sanidine implying that the chemical composition and the degree of Al/Si disorder have minor influence on D/H interdiffusion in alkali feldspars. On the other hand, the hydrogen diffusivity is strongly enhanced by water pressures, i.e. D is 0.7 log units faster at 200 MPa than at ambient pressure. When using mixed D_2O/CO_2 fluids for isotope exchange, the diffusion coefficients are systematically lower than for a pure D_2O fluid, which demonstrates that the enhancement of hydrogen diffusivity is due to water fugacity and not to pressure.

Diffusion of water through quartz: the use of synthetic fluid inclusions

Bakker, R.J.
Dept. of Applied Geosciences and Geophysics, Mineralogy and Petrology, University of Leoben, Austria (bakker@unileoben.ac.at)

Diffusion of water and water-related species, such as D_2O, $H_2{}^{18}O$, H_2, O_2 through anhydrous quartz were experimentally investigated in this study by analyzing the properties of fluid inclusions. Fluid inclusions with known fluid composition and density were synthesized in anhydrous natural quartz. The fluid inclusions are synthesized in cylindrical cores that were drilled in specific crystallographic orientations from the starting material. Micro-cracks are formed in those cores by rapid cooling after heating up to about 400°C. The fluid inclusions are synthesized by crack-healing at high experimental temperature and pressure in autoclaves with a confining hydrostatic pressure (argon). The experimental conditions were selected within the α-quartz or β-quartz stability field (max. 700°C and 1 GPa). The inclusions were characterized by a detailed petrographical study (distribution and morphology), microthermometry and Raman spectroscopy. Subsequently, those inclusions were re-equilibrated at high temperature and pressures in a fluid environment that differs from the included fluid. Re-equilibration conditions are selected at similar temperature-pressure conditions to minimize the effect of pressure gradients that could induce additional mechanisms of fluid inclusion alteration. The imposed gradients in chemical potential (or concentration) between fluid inclusions and the outside of the crystal provoke diffusion of the specific fluid components. Any change in the properties of the original fluid inclusions were detected and quantified mainly by microthermometry and Raman spectroscopy. A relationship between the length of the diffusion path (depth of inclusion below the crystal surface) and fluid inclusion properties were expressed in a "concentration" profile along the crystal, that was used to determine a three dimensional diffusion model and corresponding diffusion coefficients.

The available mathematical diffusion models and temperature dependent diffusion constants for water-related species through quartz are not consistent with the obtained results, which is mainly caused by the difficulty by which those parameters were determined. Therefore, a new mathematical diffusion model was developed according to the boundary conditions of the experiments as a specific solution of the Fick's laws.

The new diffusion model is applied to the study in re-equilibration of natural fluid inclusions, and results in extremely fast re-equilibration rates. Diffusion according to this model may be restricted and partly inhibited by several important boundary factors, such as the low porosity in metamorphic rock and relative low temperatures in sedimentary and diagenetic rocks. The imprecision of estimated diffusion coefficients and the undetermined accuracy do not allow reliable diffusion calculations. A computer-program has been developed to perform mathematical experiments on the re-equilibration-rate of randomly located fluid inclusions in spherical quartz grains. The diffusion of H_2O, CO_2, CH_4 and NaCl can be taken into account in this computer model, which is freely downloadable from the web site http://fluids.unileoben.ac.at.

Isotopic diffusion of hydrogen in apatite

Ingrin, J.*, Calvot, G., Condamine, P. & Sicard, D.
LMTG, Université de Toulouse, CNRS, IRD, OMP, Toulouse, France (*ingrin@lmtg.obs-mip.fr)

Kinetics of hydrogen - deuterium exchange were investigated by FTIR spectroscopy on two gem quality single crystals from Durango (Mexico) and Madagascar. Annealing experiments were performed at ambient pressure, between 973-1273 K under a flux of argon enriched in D_2 and D_2O. During exchange all the OH absorption bands have the same behaviour, but the kinetics are different with the direction of diffusion:

$$D_{\perp C} = D_0 \exp\left[\frac{-(150 \pm 22)\,\mathrm{kJ/mol}}{RT}\right], \log D_0\,(\mathrm{m^2/s}) = -7.7 \pm 1.0$$

$$D_{//C} = D_0 \exp\left[\frac{-(124 \pm 21)\,kJ/mol}{RT}\right], \log D_0\,(m^2/s) = -9.9 \pm 0.9$$

The diffusion in the basal plane of the crystal is faster than the diffusion perpendicular to it in the direction [001], with almost one order of magnitude difference. The diffusion rates are faster than the diffusion rates measured by Brenan [1] for the exchange of H, Cl and F at room pressure. However, our rates of diffusion are closer to the average result exchange rates found by Brenan [1] at high pressure. This suggests that the exchange of H, Cl and F in apatite could be controlled at high pressure by the mobility of hydrogen.

The knowledge of hydrogen diffusion in apatite can be used to measure fast event in volcanic processes.

Water concentrations in the lithosphere from three different tectonic settings of the Carpathian-Pannonian region

Kovács, I.[1*], Falus, Gy.[1], Hidas, K.[1,2], Szabó, Cs.[2] & Ingrin, J.[3]
[1]Eötvös Loránd Geophysical Institute of Hungary, Budapest, Hungary ([*]kovacsij@elgi.hu)
[2]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary
[3]LMTG, Université de Toulouse, CNRS, IRD, OMP, Toulouse, France

The identification of "water" (i.e., OH^-, H_2O) as a trace element at defect sites in nominally anhydrous minerals (NAMs for short) has drastically changed the concept of "water" storage in the upper mantle and crust. In the past decades our knowledge on the lithosphere and astenosphere beneath the Carpathian-Pannonian region (CPR) has been greatly improved by the studies of xenoliths hosted in the Plio-Pleistocene alkaline basalts [1]. Studying "water" in xenoliths of the CPR improves considerably our understanding on its concentrations and on its possible effect on rheological properties in a well-known geological setting. A new infrared technique [2] utilizing unpolarized light enables accurate determination of water concentrations in NAMs even from fine-grained mantle xenoliths. Peridotite xenoliths from three Plio-Pleistocene alkaline basaltic localities were studied in different tectonic settings (BBH, NG, ETB). The Bakony-Balaton Highland (BBH) is in the center of the CPR and the lithosphere beneath the area suffered considerable extension in the Miocene, therefore the lithosphere is considerably thinned (~60 km) and characterized by high heat flow. The Nógrád-Gömör area (NG) is in a transitional tectonic setting as its southern part is characterized by a thinned lithosphere similar to BBH, but the lithosphere thickens gradually towards the north and at its northernmost part it shows a thickness similar to the ambient (100-120 km) lithospheric thickness in the CPR. The East Transylvanian Basin (ETB) is in a different tectonic setting as it was not affected by the Miocene extension. The ETB area has normal lithospheric thickness, but it is close to the youngest subduction system in the CPR. Our preliminary results indicate that the concentration of "water" in NAMs of the shallow lithosphere (<60km) close to the young subduction along the Eastern Carpathians (ETB) and in the transitional setting (NG) are higher than in the shallow lithosphere of the BBH situated in the central CPR. These results may imply that the lithospheric mantle in the ETB [3] and NG areas has higher water concentrations due to the Miocene subduction in the ETB and the smaller or transitional extension in the NG. This is an indication that water concentration in the lithosphere may be used as an additional „tool" to put constraints on the geodynamic history of a particular lithospheric column.

IR-imaging of synthetic crystals and natural rocks

Stalder, R.
Institut für Mineralogie und Petrographie, Universität Innsbruck, Austria (roland.stalder@uibk.ac.at)

During the last decades IR spectroscopy has been the major technique to characterise the water incorporation in nominally anhydrous minerals in terms of structural environment, orientation of the OH dipole and quantification of water content. When using single element detectors the spatial resolution is limited to about 20µm, because of significant diffraction of the IR radiation at the rim of the aperture masking the analysed spot.

By the application of a focal plane array detector (FPA) no aperture is needed and a pixel resolution of <3 µm (i.e. in the order of the wavelength of the IR radiation) can be reached.

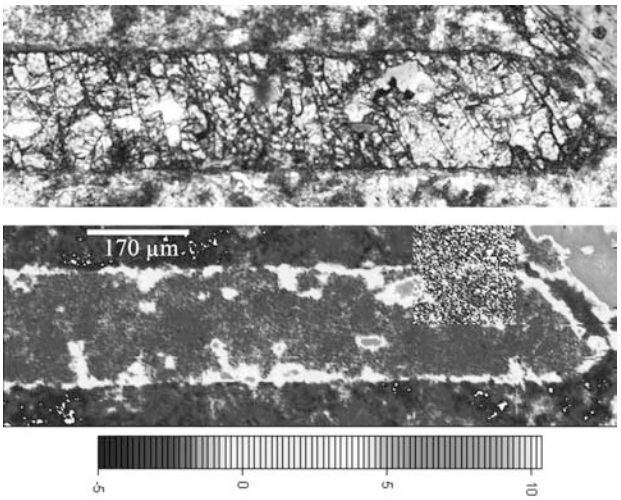

Fig. 1: Cpx from a carbonatite from Alnö/Sweden in transmitted light (above) and as IR-absorption image of the integral absorbance of the band between 3630 and 3740 cm^{-1} (below), characteristic for OH in mica and amphibole.

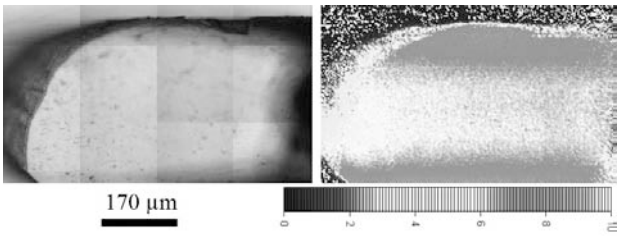

Fig. 2: Synthetic enstatite doped with Cr and Al synthesized at 25 kbar and 1150°C in transmitted light (left) and as IR-absorption image of the integral absorbance of the band between 3490 and 3590 cm^{-1} (right), which is characteristic for tetrahedral OH-defects in Opx.

In this study an IR-microscope equipped with a focal plane array detector consisting of 64 x 64 MCT-pixel is applied to image IR absorption bands of a broad variety of natural and synthetic samples, ranging from oriented single crystals from high-pressure experiments to thick sections of igneous and metamorphic rocks. The work is focussed on the detection of nominally OH-bearing micro-inclusions in nominally anhydrous minerals (Fig. 1) and the distribution and zonation of OH-defects in single crystals (Fig. 2).

Experimental rehydration of mantle pyroxenes

Sundvall, R.* & Skogby, H.
Dept. of Mineralogy, Swedish Museum of Natural History, Stockholm, Sweden (*rickard.sundvall@nrm.se)

The role of low water contents occurring in the nominally anhydrous minerals (NAMs) of the upper mantle has received a strong interest during recent years, since these phases are capable of storing water in the upper mantle. However, one crucial question that has not yet received a satisfying answer is: To what extent has hydrogen been lost in mantle xenoliths during ascent process, and how representative are the water concentrations reported from these xenoliths for the original conditions of the upper mantle?

From a considerable amount of studies of dehydration kinetics of pyroxenes and other mantle NAMs it is clear that dehydration may occur relatively fast following the redox reaction:

$$OH^- + Fe^{2+} = O^{2-} + Fe^{3+} + \tfrac{1}{2}H_2 \qquad (1)$$

This reaction proceeds by the diffusion of protons and electron holes (polarons) and appears fast enough to allow substantial changes in H concentrations during the time and temperature regimes of most magma ascent processes. However, the reactions controlling the host defects associated with H incorporation (i.e. vacancies and charge-deficient substitutions) involve cation diffusion, with kinetics typically two orders of magnitude slower than that for redox exchange [1]. This means that the host defects have a much higher likelihood to be preserved than the hydrogen itself. Hence, it appears possible to experimentally restore lost hydrogen into the structure by driving reaction (1) backwards, as long as the temperature and time of such experiments are limited to leave the defect state of the structure largely unchanged.

We have performed a systematic study on a range of ortho- and clinopyroxene samples from different mantle occurrences to investigate their re-hydration capacity. The experiments were performed as step-wise heat treatments in 1 atm. H_2 of crystallographically oriented crystal sections. FTIR spectroscopy was used to monitor the change in OH concentration after each heating step. The results show that most natural samples do not respond significantly to thermal annealing in H_2 under these conditions. However, two of twelve studied samples show a strong stepwise increase in water contents that level off to a saturation value. Prolonged heat treatments in H_2 cause a slight decrease of the water contents. The results indicate that most mantle samples have not lost substantial amounts of water during late stages of the ascent process, and that it is possible to experimentally restore water contents in samples which do have lost water by the redox reaction (1).

Evidence of structural OH groups in xenotime

Talla, D.[1,2*], Beran, A.[2], Losos, Z.[1] & Skoda, R.[1]
[1]Institute of Geological Sciences, Masaryk University, Brno, Czech Republic (*sutrar@volny.cz)
[2]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria

Xenotime, YPO_4, a well-known accessory mineral in the Earth's crust, has been subject to FTIR-spectroscopic investigations. A series of absorption bands, of which the most prominent peak occurs at 3519 cm^{-1}, has been determined in xenotime samples from different localities. The occurrence of these bands indicates the presence of traces of structurally bound hydrogen atoms in the xenotime structure.

Based on their pleochroic behaviour, determined by polarized IR measurements, the studied absorption bands can generally be divided into three groups. Whereas those centered at lower wavenumbers up to 3550 cm^{-1} have their absorption maxima parallel to the crystallographical *c*-axis, absorption phenomena at higher energies are generally most pronounced with the polarization direction of the IR beam perpendicular to the main crystal axis. Finally, a weak band doublet with a different degree of orientation in respect to the crystallographical axes occurs at wavenumbers exceeding 3600 cm^{-1}. The high wavenumber of these bands, along with the poor degree of their pleochroism, is indicative of submicroscopic inclusions of phyllosilicates, such as sericite [1,2].

A more detailed investigation of the band pleochroism within both 'intrinsic' OH absorption bandgroups, supported by spectral measurements at LN_2 temperature, confirms further variations of the pleochroic behaviour with respect to the crystal structure. The IR spectra recorded at low temperature are characteristic with enhanced band resolution, also aiding in the determination of hidden peaks.

Based on the O_D-O_A distance correlation diagrams [3] and with regard to the crystal structure of xenotime [4], several possible OH defect incorporation sites have been determined. Bands displaying absorption maxima parallel to the *c*-axis are indicative of a hydrogen atom bound to the corner oxygen of either a vacant PO_4 polyhedron, or an occupied one, associated with a vacancy on the Y site. OH dipoles oriented nearly perpendicular to the *c*-axis may also be associated with the mentioned Y-site vacancy. In general, the role of the replacement of Y by $REEs^{3+}$ as well as P^{5+} by Si^{4+} has to be taken into account to explain minor differences in the OH dipole orientation as well as band splitting.

The results of heating experiments confirm the presence of several types of structural OH groups in xenotime, but also cause new OH absorption phenomena at lower wavenumbers.

The results of sample deuteration at 900°C prove a different response of the various OH defect types to this procedure, as maximum absorption of prominent O-D bands occurs solely perpendicular to the *c*-axis.

Xenotime is isostructural with zircon, where the presence of hydrous defects is now well established. The results of the current study can be used among other for a valuable comparison of both mentioned phases.

Water in tektites by proton-proton scattering, IR- and Raman spectroscopy

Thomas, S.-M.[1*], Thomas, R.[2], Reichar, P.[3], Bina, C.R.[1] & Jacobsen, S.D.[1]
[1]Dept. of Earth and Planetary Sciences, Northwestern University, Evanston, IL, USA
([*]smthomas@earth.northwestern.edu)

[3]Universität der Bundeswehr München, Neubiberg, Germany

Raman spectroscopy and proton-proton (pp) scattering routines have been developed to determine water contents ranging from a few wt ppm to wt% in glasses and nominally anhydrous minerals [1,2]

Those routines are promising examples of quantification tools to determine material specific molar absorption coefficients for infrared (IR) spectroscopy. Material specific absorption coefficients are required because general IR calibrations do not necessarily apply to minerals and silicate glasses with water incorporated in the form of OH groups.

Absorption coefficients and water contents for a set of tektite glasses were independently determined with pp-scattering, IR and Raman spectroscopy. First precise measurements of water content in this material were only reported in the 70s using IR spectroscopy. Accordingly, the water content in tektite glasses is very low, ranging from 2 to 300 wt ppm H_2O [3] and has been used for debating their origin, terrestrial or lunar. However, independent studies using advanced techniques are not available.

In this study we will present new measurements and test, discuss and review available data, the feasibility of existing IR calibrations and implications for tektite glass origin.

Environment of diamonds in eclogites from kimberlites (Yakutia): application to their genesis

Spetsius, Z.V.[1*] & Kamenetsky, V.S.[2]
[1]Scientific Investigation Geology Enterprise, ALROSA Co Ltd, Mirny, Russia ([*]spetsius@cnigri.alrosa-mir.ru)
[2]ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Tasmania, Australia

Eclogite xenoliths from kimberlites worldwide display evidence of partial melting and metasomatism, caused by introduction of K-Na–rich fluids. There is compelling evidence for a late and multistage formation of diamonds in eclogites that is connected with partial melting and metasomatism [1,2]. The primary eclogite minerals and various secondary phases around diamonds in eclogites from the Udachnaya pipe were investigated by ESM with EDS in order to elucidate the relationships between diamonds and metasomatic processes.

Diamonds in eclogites are distributed between rock-forming garnet and clinopyroxene, and in most cases surrounded by metasomatic minerals. These minerals represent different stages of metasomatic events that start as a partial melting of primary garnet and clinopyroxene. The crystallization products of this reaction, typically represented by a "spongy" cpx around primary omphacite, include secondary clinopyroxene (with lesser Na_2O and Al_2O_3), feldspar and glass. Primary garnet also shows evidence for partial melting with typical development of kelyphitic rims. Intragranular veins of crystallized partial melt are represented by spinel, plagioclase, amphibole and phlogopite. Metasomatic assemblages around diamonds are rich in carbonate, apatite and sulfide blebs.

The compositions of secondary phases suggest that these metasomatic and partial melting events took place at decreasing P and varying T, usually tlower than the equilibration T of the rock-forming garnets and clinopyroxenes. The compositions of newly-formed minerals indicate that melting was not isochemical, but involved the introduction of metasomatic fluids rich in alkalis, mainly K, and probably volatile elements, such as carbon. Fluids play an important role in initiating partial melting of eclogites and metasomatic growth of diamonds.

The diamonds in xenoliths can have unusual forms of growth such as hopper crystals, which include partially melted clinopyroxenes. Some diamonds show skeletal growth and have captured secondary pyroxene as inclusions. There are also crystals that look like "coated" diamonds. These observations suggest that some of the diamonds in eclogites grew simultaneously with the metasomatic minerals in non-equilibrium, metastable conditions. Diamonds crystallized in a volatile-rich melt or formed from a fluid. Metasomatic processes occurred over a broad spectrum of PT-conditions, as well as compositions of both original rocks and mantle fluids that are now recorded in the secondary mineral assemblages.

The partial melting of primary eclogitic minerals was initiated by metasomatic fluids upon entrapment of xenoliths by the kimberlite magma, and continued during upward movement of the kimberlite to depths of ~30 km. Metasomatic growth of diamonds in eclogite xenoliths could be repeated and may have been closely associated with metasomatic influx that resulted in partial melting. Spatial correlations exist between the presence of some diamonds and the partial-melt products, as well as metasomatic zones. We propose that the growth of some diamonds was associated with partial melting and metasomatism that further promoted formation of second generation of diamonds, as well as last-stage fibrous diamond coatings, some microdiamonds, and cubes.

"Maltese-cross" diamonds: a spectroscopic approach to understanding formation conditions and element partitioning

Howell, D.[*], Griffin, W.L., O'Reilly, S.Y., O'Neill, C., Pearson, N. & Grant, K.
GEMOC, ARC National Key Centre, Macquarie University, Sydney, Australia ([*]dhowell@science.mq.edu.au)

An interesting set of diamond samples (locality unknown) shows a variety of 'maltese-cross' sectorial growth features (Fig. 1). The samples are all in the form of plates cut from the centre of the original diamonds. They are characterised by high nitrogen concentrations (>1800 ppm) and 10–20% IaB nitrogen aggregation.

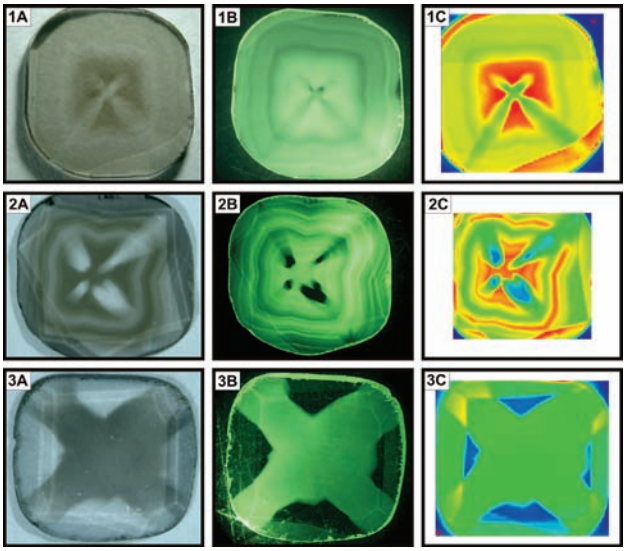

Fig. 1: Images of 3 diamonds from the collection of 13. Images A are taken under visible light, B are taken under UV & C are false colour IR maps showing the relative intensity of the 3107 cm^{-1} (hydrogen) band (blue shows lowest absorption and red the highest).

A new method of IR mapping that can deconvolute several thousand spectra from an individual stone is being applied to these samples. This novel technique can produce false-colour maps showing the distribution of nitrogen content and aggregation states, as well as hydrogen and platelet defects. These maps should allow for easier characterization of samples based upon their concentration and distribution parameters of these various defects [1]. They may also provide data regarding the preferential incorporation of nitrogen on the octahedral faces compared to the cube faces [2,3].

Nitrogen incorporation in diamond has been interpreted as being both compatible [4] and incompatible [5]. The incompatible-behaviour model suggests that high nitrogen concentrations occur due to rapid disequilibrium growth, while slow equilibrium growth would produce nitrogen-free (Type II) diamonds. How the interpreted growth histories of these samples fit into this argument will be of great interest.

Combined FIB/TEM and micro computer-tomography of polycrystalline diamond (framesite) from Orapa, Botswana

Jacob, D.E.[1*], Wirth, R.[2], Enzmann, F.[1] & Kronz, A.[3]
[1]Dept. of Geosciences and Earth System, Science Research Centre, Johannes Gutenberg-Universität, Mainz, Germany
([*]jacobd@uni-mainz.de)
[2]GFZ Potsdam, Germany
[3]Geowissenschaftliches Zentrum der Universität, Göttingen, Germany

Micro- and nano-inclusions in polycrystalline diamonds provide a unique source of information on the nature and timing of small scale processes that lead to diamond formation [1,2] and complement research on fibrous diamonds as well as more "traditional" inclusion suites in gem diamonds.

A single specimen from the Orapa kimberlite was studied in detail by SEM, EPMA, FIB-assisted TEM and µCT. It is the first time that these methods were applied in combination to a single framesite specimen. The beauty of this approach lies in the resulting dataset that combines 3D-structual data by µCT with a resolution of ca. 1.3µm per voxel (see Fig. 1) with a "seamless" extension into nanometre-scale resolution achieved by FIB/TEM [3].

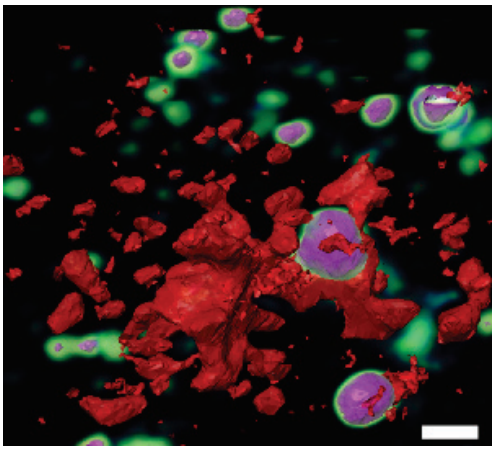

Fig. 1: High-resolution µCT showing magnetite (purple) surrounded by hematite (green) and open pore space (red) in polycrystalline diamond. The diamond is rendered invisible in this view. Scale bar is 100µm.

Macro-inclusions, larger than 5µm, in the specimen are magnetite, FeS, low Cr garnet ($Py_{50}Alm_{39}Grs_{11}$) and omphacite as discrete grains in the interstices. TEM analyses of 25 FIB foils yielded a micro-inclusion assemblage of magnetite, hematite, FeS, rutile, omphacite and C-H-O fluid [4].

Hematite was always found to surround magnetite (Fig. 1), often in paragenesis with a sheet silicate. Diamond in the vicinity of these minerals is always corroded, implying that this paragenesis is of late (possibly surface) origin. In contrast, one FeS micro-inclusion was found to be rimmed with magnetite and a layer of amorphous carbon towards the inclusion-diamond interface. This clearly attests to formation of this paragenesis in the diamond stability field.

Importantly, the micro-inclusion suite described here is distinct from that found in fibrous and in microdiamonds. Instead of carbonates and halides, the micro-inclusion suite here consists of the typical eclogitic minerals (rutile, garnet, omphacite, sulphide) plus a C-H-O fluid.

Finding primary fluid inclusions in carbonado diamond and its implication to the origin

Kagi, H.[1*], Sakurai, H.[1], Ishibashi, H.[1] & Ohfuji, H.[2]
[1]Geochemical Research Center, University of Tokyo, Japan
([*]kagi@eqchem.s.u-tokyo.ac.jp)
[2]Geodynamic Research Center, Ehime University, Matsuyama, Japan

Carbonado is a group of natural polycrystalline diamonds whose origin is still controversial. Our recent study on infrared absorption spectra and Raman spectra of Central African carbonado reported the presence of fluid inclusions and high residual pressure in the diamond [1]. These results suggested that C-O-H mantle fluid was trapped in the carbonado sample and carbonado had grown in the volatile-rich environment in the mantle. However, it was still unclear that the fluid inclusions in carbonado existed inside of diamond grains or in the grain boundaries. In this study, we precisely investigated location of the fluid inclusions from spectroscopic measurements and TEM observations.

A carbonado grain with hundreds of micrometer in diameter was heated incrementally at temperatures from 700 to 1100°C under vacuum. After heating at each temperature condition, infrared absorption spectra were measured. Absorption bands assignable to liquid water were observed up to 950°C right before graphitization occurred. This observation strongly suggests that the fluid was trapped inside of diamond grains.

For obtaining direct evidence of fluid inclusion existing inside of a diamond grain, we conducted TEM observations on an FIB-fabricated thin foil of carbonado. Fig. 1 shows a void found in the carbonado sample. The void was surrounded by (111) equivalent crystal faces. The octahedral void controlled by crystal habit of host diamond strongly suggests that the void is the negative crystal of diamond. The existence of negative crystal of diamond indicates that the fluid equilibrated with diamond crystals. The present study supports that the growth environment of carbonado was in the mantle being rich in C-O-H fluid.

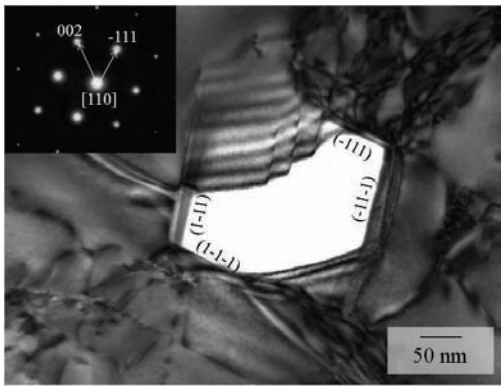

Fig. 1: TEM image of a void in FIB film of carbonado obtained using the [110] convergent beam.

Experimental study of syngenetic relations of diamond and its inclusions in the heterogeneous system eclogite-carbonatite-sulfide-diamond at 7.0 GPa

Vasiliev, P.[1*], Okoemova, V.[1], Litvin Y.[2] & Bobrov, A.[1]
[1]Geological Faculty, Moscow State University, Moscow, Russia
([*]prokvsailiev@gmail.com)
[2]Institute of Experimental Mineralogy, Chernogolovka, Russia

The role of physicochemical experiment is decisive for understanding of chemical and phase state of mantle diamond-forming media [1]. Application of the criterion of syngenesis of diamonds and primary inclusions is special importance for investigation of the systems with compositions similar to natural multi-component diamond-forming media. We studied melting relations for syngenesis of diamond and inclusions in the system eclogite (garnet +clinopyroxene) – K-Mg-Ca-carbonatite – sulfide (mixture of pyrrhotite, pentlandite, and chalcopyrite) – diamond at 7.0 GPa by the analysis of a fragment of the syngenesis diagram within the pseudo-binary section eclogite50-carbonatite50-diamond. The main element of this diagram is the curve of diamond solubility in completely miscible carbonate-silicate melts depending on temperature. The diagram shows melting relations in carbon-saturated diamond-forming carbonate-silicate melts with silicate (garnet and clinopyroxene) and carbonate (magnesite, aragonite, and K-carbonate) mineral phases.

The syngenesis diagram for the sulfide-diamond system contains the curve of diamond solubility in sulfide melts depending on temperature and demonstrates the areas where diamond growing in carbon-sulfide melts captures inclusions of sulfide melts and minerals. The general diagram of the multi-component eclogite-carbonatite-sulfide-diamond systems is a combination of two discussed diagrams. It demonstrates two curves of diamond solubility in sulfide and carbonate-silicate melts. The results obtained provide evidence for complete immiscibility of carbonate-silicate and sulfide components of parental melts and predominant crystallization of diamond in carbonate-silicate media. This is consistent with the carbonatite (carbonate-silicate) model of diamond genesis [1].

Mantle-carbonatite genesis of diamond by mineralogical and experimental evidence

Litvin, Yu.A.
Inst. of Experimental Mineralogy, Russian Academy of Science, Chernogolovka, Moscow Region, Russia
(litvin@iem.ac.ru)

The physicochemical characteristics of the growth medium for most mantle-derived diamond can be only disclosed by combined use of mineralogical and experimental data. Diamond-hosted primary inclusions under residual pressure are representatives of the parent media. The parental compositions are multi-component and heterogeneous: major and minor components include oxides of Mg, Ca, Fe, Ti, Zr, Al, Si; silicates of Mg, Fe, Ca; alumino-silicates of Na, K, Mg, Ca, Fe; Fe, Ni, Cu sulfides; Ca phosphate; carbonates of Mg, Ca, Fe, K, Na, K; Na chloride; Si, Fe carbides; H_2O, CO_2, CH_4 fluids, native Fe, etc. The syngenesis of diamond and its primary inclusions is well-grounded. The importance of any of these heterogeneous materials in the crystallization of diamond cannot be evaluated by mineralogical data alone. Attempts to determine the most efficient medium in high-pressure experiments (by diamond "synthesis") fail because not one but a series of primary included materials (silicate-carbonate, carbonate, silicate, sulfide, chloride, metal, C-O-N-fluid…) were recognized. The only way out of the situation is the use of experimental criteria demanding that the growth medium should be equally efficient for the formation of diamond and its syngenetic phases. Experimental studies on diamond-forming multi-component heterogeneous systems peridotite-carbonatite-carbon, eclogite-carbonatite-carbon, grospydite-carbonatite-carbon, sulfide-diamond, eclogite-carbonatite-sulfide-diamond were carried out at 7.0 – 8.5 GPa and 1200 – 2000°C. It was found that (1) completely miscible carbonate-silicate melts saturated with dissolved carbon satisfy the syngenesis criterion because diamond forms together with silicate and carbonate minerals of peridotite and eclogite parageneses; (2) sulfide melts are completely immiscible with the carbonate-silicate ones and inconsistent with the syngenesis criterion, (3) diamond formation in peridotite-carbonatite-carbon and eclogite-carbonatite-carbon melts of variable composition is controlled by carbonatitic compositions (< 30 – 35 wt % silicate constituent). This is compatible with the mantle-carbonatite version of diamond genesis [1]: the growth medium for diamond and inclusions consists of the major carbonate and silicate components and phases ("paragenic"), contains minor admixed soluble ones ("paragenic") and coexists with insoluble immiscible components and phases ("xenogenic"). On the basis of the mantle-carbonatite model, a genetic classification of primary inclusions of minerals, melts and fluids in mantle-derived diamond has been developed [2].

Major and trace element composition of diamond-forming fluids: what do they tell us?

Weiss, Y.[1*], Griffin, W.L.[2] & Navon, O.[1]
[1]The Fredy and Nadine Herrmann Institute of Earth Sciences, the Hebrew University of Jerusalem, Israel
([*]yakov.weiss@mail.huji.ac.il)
[2]ARC National Key Centre for Geochemical Evolution and Metallogeny of Continents (GEMOC), Macquarie University, Sydney, Australia

The metasomatic medium in which fibrous diamonds grew is usually preserved in the form of high-density fluids (HDFs) trapped in sub-micrometer inclusions. Major and trace elements, and the volatile content of these fluids sheds light on the mantle sources and processes which promote diamond genesis. The major-element compositions of the HDFs span two arrays: (a) between a high-Mg carbonatitic end-member and a saline one and (b) between a low-Mg carbonatitic and a hydrous silicic end-member [1]. All four end-members are rich in K. In line with this enrichment, all are highly enriched in incompatible elements compared to primitive mantle. Their REEs are fractionated with $La/Dy_{(PM\ normalized)}$ varying from 6 in the silicic HDFs to 430 in the saline compositions; Sr, Ti, Zr, Hf and Y show variable negative anomalies relative to the REEs. The highly incompatible elements, Cs – La, exhibit two patterns. One is mostly flat and has moderate decrease of concentrations with decreasing ionic radius (this pattern is designated "Bench"); the other (designated "Table") has elevated Ba, U, Th and LREE, depleted Nb and Ta and in most cases, highly depleted alkalis (K, Rb and Cs). Both patterns were found in HDFs of either major element arrays.

The appearance of similar trace elements patterns in fluids of such diverse major element compositions suggest that major and trace elements are decoupled and that they are controlled by different sources or processes. Based on the similarity of the major-element composition of the HDFs to experimental near-solidus melts of carbonated/hydrous peridotites and eclogites, we suggest that the source-rock for the high-Mg carbonatitic HDFs is peridotitic, while the one for the low-Mg carbonatitic to hydrous-silicic compositions is eclogitic. The clear array between the saline and the high-Mg carbonatitic compositions suggests the involvement of saline fluids in the generation of the high-Mg carbonatitic HDFs. Saline fluids may be the metasomatic agent that triggers the formation of the silicic to carbonatitic fluids in the eclogitic case. However, melting of carbonates or K-bearing phases in the source-rock or interaction of such sources with carbonatitic and potassic melts/fluids may also generate similar compositions. Either way, potassium and carbonate should be available during HDF generation.

The trace element abundance patterns of the high-Mg carbonatitic HDFs resemble those of kimberlites. The huge variation in Th/Nb and La/Nb in carbonatitic-silicic and carbonatitic-saline HDFs suggests the involvement of rutile or a similar phase during HDF evolution. Similar arguments, based on major and trace element patterns, may be made for the involvement of other phases, such as zircon, apatite, mica and carbonates. Rocks rich in the above phases are known from xenoliths in kimberlites (e.g., MARID, PIC and glimmerites) and in many cases show the complementary anomalies to the "Table" pattern. On a K/Rb vs Cs/Rb diagram, HDFs with "Table" patterns fall on or very close to an array forms by Rayleigh fractionation of phlogopite from a MARID-like melt. These features indicate the importance of phlogopite in the formation and evolution of diamond forming fluids.

Iron carbide inclusions within lower-mantle diamond: a result of oxidation of carbide to magnetite or the reduction of magnetite to native iron?

Kaminsky, F.[1*] & Wirth, R.[2]
[1]KM Diamond Exploration Ltd., West Vancouver, Canada
([*]felixvkaminsky@cs.com)
[2]Dept. Chemistry of the Earth, GeoForschungsZentrum Potsdam, Germany

A series of iron carbides have been identified in diamond from the Juina area, Brazil; this diamond crystal has also been shown to contain a set of carbonatitic-type inclusions. The iron carbides present are associated with magnetite, native iron and graphite, and form polymineralic inclusions of up to 7 μm in size (Fig. 1).

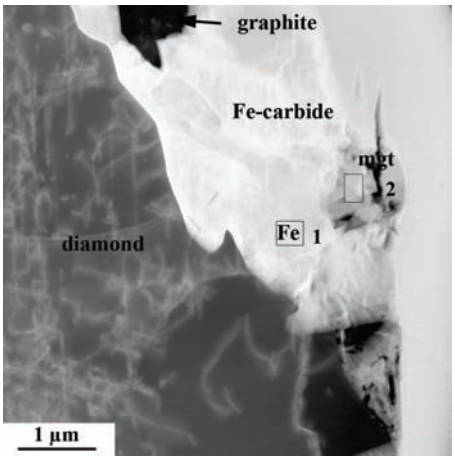

Fig. 1: HAADF image of an inclusion in diamond composed of magnetite, iron carbides, native iron, and graphite.

The studied iron carbides, by their chemical compositions, vary widely from grain to grain ($Fe_{3.98}C$ to $Fe_{1.25}C$). Chemical variations within grains are smaller, with Fe/C ratios varying within a range of 0.02 to 0.31. Minor amounts of Cr (0.03-1.30 at.%) and Ni (0.08-0.50 at.%) were identified in some iron carbide grains. Of particular interest is a nitrogen admixture in native iron.

The iron carbides form a compositional range with the following approximate formulas: Fe_4C – Fe_7C_2 – Fe_3C – Fe_2C – Fe_7C_4 – Fe_4C_3 – Fe_5C_4; as such, they are analogous to chromium carbides known from industry and are, most likely, interstitial compounds. From the six iron carbide varieties identified only one is known from a terrestrial environment, cohenite (Fe_3C). Cohenite has previously been identified in both monocrystalline diamond and polymineralic diamond aggregate. Another variety, chalypite (Fe_2C) is known only from meteorites; it predominates among the analysed grains (comprising around one third of them). The other iron carbide varieties are not known to occur in nature at this time.

There are two mechanisms which could explain the existence of this iron carbide series in a single diamond grain. The first related to the oxidation of an initial iron carbide: i.e., $FeC + O_2 \rightarrow Fe_3O_4 + C$ (graphite). This reaction occurs as the result of a change in oxygen fugacity under low pressure conditions (outside of the diamond stability field). Another scenario is that magnetite (or perhaps another iron oxide) is reduced during ascent of the host diamond to the surface, close to the boundary between the diamond/graphite stability fields, when it experienced local deviatoric stress conditions that resulted in the local recrystallisation of diamond carbon as graphite carbon. Simultaneously iron-containing phases were reduced and recrystallized to form of iron carbide(s) and native iron.

Natural silicon carbide from kimberlites: polytypes, trace elements, inclusions and speculations on its origin

Shiryaev, A.A.[1*], Griffin, W.L.[2], Tomshin, M.D.[3] & Okrugin A.[3]
[1]Institute of Physical Chemistry and Electrochemistry RAS, Moscow, Russia (*a_shiryaev@mail.ru)
[2]GEMOC, Macquarie University, Sydney, Australia
[3]Institute of Geology, Yakutsk, Russia

The origin of natural SiC (moissanite) found in carbonates, granitoids, kimberlites and other oxidised rocks is poorly understood, and it has often been assumed that the SiC is introduced during processing. However, in many cases contamination with synthetic SiC is implausible; it is clear that natural SiC (moissanite) does exist, but at present there is no consistent model for its formation. An extensive collection of moissanite grains from the Mir, Aikhal and Udachnaya kimberlite pipes, Yakutia, has been characterized in terms of structural perfection, defects, inclusions, and major- and trace-element chemistry and compared with synthetic SiC produced by various methods (Acheson, Lely).

Most natural SiC grains are 6H and 15R polytypes; some are 4H, 8H and 21R. No 3C grains were observed. Some grains (<10%) show extremely complex Raman spectra indicating strongly disordered structures, e.g., long-period polytypes. The shape of the LO band in the Raman spectra suggests the presence of significant amounts of non-compensated impurities. The spectra of some grains show vibrations related to OH groups or H in the SiC lattice. On average, the 15R grains are more enriched in impurities than the 6H grains. Cathodoluminescence maps and in-situ isotopic measurements indicate the existence of growth-related zoning on ~10-micron scale. Surprisingly, the density of dislocations and stacking faults is very low.

Our work has revealed considerable similarity between the geochemical properties (abundances of major and trace elements) of moissanites from geologically contrasting environments and stark differences with synthetic SiC. Trace-element chemistry provides a reliable method for distinguishing natural SiC from synthetics. Moissanite is virtually stoichiometric SiC with low O contents (0.1-0.3 wt%). Concentrations of some impurities (Al, B, Ti, V, Sc) are similar in natural and synthetic samples. However, the composition of natural SiC is much richer, due to the different degrees of perfection and amount/type of inclusions in natural and synthetic crystals. Inclusions are heterogeneously distributed in the host SiC and their size varies from few nanometers to hundreds of microns. They typically have rounded to negative-crystal shapes suggesting trapping of melt phases. Silicon is the most abundant inclusion phase. Less abundant are iron silicides ($FeSi_2$, $FeSi_3$) and not fully identified Si(C,O) phase(s) which could be silicon oxycarbide(s). Most chemical impurities are concentrated in the $FeSi_2$ and Si(C,O) phases. Trace-element patterns of $FeSi_2$ from different kimberlites are generally similar but also show locality-specific differences. The $FeSi_2$ is strongly enriched in LREE/HREE; extreme negative anomalies in Eu and Sm are consistent with highly reducing conditions. The overall pattern is similar to those of fibrous diamonds, suggesting formation from similar fluids. Textural and chemical features, the residual pressure on Si inclusions, and intergrowth with oxidation products (Si(C,O) phases and SiO_2) suggest that moissanite grew at high temperatures and elevated pressures and was subsequently partly oxidised, also at high T.

Black diamonds: the crustal origin for carbonado

Sautter, V.[1*], Lorand, J.P.[1], Cordier, P.[2], Rondeau, B.[3], Leroux, H.[2] & Meibom, A.[1]
[1]Laboratoire de Minéralogie et Cosmochimie du Muséum, UMR 7202, Paris, France (*vsautter@mnhn.fr)
[2]Laboratoire de Structure et Propriétés de l'Etat Solide, UMR CNRS-Université Lille, Villeneuve d'Ascq, France
[3]Laboratoire de Planétologie et de Géodynamique, UFR des Sciences et des Techniques, Nantes, France

Carbonado is a polycrystalline variety of black diamond that occurs as pebbles in mid-Proterozoic (~1.4 Gy) sedimentary deposit and is geographicxally restricted to Brazil and Central Africa. Its genesis remains one of the most controversial questions in diamond geology [1]. Crustal and mantle [2] formation processes have been debated and even an extraterrestrial origin [3] has been proposed. We present a carbonado from Bahia (Brazil) with a texture resulting from a three-stage growth process: black diamond clasts (up to 500 µm: stage-1) embedded in a grayish fine-grained matrix (stage -2) are associated with columnar transparent diamond (stage-3). Pyroxenitic assemblages of augite, ilmenite and phlogopite (all Fe-rich minerals) are shielded in primary diamond clasts, providing direct evidence for carbonado formation on crustal seeds under oxidizing conditions. Metallic phases (Fe, Ti, Cr, Cu, Al, and alloys of Fe-Cr, Fe-Mn and SiC), that require extremely reducing formation conditions, occur exclusively in the fine-grained carbonado matrix (stage-2). The $\delta^{13}C$ composition of the diamond clasts and fine grained matrix falls within the range -27‰ to -32‰. This points toward sedimentary organic materials as the source of carbon for the carbonado agregate. Then carbonado crystallized in a dynamic subduction zone environment. A later shearing event granulated the clasts and coincided with a dramatic drop in fO_2, due to the infiltration of reduced fluids generated by the serpentinization of mafic minerals. This later event led to the reduction of silicates into metallic phases.

Synthesis of ultrahard nano-polycrystalline diamond at high pressure and temperature using a large-volume multianvil apparatus

Irifune, T.[1*], Isobe, F.[1], Shinmei, T.[1], Sanehira, T.[1], Ohfuji, H.[1], Kurio, A.[1] & Sumiya, H.[2]
[1]Geodynamic Research Center, Ehime University, Matsuyama, Japan ([*]irifune@dpc.ehime-u.ac.jp)
[2]Electronics and Materials R&D Laboratories, Sumitomo Electric Industries, Ltd., Itami, Hyogo, Japan

Since the first report of synthesis of ultrahard nano-polycrystalline diamond (NPD) by direct conversion from graphite using multianvil apparatus [1], we have been trying to synthesize larger volumes of NPD for scientific and industrial applications. For this purpose, we have recently constructed a large-volume multianvil apparatus (BOTCHAN-6000) operated in a 6000-ton hydraulic ram at GRC, Ehime Univ., which enabled us to synthesize flawless NPD rods with dimensions as large as 8 mm in both diameter and length.

We use second-stage tungsten carbide cubic anvils with edge lengths of either 52 mm or 65 mm, with the largest truncation edge length (TEL) and the edge length of the octahedrral pressure medium (OEL) being TEL=18 mm and OEL=30 mm, respectively. Using the largest cell assembly, we are able to produce pressures of ~15 GPa (at a press load of ~4000 tons) and temperatures up to ~2700K, where a starting graphite rod of about 1 cm in diameter and length can be accommodated. Attempts to synthesize further larger NPD rods are currently planned with a larger anvil of 75 mm edge length, which should yield rods with dimensions even exceeding 1 cm.

These synthesized NPD rods were found to be easily processed with a pulse laser, followed by chemical etching and/or polishing with diamond powders, to form various shapes. We have been applying our NPD anvils to some high-pressure apparatus, such as diamond-anvil cell, multi-anvil apparatus, and Drickamer-type apparatus. Some of the early results on the performance of NPD anvils will also be reported in the talk.

Influence of graphite crystallinity on the microtexture of polycrystalline diamond obtained by direct conversion

Ohfuji, H.[*], Okimoto, S., Kunimoto, T. & Irifune, T.
Geodynamics Research Center, Ehime University, Matsuyama, Japan ([*]ohfuji@sci.ehime-u.ac.jp)

The influence of crystallinity of polycrystalline graphite rods on the resulting textures of nano-polycrystalline diamond (NPD) synthesized by high pressure and high temperature experiments [1,2] was investigated through comprehensive analysis using Raman spectroscopy, X-ray diffractometry and electron microscopy. High pressure and temperature experiments were conducted at 16 GPa and at 2200 K using a 3000 ton multianvil press. Four types of high-purity graphite rods (G1, G2, G3 and G4) purchased from different companies were used as starting materials and were pressurized and heated all together in a high-pressure cell assembly.

Raman spectroscopy measurements of the four graphite starting materials showed various ratios of D band (1350 cm^{-1}) and G band (1580 cm^{-1}) intensities ranging from (D/G =) 0 to 0.34. Since the D/G intensity ratio reflects the crystalline state of graphite such as lattice defect density within each analyzed area (ca. 1 μm), the observed Raman data suggests that graphite crystals with a variety of crystallinity coexist in a rod sample. This is probably related to its manufacturing process, in which relatively large graphite flakes (coke) are mixed with binder pitch, which will transform to fine graphite particles after baking treatment to make a rod shape. The graphite crystallite sizes estimated using the Tuinstra-Koenig equation [3] range from 10 nm to 1 μm, which is in a good agreement with direct observation by TEM. G1 and G2 samples consist of graphite particles with relatively larger crystallite sizes than G3 and G4. It is also noted that G4 sample is unlikely to have large crystals more than 400 nm.

TEM observations of the recovered samples showed that grain size distribution of diamond nanocrystals is apparently different. NPDs synthesized from G1 and G2 starting materials have a grain size range of 40-100+ nm, whereas those obtained from G3 and G4 show smaller grain size distributions (mostly, 30-60 nm). The formation of lamella structure was observed commonly in the recovered samples except in that synthesized from G4.

Our results show that smaller the crystallite size of the starting graphite samples used, smaller the individual grain size of the synthesized NPD. This is probably due to increase in relative number of dangling bonds (sp3-like bonds) at crystal edges and lattice defects, which provide preferential sites for diamond nucleation, in smaller graphite crystals. In addition, the volume fraction of the lamella structure likely correlate positively with the relative frequency of well-crystallized large graphite flakes in the starting material, as suggested our earlier work [4]. Therefore, the microtexture of NPD can potentially be controlled by choosing the crystalline states of the starting graphite sources.

Transformation mechanism of graphite to diamonds in ureilites revealed by TEM observation

Nakamuta, Y.[1*], Toh, S.[2] & Aoki, T.[1]
[1]University Museum, Kyushu University, Fukuoka, Japan
[2]HVEM Laboratory, Kyushu University, Fukuoka, Japan
([*]nakamuta@museum.kyushu-u.ac.jp)

Diamond in ureilites was first reported in 1888 [1]. The genesis of diamond in meteorites has been a problem of many years. The existence of compressed graphite associated with diamond reveals that diamonds in ureilites formed as a result of shock conversion of graphite [2]. The mechanism of conversion from graphite to diamond has also been discussed based on high-pressure experiments (e.g., [3]) and molecular dynamics (e.g. [4]). However, direct observation of diamond in ureilites suggesting a conversion mechanism has not been done until now. In this study, we observed diamonds associated with graphite by high resolution transmission electron microscopy (HRTEM).

A carbon-rich grain about 50 microns in size which pseudomorphs graphite was taken out of a polished thin section (PTS) of the Goalpara ureilite. X-ray powder diffraction analysis using a Gandolfi camera shows the grain is a mixture of hexagonal and cubic diamonds and graphite. Thin films for TEM observations were prepared by the focussed ion beam (FIB) technique. The graphite pseudomorph was observed by TEM in the three unique directions of graphite, i.e. with an electron beam parallel to [001], [010] and [210] of the original graphite. Fig. 1 shows a selected-area electron diffraction pattern taken with the electron beam parallel to the [001] of the original graphite. The diffraction pattern is composed of those from three-layered rhombohedral and two-layered orthorhombic polymorphs of carbon. The rhombohedral one is suggested to be similar to n-diamond [5] and the orthorhombic one to the intermediate phase proposed by [4], from the observations from the directions parallel to [010] and [210] of original graphite, respectively. These results reveal that a sliding of graphite layers is the initial dominant process in the conversion of graphite at high P and T, and then hexagonal and cubic diamonds form through a buckling of atoms in graphite layers.

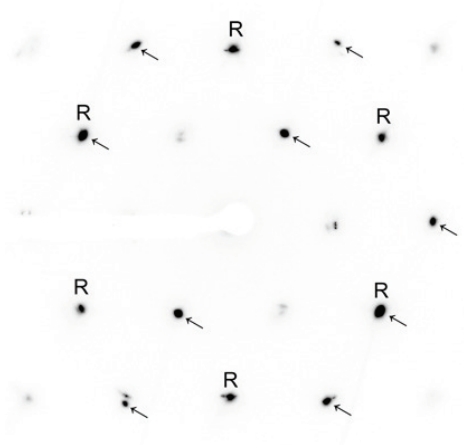

Fig. 1: Selected area electron diffraction pattern taken with an electron beam parallel to the [001] of original graphite. R: reflections from a three-layered rhombohedral polymorph of carbon; arrow: reflections from a two-layered orthorhombic polymorph of carbon.

Monomineral thermobarometry for the diamond inclusions from Siberia: genetic links

Ashchepkov, I.[1*], Pokhienko, N.[1], Afanasiev, V.[1], Logvinova, A.[1], Pokhienko, L.1, Ntaflos, T.[3], Ionov, D.[4], Kuligin, S.[1] & Mityukhin, S.[5]
[1]IGM SB RAS, Novosibirsk, Russia ([*]garnet@uiggm.nsc.ru)
[2]IGC SB RAS, Irkutsk, Russia
[3]University of Vienna, Austria
[4]Université J. Monnet, Saint-Etienne, France
[5]ALROSA Company, Russia

The methods of the monomineral thermobarometry used for the reconstruction of the mantle sections beneath the kimberlite pipes [1] allow to determined PT range for the diamond inclusions (DI) and diamond bearing associations. They show various conditions for the crystallization of diamond for in mantle lithosphere beneath the Yakutia. Most of DI [2-6 and ref their in] (Cr-pyropes, Mg -opx) form Mir and Udachnaya pipes are referred to the cold geotherms 35 (partly 33 mvm-2) at the pressure range from 35 to 80 kbar. Cr- pyropes (Ti-bearing) partly drops the on the heated area near convective branches 40-45 mvm-2 convective geotherms. Most Cr- rich pyroxenes refer to the coldest or heated (metasomatic type) at the deeper parts of the mantle columns while mildly Cr-rich varieties refer to the conditions of the crystallization from the melts related to the protokimberlites and associated carbonatites near the Graphite-Diamond boundary (G-D). They are more widely distributed in mantle beneath the Mir pipe where the essential part of mantle column from 50 to 35kbar was subjected to the refertilization. But chromite PT estimates mostly refer the heated conditions of the convective branch at the lithosphere base (~70-60kbar). They are most typical for the Alakite pipes. Diamond bearing eclogites show the some separate levels of crystallization with the high T-range reflecting conditions 35 to 45 mvm-2 mostly in the 60-50 kbar interval. They coincide with the levels of the intensive heating in the mantle columns. Thus the mantle inclusion in different part of the Earth mantle in general repeats the conditions of the whole mantle column. They reflect higher PT gradients in ancient time. In Africa they are hotter in general and often trace advective branches. While in the thicker and colder lithosphere beneath the Slave craton DI reveal colder and deeper in general conditions. In Siberia many of DI especially Chr as well as Diam- eclogites reflect the heating by protokimberlite RBRF05-05-64718, ALROSA 77-2;65-3; 2-05.

A theoretical examination of diamond precipitation from fluids in the Earth's mantle

Crossingham, A.[1*], Huizenga, J.M.[2], & Viljoen, K.S.[1]
[1]Dept. of Geology, University of Johannesburg, South Africa
([*]alexandrac@postgrad.uj.ac.za)
[2]Dept. of Geology, North-West University, Potchefstroom, South Africa

Diamond precipitation may occur as a result of the infiltration and mixing of oxidised and/or reduced mantle fluids with surrounding mantle peridotite [1]. If so, important aspects that should be considered include fluid speciation, carbon speciation (CH_4, CO_2, or carbonate), as well as the oxidation state of the surrounding lithosphere (Fig. 1).

Mantle xenoliths from the Kaapvaal Craton have been widely studied, in order to determine e.g. the relationship between pressure, temperature, and oxygen fugacity in the Earth's mantle [2]. These studies have shown that (1) the sub-lithospheric mantle beneath the Kaapvaal Craton is relatively reduced i.e. oxygen fugacity varies between 1 and 3 log units below the FMQ buffer, and (2) oxygen fugacity is strongly correlated with depth in that the mantle becomes increasingly reduced with increasing depth. The observed correlation between pressure, temperature and oxygen fugacity allows for the modelling of fluid composition in the mantle within the C-O-H system [3].

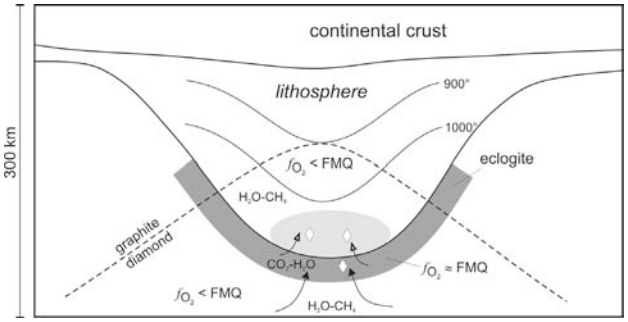

Fig. 1: Vertical section through the continental crust and underlying mantle. Diamonds are typically formed in relatively cold, deeper parts of the mantle (shaded area), probably along the the contact of oxidized and reduced lithologies [1]).

Aspects of the current study include the theoretical analysis of fluid infiltration and mixing, in the Kaapvaal Craton, in relation to the crystallisation of diamond. This involves the theoretical examination, using thermodynamic data and related calculations, of the effect of variations in oxygen fugacity of the host mantle on the composition of possible 'ambient' (equilibrium) fluids in the mantle, and the effect of various introduced fluids (e.g. methane, CO_2) and combinations of fluids, on the degree of carbon oversaturation in the mantle, and consequent diamond crystallization. These calculations suggest that the most ideal conditions for diamond precipitation are low fluid-rock ratio systems of which the oxygen fugacity is controlled by the rock system.

Informative value of the diamonds' minerals-indicators study

Makeyev, A.B.
Dept. of Petrography, Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry RAS, Moscow, Russia (abmakeev@mail.ru)

The brief historic note on the discovery of diamond fields in Russia emphasizes the leading role of the mineralogical methods of search, giving also the overview of the recent achievements in the studies of minerals-indicators. One of the most valuable discoveries in this field is that of the syngenetic metal films on the surface of diamonds (Fig.1). The metal films were found on the diamonds of all the diamond-bearing provinces of Timan, Perm and Arkhangelsk regions, Yakutiya, as well as on diamonds from deposits of China, Angola, and Brazil [1–3]. Noteworthy, 40 to 100 per cent of the examined crystals were covered with thin (0.1–1.0 mcm) metal films of various chemical compounds (Au, Ag, Cu, Au_7Ag, Au_2Pd_3, Au–Cu–Ag, Au–Cu–Hg–Pd, Cu_5Au_3Ag, Au_4Cu_3Ag, Al, Pb, Sn, Bi, Zn, Cu–Zn, Cu_2Zn, Cu–Zn–Pb, Cu_3Zn_2, Cu_3Sn, Zn–Cd(S), Pb–Sn, Pb–Sn–Cu(Au), Fe, Ni, Cr, Ti, W, Ta, Fe_7Cr, Fe_7Cr_2Ni, Ni–Fe, Ti–Fe, W–Mo, W–Ni–Mo, Fe–Cd, Fe–Cr–Mo, Fe–Zn, Cr–Zn, Cr–Zn–Mg, Fe–Zn–Mg, Sn–Fe, Fe–Ni–Cu, Sn–Fe–Cu, Fe–Ni–Pt, Fe–Cu, $(Ce,Nd,La,Y)_2O_3$ Zr–Yb), which were preserved only in negative forms of relief (in prints, twin seams, holes, and between vicinal forms of growth). At the fresh split of one carbonado next to the center there was discovered a diamond crystal covered by the buried titan dioxide film (former metallic titan film) [4]. We believe that the presence of metal films on diamonds discloses the mechanism of diamonds' growth in nature, namely their growth from solution in metal melt.

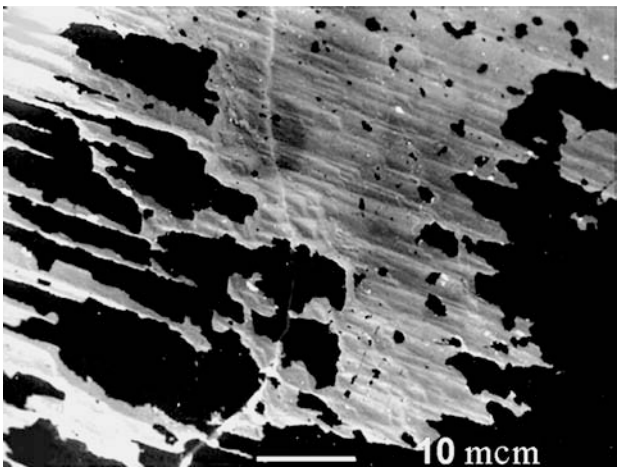

Fig. 1: The fragment of thin half-effaced metal gold-palladium (Au_2Pd_3) films on the surface of curvishaped diamond of Ichetju deposit (Middle Timan, Russia).

The compounds of metal films on diamonds can serve a source for preparation of new charge receipts for growing artificial diamond crystals. In addition, the article contains the results of the research of curvishaped diamonds by cathodoluminescent which show that curvishaped habits of diamond crystals of urals-brazilian type can be admitted a form of growth or solution only after individual study.

Organic-looking carbon and nitrogen isotope compositions in mantle derived diamondites: mantle fractionation vs. reworked crustal organics?

Mikhail, S.[1,2*], Dobosi, G.[3], Verchovsky, S.[2], Jones, A.[1] & Kurat, G.[4]
[1]Dept. of Earth Sciences, University College of London, UK (*s.mikhail@ucl.ac.uk)
[2]PSSRI, The Open University, Milton Keynes, UK
[3]Inst. for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary
[4]Naturhistorisches Museum, Vienna, Austria

Diamondites (polycrystalline diamonds, framesites) are fine to coarse-grained (from 50 μm to >1 mm) rocks consisting almost entirely of diamonds with abundant pores and cavities [1]. Most of them contain silicates (mainly garnets, and less frequently clinopyroxenes) which are mostly interstitial or occupy the space in cavities and often contain inclusions of euhedral diamonds, giving evidence for a cogenetic origin of these phases. However, olivine, which is the most common mineral of the upper mantle, is not present in diamondites.

Carbon and nitrogen isotope ratios and nitrogen contents have been studied in diamonds from diamondites of unknown origin (presumably from southern Africa) that have previously been studied in detail for garnet geochemistry and carbon isotope composition [2,3]. Nitrogen aggregation states have also been determined in a subset of samples. Both carbon and nitrogen isotope ratios show wide range of variation within the sample set (mean values for $\delta^{13}C$ and $\delta^{15}N$ are -16.9 ± 7.2 ‰ and +11.9 ± 8 ‰, respectively), which suggest an "organic-looking" signature. The nitrogen content of the diamonds from the diamondites is generally high (above 500 ppm on the average), and the aggregation states of the nitrogen vary between 16 to 100 % 1aB with a mean value of 78 %. There is no relationship between the isotope ratios of the diamonds and the compositional characteristics of the associated silicate phases (mainly garnets) in the diamondites.

The coupled carbon and nitrogen isotope composition of the diamondites can be interpreted in two ways: (1) Reworking (either recycling via remobilisation of the lower lithosphere or subduction) could have provided the C and N which have preserved their 'organic-like' signatures; or (2) the loss of ^{13}C rich oxidised C from the system by carbonisation of olivine (explaining the lack of olivine inclusions in diamondites) during diamondite crystallisation would result in increasing of the N/C ratio and decreasing of the $\delta^{13}C$ value, the small variation in $\delta^{15}N$ to higher values (at this early stage) is thought to be a function of the removal of a small fraction of N from the substrate. This is followed by continuous diamond formation where oxidised carbon is lost via silicate carbonisation and the formation of carbonates (decreasing $\delta^{13}C$ in the source) and N is removed from the source by being partitioned into the crystallising diamonds (increasing $\delta^{15}N$ in the source). During such progressive crystallisation of diamondites the C and N isotope compositions can be fractionated to extremely 'organic-like' values. We find that both models warrant sufficient discussion for this data set.

[3]Institute of Geology and Mineralogy, Novosibirsk, Russia

High potassium activity in fluids and melts producing kimberlitic diamonds worldwide is recorded in fluid/melt and mineral inclusions in them (cf. [1]). In order to characterize a structural position of K in diamonds, we have firstly examined XANES spectra at the K K-edge of two types of K-bearing inclusions in kimberlitic diamonds: (1) fluid/melt microinclusions in fibrous diamonds from Brazil [2], (2) individual macroinclusion of K-bearing clinopyroxene (0.73 wt.% of K_2O), KCpx, in a gem stone from Yakutia. Spectra were collected at the LUCIA beamline at SLS.

The "bulk" spectra for the fluid/melt inclusions were obtained from numerous submicron inclusions covered by the beam of FWHM ~10 μm. Despite noisiness of the spectra (Fig. 1) they could be described as superposition of contributions from KCl and K-silicate glass. Spectra are similar to those of synthetic glasses produced from the chloride-carbonate-silicate melts immiscible with the chloride-carbonate liquids [3].

The spectrum of the KCpx macroinclusion (Fig. 1) is consistent with the theoretical spectra (full multiple scattering approximation using feff8.2 code) of KCpx structures simulated via lattice dynamics [5] and produced experimentally [6], suggesting a disordered distribution of K in the Cpx structure. The spectrum of another inclusion resembles mica. However, K environment in various micas is rather similar and unique identification of the mineral requires additional information.

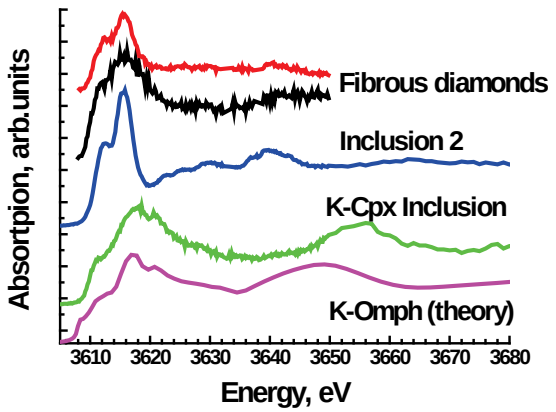

Fig. 1: K K-edge XANES spectra of fluid/melt and macroinclusions in diamonds.

Solid inclusions in carbonados

Sukharev, A.E.[1*], Petrovsky, V.A.[1], Silaev, V.I.[1] & Martins, M.[2]
[1]Institute of Geology, Komi Scientific Center, Ural Division, Russian Academy of Sciences, Syktyvkar, Russia
([*]sukharev@geo.komisc.ru)

The urgency of researches of micropolycrystalline diamonds is defined by that, as now not only the opposite opinions on genesis carbonados are kept in all acuteness, but sometimes in general filogenetic identity and genetic affinity with monocrystalline diamonds calls into question. The object of our researches is carbonados from recent and neogene-quaternary alluvial placers of basic diamond territories of Brazil. Gas-fluid phase of carbonado and associated minerals were studied with pyrochromatograph technique using chromatograph, equipped by pyrolytic add-on device. Gas composition was determined in the mode of two-stage (20-500 and 500-1000°C) and multi-step (20-300 and further at 100°C) heating. In pyrolyzate carbonados obtained as a result of multistage heating, are found out (in sequence of reduction of the contents) H_2O, CO, CO_2, N_2, H_2, CH_4, C_4, C_3, C_2. During heating the structure allocated from carbonados of gases changes from CO_2-water up to NO_2-H_2O-wastegaseous. In carbonados we established more than 100 kinds of mineral inclusions. We attributed the most part of xenomineral impurities attributed to epigenetic inclusion type, among those we distinguish products of condensation of mantle-magmatic fluids (epigenetic inclusions of the first type) and exogenic mineralization, which developed during diagenesis of the diamond object on the terrestrial surface (epigenetic inclusions of the second type). We attributed syngenetic inclusions of phase-homogeneous solid solutions to those based on zircon, which prototype is possible to consider inclusion Ti-Fe-Si-Zr-Al oxides solid solutions we established earlier in the Uralian monocrystalline diamonds. Besides in carbonados us have been revealed micro-nanoscale mineral and fluid inclusions in individuals of actually diamond phase: cerianite, rutile, zircon, α-Fe (Cr), quartz, apatite, mica, Pb-Zn, communities of liquid and gas phases of not established structure, KCl, Al_2O_3, S, Ca-K-Fe-Ti-aluminosilicate. The data received allow refusing from rough genetic opposition between polycrystalline and monocrystalline diamonds. It is possible, that these minerals represent only variations of products of uniform process mantle diamonformation. Researches were carried out with use SEM, TEM, spectral semiquantitative and instrumental neutron-activated analyses, photoroentgenostructure, Raman spectroscopy and photo-FIB-methods (Focus ion Beam, GeoForschungsZentrum, Potsdam, Germany), gas mass-spectrometry, ESP, photo-, roentgenoluminescence and gas pirochromotography.

Trace element geochemistry and Ni thermometry of garnet inclusions in peridotitic diamonds from Premier and Finsch, South Africa: implications for diamond formation

Viljoen, K.S.[1,6*], Harris, J.W.[2], Ivanic, T.[3,4], Richardson, S.H.[5] & Whitehead, K.[5,6]

[6]Previously: Geoscience Centre, De Beers, South Africa

It is apparent that highly depleted harzburgite in the sub-cratonic lithosphere may be subject to refertilisation [1], which might also result in the crystallisation of diamond [2]. This could, for instance, explain the presence of a lherzolitic diamond population in the worldwide diamond inclusion database (in addition to commonly observed harzburgitic diamonds).

Some kimberlites, e.g. Premier and Orapa, are characterised by a higher eclogite+lherzolite:harzburgite diamond paragenesis relative to e.g. Venetia, Finsch and De Beers Pool [3], suggesting that these diamonds crystallised in refertilised mantle. The purpose of this study is therefore to investigate the contrasting conditions of formation of peridotitic diamonds from Premier and Finsch.

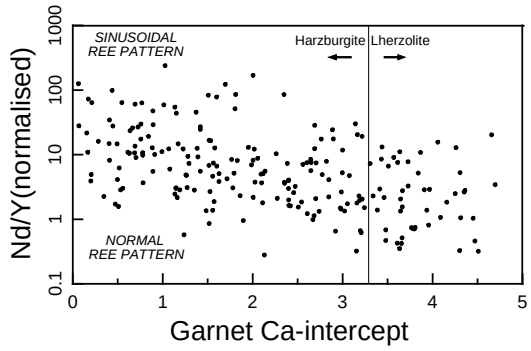

Fig. 1: Chondrite normalised Nd/Y plotted as a function of the Ca-intercept [4] for peridotitic garnets occurring as inclusions in diamonds.

Peridotitic garnets in diamonds from Premier provide evidence for refertilisation of subcalcic harzburgite through infiltration of a metasomatic medium characterised by relatively elevated Y, Zr, and Ti. During re-enrichment highly depleted subcalcic harzburgite with sinusoidal rare earth element patterns in the garnets were converted to more calcic harzburgite, and lherzolite, with a progressive change in rare earth element patterns in the garnets from sinusoidal to 'normal' REE patterns (LREE depleted, flat HREE; Fig. 1). Ni-thermometry on garnet inclusions provide evidence for increasing temperature during this process, a likely consequence of the infiltration of basaltic magma into, and mixing with, highly depleted harzburgite [5].

In contrast, peridotitic garnets in diamonds from Finsch are characterised by comparatively low inclusion encapsulation temperatures, dominantly sinusoidal REE patterns, and low Ti and Y but variably elevated Zr – a likely signature of low-temperature, fluid-dominated metasomatism accompanying diamond crystallisation [1].

Granulite lower crust: dry, but full of fluids

Touret, J.L.R.
Musée de Minéralogie, Mines-Paristech, Paris, France
(jacques.touret@ensmp.fr)

About 40 years ago, the discovery of CO_2-rich inclusions in granulites has initiated a debate which is still an important issue in metamorphic petrology. Experimental and stable isotope data have led to the conception of a "fluid-absent" model, opposed to the "fluid-assisted" hypothesis, derived from fluid inclusion evidence. Besides CO_2, other fluids have been found to be of importance in these rocks, notably concentrated aqueous solutions (brines), also able to coexist with granulite mineral assemblages at high *P* and *T*. Brines also occur in inclusions, but they are much smaller and less spectacular than the CO_2-bearing ones («collapsed» inclusions). This is easily explained by the slope difference between aqueous and CO_2-isochores, respectively, compared to the isobaric-cooling post–peak P-T path commonly encountered in granulites [1].

But brines have left their trace in an impressive array of metasomatic effects, systematically found in granulite terranes, notably in high-temperature (UT, UHT) types: intergranular K-feldspar veining and quartz exsolution (myrmekites) at quartz-feldspar of feldspar-feldspar grain boundaries, carbonate metasomatism along km-scale shear zones (Norway, India), "incipient charnockites" cross-cutting a variety of metamorphic protoliths (India, Sri Lanka, Scandinavia), high oxygen fugacity in many granulites (India), prohibiting graphite deposition during CO_2-streaming (Archean granulites), etc. All together, this impressive amount of evidence suggests that the amount of fluids in the lower crust, under peak metamorphic conditions, was very large indeed, far too important to be only locally derived. Then, except for remnants contained in inclusions, these fluids have left the rock system during postmetamorphic uplift.

Fluid remnants identical to those occurring in deep crustal granulites are also found in mantle minerals, including diamonds. Major mantle fluid source is related to the final stages of melting processes: late magmatic emanations from alkalic basaltic melts, carbonate-metasomatizing aqueous fluids issued from igneous carbonatites. Even if a local derivation of some fluids by crustal melting cannot be excluded, most lower-crustal granulite fluids seem to have the same origin [2]. They are transferred from the mantle into the crust by synmetamorphic intrusives, also responsible for the high thermal gradient typical of granulites, notably HT- and UHT-types.

These are mostly found in Precambrian times, generated during a small number of time intervals: e.g., around 500, 1000, 1800, 2500 Ma. HT-granulites forming events occur at world-scale in supercontinents or supercratons, either at the end of amalgamation, or shortly before breaking-off [3,4]. They provide a mechanism for a vertical accretion of the continental slab, which complement the more classical way of lateral accretion above subduction zones at convergent boundaries.

Using different methods to determine the composition of upper mantle fluid inclusions from the Central Pannonian Basin

Berkesi, M.[1*], Dubessy, J.[2], Kovács, I.[3], Szabó, Cs.[1], Perucchi, A.[4] & Vaccari, L.[4]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]marta.berkesi@gmail.com)
[2]Nancy University, Vandœuvre-les Nancy Cedex, Nancy, France
[3]Eötvös Loránd Geophysical Institute, Budapest, Hungary
[4]ELETTRA Synchrotron Light Laboratory, Trieste, Italy

Individual fluid inclusions in upper mantle xenoliths from the Central Pannonian Basin (western Hungary) are hosted either in rock-forming silicates (olivine and pyroxenes) or in interstitial glasses. To determine their composition, microthermometry coupled with Raman microspectroscopy was applied on silicate hosted fluid inclusions. Based on microthermometry, the fluid phase in the inclusions is dominantly CO_2, whereas the room temperature Raman analyses also confirmed the presence of H_2S as additional volatile and magnesite as a solid phase. At the wall of fluid inclusions, the band of liquid water was also found rarely. Moreover, high temperature Raman microspectroscopy (120-150°C) revealed the presence of H_2O in each fluid inclusion as a band corresponding to the dissolved H_2O in the CO_2-rich phase. Even though the complete homogenization of the fluid inclusion cannot be recognized, at high temperature the distribution of dissolved H_2O in CO_2 is presumably uniform, which allows (semi-) quantification of spectra of the CO_2-rich phase. At 150°C, the calculated H_2O content in silicate-hosted fluid inclusions from the studied series ranges from 0.1 to 7 mol% (with one exception at 11.7 mol %) and shows an average value of 3.6 mol%. To calibrate the molar percentages of CO_2 and H_2O in natural fluid inclusions, calculated using the Raman spectra, silica fused synthetic capillary fluid inclusions were also prepared and applied subsequently. Because of optical reasons and a problem caused by fluorescence, the above mentioned techniques could not be used for the glass and its bubble inside. However, infrared spectroscopy allowed to determine the H_2O content of the wall-rock pyroxenes (orthopyoxene: 91.7±27.5 ppm, clinopyroxene: 395.8±98.9 ppm) and the glass (0.55±0.2 wt.%), using the calibration method developed by Kovács et al. [1]. In addition, the infrared spectroscopy confirmed the dominance of CO_2 in the glass-hosted bubbles. Our present study provided direct evidence for the presence of H_2O within deep lithospheric fluid inclusions, which has been rarely reported (e.g., [2,3]) so far. Our results imply that fluid inclusions trapped at conditions of the lithospheric mantle generally contain small amount of H_2O which may hold important implications for the geochemical and geodynamic evolution of the Earth's deep lithosphere and upper mantle.

Fluid migration process beneath a volcanic front: H_2O-rich inclusions in mantle peridotites from Avacha volcano, the Kamchatka arc

Ishimaru, S.[1*], Arai, S.[1], Tamura, A.[2], Mizukami, T.[1], Kawamoto, T.[3], Yamamoto, J.[3] & Morishita, T.[2]
[1]School of Natural System, College of Science and Engineering, Kanazawa University, Kanazawa, Japan
([*]jaja@earth.s.kanazawa-u.ac.jp)
[2]Frontier Science Organization, Kanazawa University, Kanazawa, Japan
[3]Institute for Geothermal Science, Kyoto University, Kyoto, Japan

We characterized petrographic and geochemical features of peridotite xenoliths from Avacha volcano in detail: high depletion in melt components, refractory mineralogy (e.g., high-Fo olivine (Fo_{90-92}) and high-Cr# spinel [= Cr/(Cr + Al) atomic ratio] (0.5-0.7)), and multi-stage metasomatism. The metasomatism gave rise to enrichment of SiO_2, and/or transitional elements (e.g., Ni, and Fe) and rarely sulfur and arsenic in peridotites. The addition of SiO_2 is observed as formation of secondary orthopyroxenes with a minor amount of clinopyroxene at an expense of olivine. The secondary orthopyroxene frequently accompanies amphiboles (edenite and pargacite). In addition, we found some peculiar peridotite xenoliths mainly composed of extremely fine-grained minerals (= F-type peridotite). The F-type peridotites are almost the same as ordinary coarse-grained peridotites in terms of metasomatism, although the protolith of the former is dunite. In addition, some F-type peridotites have been metasomatized by a high-Mg, high-SiO_2 agent, being converted to clinopyroxenite, websterite or wehrlite with extremely high-Mg# [= Mg/(Mg + total Fe) atomic ratio] mineralogy (the highest Mg# of clinopyroxene is 0.99!).

Silicate minerals of Avacha peridotites frequently contain minute inclusions, e.g., chromian spinel, sulfides and fluids. The fluid inclusions are especially abundant in highly metasomatized samples, and are possibly relics of the metasomatic agent. We checked phases of the fluid inclusions in both coarse-grained (6 samples) and F-type (2 samples) peridotites to recognize only H_2O rarely with carbonate. This is one of the rare cases where the mantle wedge H_2O fluids have been detected (cf. Iraya volcano, Iwanaidake massif and Higashi-akaishi massif). We try to discuss the fluid species in the inclusions, the geochemical features and the relationships between the host peridotite features and fluid phases.

Immiscibility in a peralkaline nephelinite melt: the Oldoinyo Lengai case (Tanzania)

Sharygin, V.V.[1*], Kamenetsky, V.S.[2], Zaitsev, A.N.[3], Kamenetsky, M.B.[2] & Yemel'yanov, M.V.[1]
[1]V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia ([*]sharygin@uiggm.nsc.ru)
[2]School of Earth Sciences, University of Tasmania, Hobart, Australia
[3]Saint Petersburg State University, Saint Petersburg, Russia

Melt inclusions with silicate-carbonate immiscibility are found together with microlites (diopside, etc.) along growth zones in nepheline phenocrysts from peralkaline nephelinite lavas of the 1917 eruption of the Oldoinyo Lengai volcano, Tanzania. Coexisting fluid, carbonate-salt and sulfide inclusions are scarce. Melt inclusions with immiscible phases (10-100 μm) are represented by green glass ± gas-carbonate globules ± daughter or trapped crystals. The most typical inclusions contain glass and one gas-carbonate globule in variable proportion. In some inclusions gas and carbonate components are separated into individual phases, and gas bubble always contains some salt crystals. Trapped crystals in silicate glass are diopside, apatite, Ti-andradite and titanite, whereas daughter phases are aegirine, fluorite, Na-Mg-Ti-rich tetraferriannite, Fe-rich delhayelite and Fe-rich leucite, rarely K-feldspar and wollastonite. Carbonate globule is commonly fine-devitrified and texturally zoned, and individual phases (calcite, nyerereite, chlorides, fluorite) are rare. Same immiscible inclusions were previously described in nepheline of the 2007-2008 eruptions of Oldoinyo Lengai [1].

Heating experiments with the Oldoinyo nepheline-hosted inclusions (silicate glass + gas-carbonate globule) have shown that first changes are observed in a gas-carbonate globule at 470-510°C and assigned to recrystallization of phases. The carbonate-rich component of gas-carbonate globules melts instantaneously at 550-570°C. Silicate glass fuses at 600-670°C. The appearance and then disappearance of blebs of different salt liquids (fluoride, chloride or sulfate) occur in both silicate and carbonate melts at 670-810°C. The salt and carbonate blebs then amalgamate into one large globule, which gradually decreases in size and gas bubble in it also decreased in size at 800-900°C. The gas-carbonate melt globule homogenizes at 900-940°C. At this temperature phase composition of the melt inclusions is silicate melt + carbonate-rich melt. Quenching of inclusions led to the initial phase composition.

The silicate glass is peralkaline and strongly varies in SiO_2 (43.6-53.0), FeO_t (7.5-18.6), CaO (1.0-7.2), alkalis (16.5-24.5) and SO_3+F+Cl (1.0-4.3 wt.%). This glass is poor in H_2O (0.1-0.6 wt.%), Cr and Ta (<10 ppm) and rich in Ba (1720-6490), Sr (1880-6700), Zr (1440-2200), REE (520-1040), Nb (450-980), Rb (250-460) and Li (240-390 ppm). The EDS and EMPA data have show that the carbonate globules are natrocarbonatite in composition and Na, Ca, K, C, Cl, F, S and P are major components, like in the Oldoinyo natrocarbonatites.

Our study of nepheline-hosted inclusions in nephelinite lavas advocates very complicated history during cooling of initial silicate melt as suggested by [2]. The silicate-natrocarbonatite immiscibility took place at temperature above 900°C and nepheline phenocrysts crystallized from immiscible liquids in an intermediate chamber. After trapping of inclusions by nepheline (closed system) the gas phase and different salt liquids may be separated from natrocarbonatite melt in the 900-600°C range. In nephelinite lavas (open system) the silicate-natrocarbonatite immiscibility phenomenon is commonly hidden, owing to degassing of silicate melt, separation of carbonate melt from silicate melt and/or reaction of carbonate melt with primary silicate minerals.

Carbonate melts in the Earth's mantle

Caracas, R.[1*], Cohen, R.E.[2] & Gygi, F.[3]
[1]Laboratoire de Sciences de la Terre, ENS de Lyon, CNRS, Lyon, France ([*]razvan.caracas@ens-lyon.fr)
[2]Geophysical Laboratory, Carnegie Institution of Washington, USA
[3]Dept. of Applied Science, University of California, Davis, USA

We perform a molecular dynamics study of the properties of the carbonated silicate melts at realistic thermodynamic conditions of the Earth's mantle. We employ the Qbox package based on a highly efficient plane wave and pseudopotentials implementation of the density-functional theory.

We work on three distinct compositions: Mg_2SiO_4, $16Mg_2SiO_4+CO_2$ and $16Mg_2SiO_4+MgCO_3$ and study the effect of the carbonization on the melt properties as well as the difference in effects between the CO_2 molecule and the CO_3^{2-} anionic group. We focus on the Earth-relevant isotherm at 3000K.

At ambient pressure the silicon is in tetrahedral coordination as SiO_4 with little or non-existent. The O atoms are the most mobile in the system. The diffusion of the CO_2 molecule takes place through intermediate unstable CO_3^{2-} states. In agreement with previous studies on pure magnesium silicate melts the polymerization of the tetrahedra is enhanced by pressure; the onset of the five-fold coordination of the silicon atoms occurs above 40 GPa. The formation of the CO_3^{2-} states out of the CO_2 molecule is equally enhanced by pressure; the effect of the temperature is minimal. The thermal dilatation of the CO_2-bearing fluid is about 1GPa/1000K at ambient pressures. The density differences due to the addition of CO_2 and of $MgCO_3$ to the Mg_2SiO_4 melts are minimal at ambient pressures and 3000K, and can be related only to the mass addition. At higher pressures CO_2 decreases the density of the Mg_2SiO_4 melts.

Nanogranite and melt inclusions: new tools in crustal anatexis

Cesare, B.[1*], Ferrero, S.[1], Bartoli, O.[2], Braga, R.[3], Salvioli-Mariani, E.[2], Acosta-Vigil, A.[4], Meli, S.[2] & Groppo, C.[5]
[1]Dipt. di Geoscienze, Università di Padova, Italy ([*]bernardo.cesare@unipd.it)
[2]Dipt. di Scienze della Terra, Università di Parma, Italy
[3]Dipt. di Scienze della Terra e Geologico-Ambientali, Università di Bologna, Italy
[4]Inst. Andaluz de Ciencias de la Tierra, CSIC, Granada, Spain
[5]Dipt. di Scienze Mineralogiche e Petrologiche, Università di Torino, Italy

The growth of peritectic minerals during incongruent melting reactions represents an ideal situation for the entrapment of inclusions of anatectic melt. Although this is a straightforward theoretical consideration, melt inclusions in anatectic rocks, and in particular in metapelitic migmatites, have received very little consideration in the past, with just a few exceptions [1,2].

Based on the experience acquired with glassy inclusions in enclaves, we started a systematic research looking for inclusions of anatectic melt in garnet and other peritectic phases in crustal anatectic migmatites from various localities worldwide, until we found them in the granulites from the Kerala Khondalite Belt, India [3]. Here, tiny inclusions are hosted within garnet: those between 15-25 μm are fully crystallized to a Qtz-Ab-Kfs-Bt cryptocrystalline aggregate, whereas those <15 μm are completely glassy. Both re-melted cryptocrystalline and glassy inclusions have a peraluminous, ultrapotassic granitic composition which does not correspond to a "minimum melt" and points to melting temperatures well above minimum or eutectic temperatures, in agreement with the UHT origin of the rock. Given the microstructural and chemical features, we named "*nanogranite*" the cryptocrystalline aggregate within these inclusions, and concluded that nanogranite is the crystallized melt that was trapped by peritectic minerals growing during anatexis.

Since then, nanogranite inclusions have been found also in migmatites from other geological settings of various P-T conditions, such as the Ulten Zone (Italy), Ronda (Spain) and the Barun Gneiss (Nepal). Inclusions are hosted in garnet at all these localities, and also in ilmenite at Ronda.

The study of nanogranites is analytically challenging, as inclusions are very often <10 μm in diameter, and mineral grains in them <1 μm. Therefore we combine field emission gun-based SEM and EMP techniques with synchrotron-based micro-XRD and micro-XRF. Being particularly interested in the bulk composition of the trapped anatectic melt, nanogranites are experimentally re-melted both in the high-temperature stage and in a piston cylinder apparatus.

We present and discuss the textural and microanalytical data recently obtained from nanogranites and their melting products. Comparison of results from the different occurrences allows making important petrological inferences, such as differences in the P-T conditions of anatexis and fluid activity among the various cases, and confirms the importance of these inclusions as a new tool for the study of crustal anatexis. In fact, the composition of anatectic melts in migmatitic terranes can now be directly analyzed rather than assumed.

After entrapment, the preservation of inclusions depends on the extent of chemical interaction with the host mineral, and on the mechanical behaviour of the host during the subsequent history. Therefore, melt inclusions should be targeted in strong and refractory minerals from the least deformed rock domains.

Hydrosilicate liquids as a medium for metal transport in experiments and nature

Smirnov, S.Z.[1,2*], Thomas, V.G.[1] & Kamenetsky, V.S.[3]
[1]Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (*ssmr@uiggm.nsc.ru)
[2]Novosibirsk State University, Novosibirsk, Russia
[3]CODES, University of Tasmania, Hobart, Australia

The latest stages of evolution of felsic magmas play important role in formation of ore-forming media. At these stages the magmatic system divides into variety of fluids that coexist immiscibly with parental melt. Some of them are crucial for postmagmatic ore and mineral formation. Aqueous fluids and hydrosaline melts (brines) are capable for transporting metals from magmas to ore deposits. Hydrosilicate liquids (HSL) with molar SiO_2/H_2O~1 are suggested to be another alternative, explaining joint metal and silica transport in late magmatic and post magmatic hydrothermal systems.

This study is focused on the HSL, which appear when alkali or salt of weak acids are added to the system SiO_2-H_2O. Polymerization of dissolved silica in those systems results in formation of viscous liquid, which is supposed to have colloidal nature. We have studied the effect of addition of Al_2O_3, NaF, NaCl on the formation of the HSL in the system Na_2O-SiO_2-H_2O and their ability to concentrate rare litophile elements at 600°C and 1.5 kbar.

Experiments show that addition of Al_2O_3 promotes the formation of HSL with lower SiO_2 and H_2O content as compared to the system Na_2O-SiO_2-H_2O. Addition of NaF or NaCl has no effect on the process of HSL formation. However NaF is concentrated predominantly in the HSL, while NaCl – in the aqueous fluid. Rb, Cs, Ta, Sn, Mo, W and Zn are concentrated in various degrees by the HSL. Concentrations of Cs and Mo in HSL are about 3.6 times higher than in aqueous fluid. Rb and W contents in HSL exceed those of the aqueous fluid by 5.1 times. The highest degrees of concentrations were recorded for Sn, Zn (C_{HSL}/C_{aq}=19.9 and 50.7 respectively) and Ta. The latter is completely accumulated by HSL. It is expected that the metals should fractionate between HSL and coexisting aqueous fluid according to theirs affinities to Cl or F.

Based on the data from experiments we conclude that HSL may form in nature when alkaline aqueous fluid reacts with felsic magma or granitic rock. With time and decreasing temperature HSL can easily exchange elements with coexisting fluids. This leads to change their chemistry and physical properties. Further evolution of HSL can result in mineral assemblages that are dominated by clay minerals or zeolites. Thus we can find evidence of natural HSL with unchanged compositions only if they are isolated as inclusions in minerals. Inclusions of melts from the roots of miarolitic quartz from granitic pegmatites can be regarded as examples of natural HSL [1,2]. They are composed of crystalline micaceous aggregate and aqueous solution of orthoboric acid. These inclusions were re-melted or homogenized in autoclaves under 2 – 3 kbar external pressure of H_2O at 600-650ºC. The quench glasses of these inclusions after re-melting or homogenization have molar SiO_2/H_2O~1 and contain unusually high concentrations of B, F and metals (Ta, Nb, Be, Rb and Cs).

The natural and experimental data suggest that hydrosilicate liquids should be considered as a medium for metal transport in late magmatic and postmagmatic mineralization, which is related to evolution of felsic magmas.

Constraining asthenosphere-lithosphere interactions from fluid/melt inclusion study of Qiaoshan xenoliths, Linqu, Shandong Province, E. China

Ni, P.[1*], Liu, J.Q.[1,2] & Chen, L.H.[1]
[1]State Key Laboratory for Mineral Deposit Research, Institute of Geo-Fluid, School of Earth Sciences and Engineering, Nanjing University, Nanjing, China (*peini@njut.edu.cn)
[2]Earthquake Administration of Jiangsu Province, Nanjing, China

Earth's mantle fluids influence not only phase transformation of mantle minerals and rheology of mantle, but also melting behaviour of mantle peridotites. Fluid inclusions in mantle xenoliths provide the most direct mean to improve our understanding of the nature and the physicochemical condition of mantle fluids.

We conduct a case study of fluid/melt inclusions from Qiaoshan xenoliths, Linqu (Fig. 1) which represent fertile mantle of the North China craton (NCC). In order to determine the chemical compositions of the trapped mantle fluids, explore the origin of different fluid/melt inclusions, and their potential inter-relationships, and discuss the possible relationships between the geochemical characteristics of mantle fluids and the evolution of the NCC, detailed petrographic observation, microthermometry and laser Raman microspectroscopy were carried out.

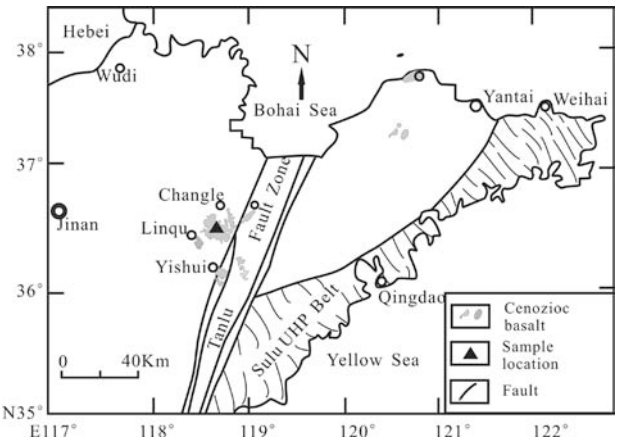

Fig. 1: The sketch map of sample location.

Two generations (four types) of fluid inclusions were identified in Qiaoshan xenoliths: (1) early CO_2 fluid inclusions, (2) early carbonatite melt inclusions, (3) late CO_2 fluid inclusions, and (4) late silicate melt inclusions. Among the early CO_2 fluid inclusions, most consist of high-density pure CO_2, while others have small amounts of other components besides of CO_2, including graphite, magnesite, Mg-calcite, CO and N_2.

Based on microthermometric works on fluid/melt inclusions, this work reveals that the entrapment temperatures of two generations fluid inclusions are about 1200°C, and their minimum entrapment pressure are 1.42 GPa and 0.80 GPa, respectively. The genetic link of early carbonatite melt inclusions with orthopyroxene suggests that they may be produced via interactions of CO_2 fluids with other mantle silicate minerals (such as olivine, clinopyroxene). Moreover, complex components in early CO_2 fluid inclusions also support that the origin of host mineral may be related to the reaction with CO_2-rich fluids. In conclusion, the compositional signatures observed in the fluid/melt inclusions of Qiaoshan xenoliths reflect recent asthenosphere-lithosphere interactions in this area.

Crack-seal cementation of natural fractures recording pore fluid evolution in tight gas sandstone reservoirs

Fall, A.[1*], Eichhubl, P.[1], Bodnar, R.J.[2] & Laubach, S.E.[1]
[1]Bureau of Economic Geology, The University of Texas at Austin, Texas, USA ([*]andras.fall@beg.utexas.edu)
[2]Dept. of Geosciences, Virginia Tech, Blacksburg, Virginia, USA

Natural opening-mode fractures in tight gas sandstone reservoirs are partially cemented with crack-seal quartz cement bridges that precipitated synkinematically with fracture opening. Fluid inclusions trapped in the crack-seal cement increments record pressure, temperature, and fluid composition (PTX) during subsequent fracture opening and cementation. High-resolution SEM-CL imaging of quartz cements combined with fluid inclusion microthermometry and Raman spectroscopy constrain fluid evolution during fracture generation in tight gas sandstone reservoirs. Homogenization temperatures (T_h) indicate a thermal history from ~140 to 185°C in sandstones of the southern Piceance Basin and ~135-155°C in the East Texas Basin, respectively [1]. Fluid salinities range from 1 to 2.5, and 14 to 15 wt% NaCl equivalents, respectively. Coexisting hydrocarbon-saturated aqueous inclusions and hydrocarbon gas inclusions indicate that T_h represent formation temperatures. The CH_4 Raman peak position of the vapor bubble was used to determine the pressure of the aqueous inclusions at room temperature [2]. Based on microthermometry, Raman spectroscopy, and equation of state modeling, the pressures at trapping were calculated for the observed inclusions [1]. Trapping pressures range from ~60 MPa to ~100 MPa (Fig. 1) in the southern Piceance Basin, and ~30 to 60 MPa in the East Texas Basin, respectively, suggesting that fracture opening occurred under significant pore fluid overpressures.

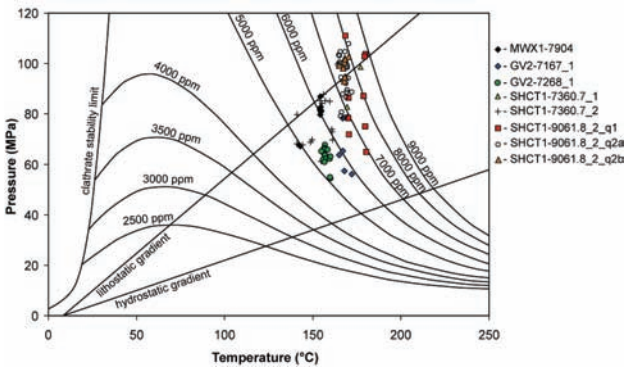

Fig. 1: P-T diagram showing isopleths in the H_2O-NaCl-CH_4 system for the 2 wt% NaCl-CH_4 pseudobinary and fluid inclusion trapping conditions in wells from the southern Piceance Basin, Colorado.

The subsequent pore fluid overpressure and fracturing is a result of hydrocarbon generations in shales and coal beds that surround the sandstones. The fractures significantly increase the permeability of the sandstones and permit vertical migration of the hydrocarbons [3].

H_2O-NaCl-KCl fluid system: purely empirical and thermodynamic modelling

Bakker, R.J.
Dept. of Applied Geosciences and Geophysics, Mineralogy and Petrology, University of Leoben, Austria
(bakker@unileoben.ac.at)

H_2O-NaCl-KCl-rich fluids occur occasionally in fluid inclusions in a variety of geological environments. The properties of this fluid provide information about the conditions of entrapment, and thereby, conditions that have affected the rock. This fluid system has already been studied extensively and modelled according to thermodynamic principles and purely empirical "best-fit" analyses. However, the provided models are internally inconsistent and are partly not reproducing the available experimental data. Therefore, new models are developed to reproduce the properties of the H_2O-NaCl-KCl fluid system, especially the liquidus at variable pressures (the solid+liquid+vapour surface, i.e. HLV), and at constant pressures (the solid+liquid surface, i.e. HL). The HLV surface reaches pressures up to 39 MPa (NaCl-H_2O-rich fluids), and the behaviour of fluid inclusions during microthermometric experiments, i.e. the dissolution of a halite crystal and a sylvite crystal in the presence of a vapour bubble, is defined according to the thermodynamic properties at this surface. The HLV surface is modelled in this study according to purely empirical "best-fit" polynomial equations, which relate temperature, pressure and composition. The HL surfaces, at constants pressures, are modelled according to thermodynamic principles, i.e., the equality of chemical potentials of components (NaCl and KCl) in each phase at equilibrium The HL-equations can be applied in the range of 300 to 1000°C, and pressures from 30 to 250 MPa, which is defined by the experimental data that is used to develop this model.

The new models are included in the software package FLUIDS [1], to be able to apply directly the mathematical functions in fluid inclusion studies and in general fluid properties investigations. The computer program AqSoWNK has been developed in REALBasic (© Real Software, Inc.) with a graphical user interface. The program is composed of two main applications: 1. salinity determination from known dissolution temperatures, at variable pressures (HLV) and constant pressures (HL); 2. dissolution temperature determination from known salinities at variable pressures (HLV) and constant pressures (HL). In addition, the program reveals thermodynamic properties, including the excess Gibbs energy and chemical potentials at selected conditions.

New equation of state for aqueous species to high temperatures and pressures

Dolejš, D.
Institute of Petrology and Structural Geology, Charles University, Prague, Czech Republic (ddolejs@natur.cuni.cz)

Aqueous fluids play a fundamental role in mass transfer in the Earth's interior. Reactive fluid flow exerts major control on mass transfer in subduction zones and during metamorphism in the crust as well as is responsible for various element enrichment and depletion patterns in magmatic, hydrothermal ore-forming and geothermal systems. Aqueous solutes include neutral and charged nonelectrolytes and electrolytes, and their thermodynamic properties are frequently described by the Helgeson-Kirkham-Flowers model [1,2]. This equation of state is, however, applicable at liquid-like water densities and below 5 kbar, and it incorporates the dielelectric constant of water, which has been experimentally measured to 600°C only.

We propose a new equation of state for aqueous species, which combines intrinsic properties with caloric and volumetric effects of species hydration. It consists of two thermodynamic contributions: (i) caloric part, which includes enthalpy, entropy and heat capacity of the species, representing intrinsic properties of the solute species and energetics of its hydration, and (ii) volumetric part, which combines hardcore volume with a contribution from volume work due to electrostriction and spatial rearrangement during the formation of a hydration sphere. The approach based on the solvent density is more accurate in the vicinity of the critical point [3,4] and it is not limited by the availability of dielectric properties of the solvent.

Accuracy of the new equation of state has been tested by evaluating solubility and speciation of representative rock-forming minerals in aqueous fluid at 25-1100°C and up to 20 kbar. Experimental solubilities for quartz, corundum, rutile, calcite, apatite, fluorite and portlandite are reproduced to better than 5 % or 0.1 log molality units. The solubility increases for a given phase by 4-5 orders of magnitudes as temperature rises from 200 to 1100°C along typical geotherms. At constant pressure, however, mineral solubilities initially increase with rising temperature, but subsequently drop. This effect is caused by a reversal in isobaric expansivity of the aqueous solvent, which propagates into the enthalpy of dissolution. The onset of retrograde solubility typically occurs at 300-400°C and it is a characteristic of all minerals.

Thermodynamic properties of aqueous species reveal systematic relationships between charge and volumetric properties. Neutral species such as $Si(OH)_4$, $Ti(OH)_4$ or $Al(OH)_3$ exhibit very small dependence on the solvent properties. In contrast, variably charged ions cause much stronger electrostriction effects and their isobaric properties are profoundly affected by the isothermal expansivity of the solvent. In both cases, only a small number of parameters (four to five) are sufficient to represent partial molal properties to very high temperatures and pressures. This also permits retrieval of the model parameters from the standard thermodynamic properties at arbitrary reference conditions (e.g., 25°C and 1 bar), which are readily available. The new thermodynamic formulation thus alleviates several drawbacks of the Helgeson-Kirkham-Flowers model and provides a promising tool for modelling reactive fluid and mass transfer in magmatic, metamorphic, hydrothermal and groundwater systems.

Modelling quartz solubility in miscible and immiscible H_2O-NaCl-CO_2 fluids

Steele-MacInnis, M.J.*, Bodnar, R.J., Rimstidt, J.D. & Lowell, R.P.
Dept. of Geosciences, Virginia Polytechnic and State University, USA (*mjmaci@vt.edu)

A fluid density-based approach (e.g., [1]) was used to develop a predictive model for quartz solubility in aqueous fluids at crustal P-T conditions. While the origins of the density model are empirical, we propose a theoretical explanation of the model. An advantage of this model is that it appears to be solute independent. For example, the model predicts quartz solubility for H_2O-NaCl as well as H_2O-CO_2 fluids, without adjusting the parameters in the model. This suggests that the model may be used to predict quartz solubility in aqueous fluids of *any* composition, including non-idealized geologic fluids with many dissolved components.

An additional advantage of the predictive capability of this model is the ability to extrapolate quartz solubility estimates to immiscible fluid systems, for which experimental quartz solubility measurements in coexisting liquid and vapor are less abundant compared to the single-phase region. Partitioning of dissolved silica between liquid and vapor has been investigated for the system H_2O-NaCl using the model developed in this study (Fig. 1). Fluid phase equilibria control the dissolution and precipitation of quartz in hydrothermal systems, where bulk quartz solubility is a function of quartz solubility in the liquid and vapor phases and the proportions of those phases present. In addition, quartz may exhibit prograde solubility with respect to temperature in the liquid phase and retrograde solubility in the vapor (or vice-versa), within the same P-T range, indicating the possibility of quartz dissolution into one fluid phase concurrent with quartz precipitation from the other.

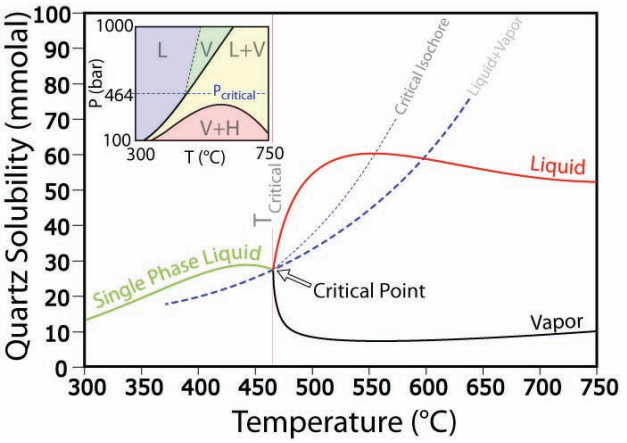

Fig. 1: Quartz solubility on the isobar of the critical pressure for a fluid of 10 wt.% NaCl. In the two-phase region, quartz solubility in the liquid is shown in red and that in the vapour is shown in black.

The model developed in this study can be used to predict the spatial and temporal evolution of quartz mineralization in hydrothermal systems, including those in which immiscibility occurs. The model can be applied to studies involving vein paragenesis, fluid inclusions, permeability evolution and reactive transport modelling. Furthermore, the density based predictive approach may be extended to other fluid-mineral systems.

Tungsten mobility in subduction zones – a high P-T synthetic fluid inclusion study

Bali, E.*, Audetat, A. & Keppler, H.
Bayerisches Geoinstitute, University of Bayreuth, Germany
(*eniko.bali@uni-bayreuth.de)

The behaviour of tungsten varies in different geochemical environments. In the presence of metallic iron it behaves siderophile, thus, $^{182}W/^{184}W$ isotopic ratios have been successfully used for timing of differentiation of planetary bodies (e.g., [1]). During mantle melting however, it behaves highly incompatible (e.g., [2]), leaving a depleted mantle behind and producing a relatively tungsten-rich crust (13 ppb vs. 1 ppm; [3,4]). Moreover, the existence of hydrothermal tungsten-ore deposits indicates that it should be mobile in aqueous fluid.

Recently, König, S. et al. [5,6] have carried out high precision W-analyses on different sets of subduction related lavas. They confirmed that tungsten, and also molybdenum, can be mobilized by subduction zone fluids, although their enrichment can be decoupled. They suggested that the reason of decoupling might be the variable redox-sensitivity of W and Mo mobility in aqueous fluids.

Currently there are no available experimental data on relevant pressure, temperature and fO_2-conditions to test this hypothesis. We carried out W-solubility experiments at 26.1 kilobars, 600 to 800°C, at fO_2 conditions -5.09 to +1.94 logarithmic units relative to the FMQ buffer, and fluid salinities between 2 and 20 wt% $NaCl_{equiv}$. The fluid was trapped as synthetic fluid inclusions in quartz and subsequently analyzed by LA-ICPMS. In order to establish realistic fluid compositions for the mantle, the maximum solubility of W in the major mantle phases in equilibrium with a W-saturated fluid should also be determined. From this one can then estimate solid-fluid partition coefficients and determine their sensitivity on the previously described variables.

Our current dataset shows that W solubility is high and nearly independent on fluid salinity at 800°C and fO_2 conditions buffered by NiNiO, suggesting that tungsten did not dissolve in form of chloride complexes. On the other hand, tungsten solubility strongly depends on oxygen fugacity, increasing from 0.30 wt% W to 3.62 wt% W as fO_2 increases from the IW to the ReReO buffer. Thus, W is more efficiently mobilized at oxidizing conditions.

Our preliminary dataset suggests that W-incorporation into clinopyroxenes decreases with increasing Al_2O_3-content, thus $D^W_{fluid/cpx}$ increases with the same parameter. Similar relationship was established by Hill, E. et al. [7] and Righter, K. & Shearer, C.K [8] for clinopyroxene-melt partitioning data. At conditions buffered by CoCoO (-1.67 log units relative to FMQ) $D^W_{fluid/cpx}$ reaches up to 240 in diopside containing 3.8 wt% Al_2O_3. This suggests that subduction-derived fluids will not lose their W content when they percolate through the mantle wedge.

Ammonium in subduction zone fluids

Watenphul, A.* & Schmidt, C.
GFZ German Research Centre for Geosciences, Potsdam, Germany (*watenphul@gfz-potsdam.de)

Ammonium, NH_4^+, can be an important constituent in many crustal and subduction zone fluids, but is usually overlooked because of analytical difficulties. Large amounts of NH_4^+ are generated by the decomposition of organic material during diagenesis. Ammonium is readily mobilized by hydrothermal processes. Geothermal brines can contain more than 1000 ppm NH_4^+. Hydrothermal deposits often display substantial ammonium halos with up to 25000 ppm NH_4^+ in the host rocks [1]. In minerals, ammonium is mainly incorporated into potassium silicates, some of which can transport NH_4^+ to eclogite facies conditions [2], or even into the mantle [3]. Usually, a large fraction of the incorporated ammonium is released upon progressive metamorphism [4] because NH_4^+ strongly fractionates into the fluid relative to mica and feldspar [5].

The behaviour of ammonium in aqueous fluids was experimentally studied to 600°C and about 1.3 GPa using a hydrothermal diamond-anvil cell. The observed Raman spectroscopic detection limit for NH_4^+ in aqueous solutions is about 0.2 molal, which explains that it is rarely reported in fluid inclusion analyses. The Raman spectra reveal that addition of ammonium chloride causes a strong reduction of the dynamic three-dimensional network of water. This points to a substantial decrease in the water activity even if only quite small amounts of NH_4Cl (<1 molal) are present. Experiments on the assemblages NH_4Cl solutions plus quartz or quartz + kyanite + K-feldspar ± muscovite show that the silica solubility is significantly lower than that in equimolal NaCl solutions. This indicates that ammonium causes an even stronger decrease in the activity of water in chloridic solutions than sodium.

At temperatures above 300°C, a significant fraction of NH_4^+ is converted to ammonia, NH_3, indicating a large shift towards acidic conditions. The NH_3/NH_4^+ ratio increases with temperature and decreases with pressure. This implies that more ammonium should be retained in K-bearing minerals coexisting with chloridic fluids upon high-pressure low-temperature metamorphism.

The kinetics of the reaction K-feldspar + kyanite + water = muscovite + quartz was much faster with NH_4Cl solutions than in comparable experiments with water. This is attributed to the enhancement of the rate-limiting alumina solubility. The nucleation and growth of mica on the expense of K-feldspar and NH_4^+/K exchange between fluid and K-feldspar occurs simultaneously. However, Raman and IR spectroscopy indicate that the incorporation of NH_4^+ into K-feldspar is even faster than the consumption of the K-feldspar during the reaction, which is already a very rapid reaction.

Ammonium has strong effects on fluid properties, element solubilities, and reaction kinetics. It is not only the determinant for the recycling of nitrogen, but also has considerable effects on the composition of crustal and subduction zone fluids and the reactions occurring during the subduction process.

Trapped high density fluids in superdeep diamonds

Brenker, F.E.[1*], Vincze, L.[2], Vekemans, B.[2], Schmitz, S.[1], De Nolf, W.[3], Janssens, K.[3], Stachel, T.[4] & Harris, J.[1,5]
[1]Geosciences Institute, Goethe University, Frankfurt/M., Germany ([*]f.brenker@em.uni-frankfurt.de)
[2]Dept. of Analytical chemistry, Ghent University, Belgium
[3]Centre for Micro- and Trace Analysis, Dept. of Chemistry, Antwerp University, Belgium
[4]Dept. of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada
[5]Division of Earth Sciences, University of Glasgow, Scotland, UK

Synchrotron based confocal X-ray fluorescence analyses were performed at the ESRF (European Synchroton Radiation Facility, Grenoble) on a set of Kankan diamonds [1,2]. Of special interest was a large Kankan diamond containing many Ca-Si-O rich inclusions (KK200). Investigations applying Raman spectroscopy yield $CaSiO_3$ walstromite, $CaSi_2O_5$ titanite and larnite (beta-Ca_2SiO_4) as inclusion paragenesis. The varying proportions of the respected phases indicate a depth of origin within the two phase field of larnite + $CaSi_2O_5$ titanite between 300 and 360 km [3].

Detailed trace element tomography of several cubo-octahedral inclusions indicate a Ca,Si-rich source, in the absence of several common mantle minerals, like olivine, garnet and Ca-poor pyroxene. This reservoir may represent metasomatized oceanic lithosphere (rodingites, ophicarbonates), metamorphosed carbonaceous sediments or a trapped carbonatitic melt. In addition investigations on the surrounding narrow fractures around the inclusions show that contrary to our expectation the fractures are actually filled with material. The fracture filling shows close similarities in trace element composition to the mineral inclusions, in addition to being generally enriched in REE. The former existence of a fluid or melt is required to transport material into these elongated fractures. This interpretation is further confirmed by X-ray diffraction measurements which indicate the presence of florencite and La-cerite crystals within the fracture fills.

The most likely interpretation is the entrapment of a volatile component during diamond growth, probably dissolved at high pressure within the solid inclusion phases. During uplift of the diamonds and associated pressure release this volatile content is expelled from the solid inclusion as a fluid and penetrates into the newly forming fractures.

Sulfide minerals in mantle xenoliths from Cretaceous lamprophyres of the Carpathian-Pannonian region

Azbej, T.*, Nédli, Zs. & Szabó, Cs.
Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (*tristan@elergeo.hu)

Alkaline basalts, lamprophyres and kimberlites hosted mantle xenoliths are significant sources of information on the composition and physical and chemical processes of the upper mantle. Sulfide minerals are common, but minor phases in upper mantle peridotite and pyroxenite xenoliths. Several papers have reported the textural and compositional features and Os-Re characteristics of sulfides occurring in alkaline basalt and kimberlite hosted xenoliths. However, less attention has been paid for sulfides in mantle xenoliths derived from lamprophyres. It is widely accepted that sulfide minerals in the mantle peridotite xenoliths can provide information on mantle depletion (i.e., melting) and enrichment events (i.e., metasomatism). Sulfide inclusions in the pyroxenite xenoliths, however, can contribute to our knowledge on crystallization processes and related metasomatism in the deep lithospheric mantle.

14 sulfide mineral bearing peridotite mantle xenoliths have been selected for detailed petrographic and geochemical study from two Cretaceous lamprophyre occurrences in the Carpathian-Pannonian Basin: NE Transdanubian Central Range (TCR, Hungary) [1] and Poiana Rusca Mts. (PRM, Transylvania, Romania) [2]. Based on textural and geochemical features of the lamprophyre hosted xenoliths, they represent highly depleted mantle portions, however, the TCR xenoliths went through previously significant mantle metasomatism as their minor phlogopite modes, with high mg-number, clearly indicate.

According to mineral petrography, two kinds of sulfide assemblages can be distinguished: 1) sulfide blebs enclosed in mantle silicates and 2) interstitial sulfides at the grain boundaries of the rock-forming minerals. In the TCR xenoliths the interstitial sulfides are predominated, whereas they can be observed very rarely in the PRM xenoliths. The single sulfide blebs consist of pentlandite, pyrrhonite, chalcopyrite, and rarely millerite and violarite in the TCR xenoliths, however millerite and violarite never have been observed in the PRM xenoliths. The TCR xenoliths are characterized by high variation of the sulfide minerals in modes, and pentlandite is always present with wide compositional range (Ni content up to 39.4 m/m%) and moderate Co content (up to 1,47 m/m%). The PRM xenoliths show much less variation in modes and no significant compositional variation of pentlandite (Ni up to 34.0 m/m%, Co up to 0.46 m/m%).

Bulk sulfide compositions, calculated by mass balance calculation, in the TCR xenoliths show extremely high variance and overlap with the compositional field of monosulfide solid solution (MSS) at 900 °C [3]. On the other hand, bulk sulfide compositions in the PRM xenoliths overlap the narrower MSS composition at 1000 °C [3]. It is highly interesting that both sulfide compositions indicate enrichment in Cu corresponding to increase in Ni content (or decrease of Fe content) which may be related to ancient fertilization process in the mantle during pre-Cretaceous times.

Genesis of the Hanle Rhyolite in comparison to the Ladakh granitoid batholith based on petrographic, geochemical and fluid inclusion studies (Ladakh Himalayas, India)

Bodor, B.[1*], Sachan, H.K.[2] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (*szurkevolvo@gmail.com)
[2]Wadia Institute of Himalayan Geology, Dehra Dun, India

Previously unknown rhyolite occurrences were found in the southern part of the Ladakh batholith near Hanle (Ladakh Himalayas, India). The Ladakh batholith is built up by intrusive bodies of granodiorite and granite. These are parts of the Trans-Himalayan batholith range which is the product of Andean-type calc-alkaline igneous activity resulting from the northward subduction of the Neo-Tethyan oceanic crust. There is only little direct evidence for the existence of extrusive rocks along the Ladakh batholith. However, rhyolite occurrences near Hanle can be one of these remnants along with the Teah and Deskhit volcanics NW of Leh.

The Hanle Rhyolite has spherulitic texture with phenocrysts of quartz, plagioclase and alteration products after mafic minerals like biotite and probably amphibole. Quartz grains contain significant amount of multiple generation fluid inclusions. Plagioclase is largely altered into clay minerals, sericite and calcite. Relics of biotite exist but they are highly altered to chlorite. The groundmass is entirely devitrified, thin laths of quartz, K-feldspar and plagioclase form the characteristic spherulitic texture.

Major element geochemistry and, principally, distribution of rare earth elements were used to describe the relation between the Hanle Rhyolite and surrounding granitoid rocks. Harker variation diagrams show that the Hanle Rhyolite fits in the evolution trend of plutonic rocks of the Ladakh batholith. It is also very close in composition to the older Dras volcanics. Rare earth element patterns also show a very close connection between plutonic rocks and the Hanle Rhyolite.

Fluid inclusion studies identified at least three different types of inclusions: 1) primary CO_2 inclusions, 2) primary, two-phase H_2O-NaCl inclusions with low salinity (max. 5 NaCl eq. wt%), and 3) secondary, two-phase H_2O-NaCl inclusions with lower salinity (1-3 NaCl eq. wt%). Secondary inclusions were also found in the granite and these may be interpreted as a common feature in the late evolution of the two rocks. Primary inclusions were found in quartz grains of the rhyolite. Co-exiting CO_2 and H_2O-NaCl inclusions suggest that the crystallization of quartz in the rhyolite took place under immiscible CO_2-H_2O conditions.

Results from geochemical data suggest that the Hanle Rhyolite was probably cogenetic with the major phases of the granodiorite intrusions and it is less likely to represent later remelting of the underlying intrusive bodies.

Zoning of copper mineralization away from an igneous heat source at Allihies, Co. Cork, Ireland: mineral and fluid inclusion evidence

Costanzo, A.*, Moore, K.R. & Feely, M.
School of Natural Sciences, Earth and Ocean Sciences, National University of Ireland Galway, Ireland
(*alessandra.costanzo@nuigalway.ie)

Lower Palaeozoic sedimentary rocks in the southwest of Ireland are cut by copper-rich vein mineralization at Allihies, an old mining village located on the western tip of the Béara Peninsula in County Cork, Ireland. Samples from metal-bearing veins at two 19th century mines (the northerly Mountain Mine and the southerly Caminches Mine) were studied in order to investigate whether there is any relationship between igneous activity elsewhere on the Beara Peninsula and the Allihies mineralization.

The primary ore mineral assemblage comprises copper, iron and molybdenum sulphides and oxides including chalcopyrite, pyrite, bornite, tetrahedrite, hematite (var. specularite), molybdenite, and chalcocite. The oxide minerals are more common at the southern Caminches Mine than the northerly Mountain Mine. The secondary mineral assemblage comprises copper, iron and molybdenum carbonates and oxides such as malachite, covelline, goethite and limonite. The main gangue mineral is quartz, which is accompanied by carbonate minerals: typically rhodochrosite in the northerly mineralization and calcite in the southerly mineralization. Thus it appears that mineralization to the north may have formed in a higher temperature, more reduced system than that to the south.

In quartz veins containing ore minerals, a large number of fluid inclusions (FI) are hosted within quartz crystals, particularly those crystals in proximity to sulphide minerals. Large (up to 80 μm in length), primary, two-phase fluid inclusions are the most abundant and are most commonly distributed along linear planes within the crystals or along crystal rims. Solid-rich fluid inclusions generally contain only one solid phase and are also considered to be primary. Microthermometric studies of primary FIs show that the temperature of homogenization (T_H) is significantly higher (mean T_H = 256°C; maximum T_H = 398°C) for the northerly mineralization than for the southerly mineralization (mean T_H = 187°C). Likewise, fluid salinity is higher for the northerly mineralization (mean = 17.28 eq.wt.% NaCl; maximum = 22.2 eq.wt.%NaCl) than for the southerly mineralization (mean salinity = 14.8 eq.wt.%NaCl). Microthermometric data also reveal a compositional difference in the fluid species between the mines: Na^+ and K+ are the dominant phases, and Fe^{2+} and Mg^{2+} are minor phases at both mines, but Ca^{2+} is present only in the southerly mineralizing fluids.

The fluids that formed the Allihies mineralization reach significantly higher homogenization temperatures and salinities, particularly in the north, than fluids that formed the regional Irish-type mineralization trend (homogenization temperature = 150-200°C, salinity = 13-20 eq.wt.% NaCl; [1]). Thus an additional local energy source is required to drive the mineralization at Allihies (with decreasing temperature and increasing oxidation from north to south), with potentially more saline fluids. Field investigations have identified an area of large mafic igneous intrusions (with some evidence of hydrothermal alteration) 3.5 km to the northwest of the Allihies Area, with smaller related intrusions close to the northern mine. This area is now a target for ongoing investigations as a potential source of heat and fluid.

Fracture filling minerals in the Baksa Gneiss Complex (Hungary): indicators of paleofluid migration

Fintor, K.*, Tóth, T.M. & Schubert, F.
Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Hungary (*efkrisz@gmail.com)

Ca-Al silicate dominant veins with characteristic paragenetic mineral sequence (di→ep→sph→ab+kfp→chl1→prh±adu→ chl2→chl3→pyr→cal1→cal2→cal3) can be found frequently in the Baksa Gneiss Complex, which forms a part of the crystalline basement of SW Pannonian Basin. Detailed petrographical, mineral chemical and fluid inclusion analysis of the vein filling minerals can reveal traces of ancient fluid migrations along fracture network of the Baksa Complex. The high calcic vein filling diopside contains numerous primary fluid inclusions exhibiting T_h: 276-362°C, and 0.7 - 2.9 *w*NaCl eq. % salinity. Subsequent epidote phase often shows growth zonation pattern with Al-rich cores and Fe-rich rims (Fig. 1a), but irregular patchy zonation also frequently occurs (Fig. 1b), which refers to retrograde dissolution-precipitation processes.

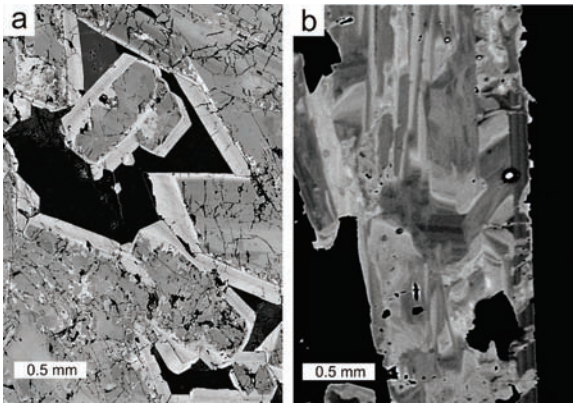

Fig. 1: a) epidote crystals with Fe-rich rims; b) irregularly zoned epidote single crystal.

Primary fluid inclusions of epidote show similar salinity (0.2-1.6 *w*NaCl eq. %) to the case in diopside but a broader range in T_h (181-359°C) values is observable. Textural patterns of albite+kfeldspar vein filling assemblage indicate cogenetic crystallization of these phases. Precipitation temperatures of the alkali feldspars (~$Or_{1.0}$ $Ab_{99.0}An_{0.0}$ and ~$Or_{99.0}Ab_{1.0}An_{0.0}$, respectively) are ~260±40°C by two feldspar thermometers [1]. Both feldspar phases show reddish-brown turbidity and contain several sub-micrometer size cavities. This special habit denotes infiltration of fluid subsequently the precipitation of feldspar. Three different chlorites can be distinguished in the veins, based on morphology and chemical composition. Decreasing Al^{IV} content of the chlorites is detectable in individual grains from core to rim, which refers to temperature decrease during chlorite crystallization. Values of chlorite thermometry [2] (T_{chl1}: 260±32°C→T_{chl2}: 222±20°C→T_{chl3}: 156±10°C) support this assumption. Sporadic pyrite crystals occur after chlorite and its composition indicate considerable amount of As, Co, Ni, Cu, Zn, and Mn in the pyrite grains. Co/Ni ratio (Co/Ni~1-5) of the pyrite grains refers to post-magmatic hydrothermal origin of this ore phase. In case of calcites, the calculated stable $\delta^{18}O$ isotope signature of water from which cal1 precipitated (-4 to -12.9‰ $\delta^{18}O$ V-SMOW) together with microthermometric results of primary fluid inclusion of cal1 indicate that this carbonate phase had to precipitated from downward-penetrating high salinity fluid.

Silicate melt and fluid inclusions in olivine phenocryst from the Gătaia lamproite (Banat, Romania)

Káldos, R.[1*], Seghedi, I.[2] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]rekakaldos@gmail.com)
[2]Institute of Geodynamics, Bucharest, Romania

Study of the approximately 1.3 Ma old Gătaia lamproite (Banat, Romania) [1] revealed that olivine phenocrysts contain large number of silicate melt, fluid and spinel inclusions in different textural positions. Presence of silicate melt inclusions and fluid inclusions in olivine phenocryst provide a unique opportunity to reconstruct stages in evolution of magma during crystallization.

Based on a detailed optical microscopic study on olivine phenocrysts, apart from the spinel, inclusions can be divided into two groups: 1) primary silicate melt inclusions and 2) coeval and coexistence secondary silicate melt and fluid inclusions based on Roedder's classification [2].

Considering that the first crystallized phase in the lamproite is olivine, therefore the primary silicate melt inclusions in the olivine phenocrysts reflect the early evolution stage of the lamproite magma. The primary silicate melt inclusions are 10 to 25 μm in size, rounded or oval in shapes, and contain clinopyroxene daughter phase, glass and one-phase bubble. The secondary silicate melt inclusions are 5 to 10 μm in size, spherical, multi-phased (daughter mineral, glass, two-phase bubble) and occur together with the secondary one- or two-phased fluid inclusions along healed fractures running across the host olivine phenocrysts.

According to the high-temperature homogenization experiments, apart from homogenization of the bubble, we observed the homogenization temperature of the primary silicate melt inclusions between 1140 and 1150 °C, which could be a minimum crystallization temperature of the olivine phenocryst and spinel inclusions. By low-temperature microthermometry measurements we recognized CO_2 as the dominant component in the bubble of the secondary silicate melt inclusions, as well as in the secondary fluid inclusions. In contrast, bubbles in the primary silicate inclusions were empty or consisted of extremely low density gas. Raman microspectroscopic analysis of the bubbles in the secondary silicate melt inclusions and the fluid inclusions detected the presence of CO, N_2 and CH_4 next to CO_2 at room temperature.

The homogenization temperatures of the bubbles of the secondary silicate melt inclusions and the secondary fluid inclusions are corresponding to the fluid densities. Applying the determined densities and the widely accepted Duan-equation [3], a minimum trapping pressure of 5-6 kbar of the coexistence secondary silicate melt inclusions and fluid inclusions can be estimated at the time of entrapment. This pressure value may represent the conditions of a magma chamber (or conduit) in the middle crust. The emplacement and the composition of the secondary silicate melt inclusions and fluid inclusions in olivine phenocrysts indicate that, besides the crystallized minerals (i.e., olivine and spinel), two different fluid phases were present, a silicate melt and a CO_2 rich volatile that formed by a melt-volatile immiscibility at the time of entrapment of the secondary inclusions in the olivine phenocrysts.

The immiscibility of water-salt fluids determined by synthetic fluid inclusions study

Kotelnikova, Z.[1*] & Kotelnikov, A.[2]
[1]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry of RAS, Moscow, Russia ([*]kotelnik@igem.ru)
[2]Institute of Experimental Mineralogy of RAS, Chernogolovka, Russia

Salt of the P-Q type (NaF, Na_2SO_4, Na_2CO_3) have inverse solubility dependence on temperature: it is about zero under 374°C. In such systems critical phenomena are observed in saturated solutions.

In order to obtain experimental evidence on salt-containing fluids, inclusions of solutions containing NaF, Na_2SO_4, Na_2CO_3 were synthesised at 300–800°C and P=0.5–3 kb by craks healing method.

The obtained results show that under t>500°C and P≥1 kbar the active interaction of fluid with quartz began, leading to formation of hydrosilicates. The interaction leads to increasing of quartz imaginary solubility.

An investigation of fluid inclusions showed that two liquids (contrary to vapor + liquid) coexist within the upper two-phase field of the phase diagramme.

In H_2O–salt (P-Q type)–SiO_2 ternary system, equilibria $V+L_1+L_2+S_1$ or $V+L_1+L_2+S_2$ are possible, absent in binary systems. In critical points of ternary system minimum temperature and pressure for critical equilibria correspond to $L_{1=}L_2+V+S_1$ and $L_{1=}L_2+V+S_2$, and not to the Q point with $L_{1=}L_2+S_{salt}+S_{SiO2}$ equilibrium.

During some fluid inclusion's heating at temperature 250ºC the liquid immiscibility took place.

The second liquid phase has appeared in saturated and unsaturated solutions and in "heavy fluid". Two salt solutions and vapor were coexistent in one inclusion at the temperature interval 250–400ºC. In multi component fluid-silica systems the possibility of equilibrium of not only two, but three, four and even more immiscible phases may occur.

At the intersection of two critical curves with vapor-liquid and liquid1-liquid2 equilibria non-variant equilibrium does not appear and transition of one critical equilibrium into another occur gradually. Therefore one can not talk about phase boundaries in this case. Apparently, this is a peculiarity of the studied system's phase diagram.

The interaction of fluid with quartz can be even more clearly seen in experiments at higher pressures and temperatures. In an experiment at 800ºC and 3 kbar, glass was observed in some inclusions together with vapor, liquid, and crystals. During heating of this inclusion, unmixing was observed in the glass phase. The ternary system water-salt-quartz includes a field of stable liquid immiscibility.

The obtained results suggest, first and foremost, that modeling of silicate-fluid systems on the basis of phase diagrams of simple binary water-salt systems may be misleading, because such a simplification implies that the sequence of phase transformations occurring in binary systems must be identical to that in the case of multicomponent equilibria.

Comparison in melt composition of two volcanoes (Hegyestű and Haláp) from the Bakony-Balaton Highland Volcanic Field (Hungary) based on primary silicate melt inclusion study

Kóthay, K.[1*], Szabó, Cs.[1] & Sharygin, V.V.[2]
[1]Lithosphere Fluid Research Lab, Dept. of Petrology and Geochemistry, Eötvös L. University, Budapest, Hungary ([*]klara.kothay@t-online.hu)
[2]Institute of Mineralogy and Petrology, UIGGM, Novosibirsk, Russia

Two volcanoes were selected in the Bakony-Balaton Highland Volcanic Field (Hungary) with different ages and slightly different modal and major and trace element features to compare original chemical composition of their magmas, based on bulk composition of olivine phenocryst hosted primary silicate melt inclusions (SMI).

The bulk compositions of the primary multiphase SMIs and crystallization sequences of the melt in the SMIs determined by homogenization experiments, furnace technique and microthermometry and Raman microspectroscopy of the fluid phases show characteristic differences, besides the similarities, between melts of the two volcanoes (Fig. 1).

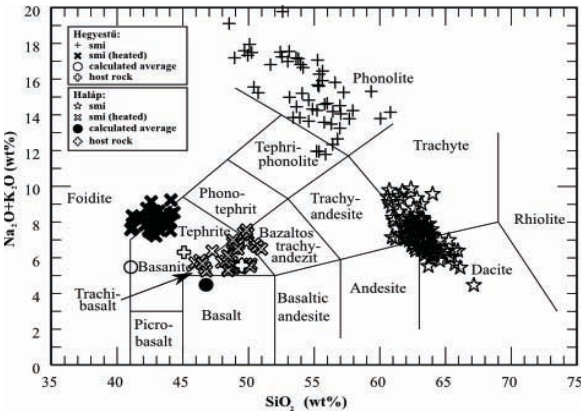

Fig. 1: TAS diagram comparing the calculated and measured bulk chemical compositions of silicate melt inclusions (SMI) and glass compositions of unheated SMI's in olivine phenocrysts of Hegyestű and Haláp volcanoes.

Bulk composition of SMIs from Hegyestű derived from a more alkaline mafic melt than that of Haláp (Fig. 1). Furthermore, with lower FeO and MgO and higher TiO_2, Al_2O_3 and CaO contents the Hegyestű melt clearly differs from the bulk composition of SMIs from the Haláp volcano. However, both melts are relatively volatile-rich, the CO_2 content of the Hegyestű melt is 2 m/m% and that of Haláp is ~1.5 m/m%.

The evolution of the magma droplets entrapped in olivine phenocrysts can be characterized at both localities by sulfide-silicate immiscibility as well as partially crystallization of daughter minerals at magma chamber level. The solidification continued and CO_2 separation from the silicate melt happened particularly at conduit level. This process in the Hegyestű SMIs follows a definite trend: sulfide bleb→ Al -spinel → rhönite → Ti-augite → apatite±rutile±ilmenite → CO_2 + glass. In contrast, the Haláp SMIs show a more variable chemical composition (Fig. 1) suggesting a more heterogeneous melt system. During their solidification they formed the following crystallization sequence: Al-rich spinel + sulfide bleb→ rhönite + amphibole + clinopyroxene → apatite + ilmenite → CO_2 + glass. The non-crystallized, highly silicic melt quenched as glass with high Na and/or K content, whereas the considerable CO_2 content occur separated as bubbles among the daughter minerals in both magmas.

Characterization of alteration, mineralization and fluid properties associated with the porphyry copper - high sulfidation epithermal transition at Red Mountain, AZ, USA

Lecumberri Sanchez, P.[1*], Bodnar, R.J. [1] & Kamilli, R.[2]
[1]Dept. of Geosciences, Virginia Polytechnic Institute and State University, Blacksburg, USA ([*]pilar@vt.edu)
[2]Western Mineral and Environmental Resources Science Center, US Geological Survey, USA

The porphyry copper deposits (PCD) in the southwestern US show variable degrees of erosion due to the complex structural evolution of the region. Frequently, the upper part of the systems is no longer present, which has limited the study of the geochemical evolution of the lithocap region of PCDs. The objective of this study is to characterize the relationships between mineralization, alteration and physicochemical properties of fluids in time and space in the lithocap, and Red Mountain has an exceptionally well-preserved lithocap, making it an ideal system to study.

The Red Mountain PCD constitutes a caldera-type subsidence structure where the dominant lithologies are andesite evolving in time toward trachyte-latite and later quartz-monzonite [1]. Three distinct mineralized regions are identified. The two primary mineralization zones are an upper, low Cu grade enargite zone associated with phyllic and pyritic-argillic alteration and a relatively higher Cu grade chalcopyrite mineralized zone associated with potassic and weak potassic alteration. The secondary mineralization is a chalcocite enrichment blanket. The enargite zone is characterized by an inner region with quartz-pyrite veins that shows sericitic halos and an outer region where quartz veins are less frequent and disseminated pyrite is abundant. The chalcopyrite zone shows abundant quartz and anhydrite veins with secondary biotite and orthoclase as well as disseminated magnetite around the veins. Small amounts of bornite are typically found in the chalcopyrite zone. The secondary chalcocite blanket is located within the enargite zone and it has been proposed that the source of copper for this enrichment zone is likely the enargite. Some of the common minerals within this region are chalcocite, covellite, pyrite, enargite and less abundant bornite and chalcopyrite.

Deposits with similar characteristics have been described at El Salvador, Chile; Sunnyside, Colorado; Lepanto-Far Southeast, The Phillipines; Recsk, Hungary. It is considered that the low grade enargite zone constitutes a high sulfidation epithermal system that is genetically related to a deeper PCD system. The presence of the deeper porphyritic part of the system related to the shallower high sulfidation epithermal system provides information about the genetic relationship between them. In this context, it is observed that the fluid inclusions (FI) in the deeper parts of the system (related to the potassic and weak potassic alteration zones) are mainly vapor-rich at room temperature (B35-B60) [2] and contain chalcopyrite daughter minerals, and halite-bearing FI with lower vapor-liquid ratio at room temperature (B15H) that frequently contain sylvite, chalcopyrite and anhydrite daughter minerals. These FI indicate that the deeper fluids are high-salinity, high-Cu. It is also observed that in the shallower parts of the system the abundance of FI with halite and chalcopyrite daughter minerals decreases, which indicates a decrease in salinity and Cu content in the fluids toward the shallower parts of the system. This change in fluid composition, mineralization and alteration characterizes the transition from a deep PCD system to a high sulfidation epithermal system

[1] Corn, R.M. (1975) *Econ. Geol.*, **70**, 1437-1447. [2] Rusk, B.G. et al. (2008) *Econ. Geol.*, **103**, 307-334

Fluid inclusion study on the barite-calcite veins of the Boda Aleurolite Formation (Mecsek Mts., Hungary)

Lenti, F.[*], Azbej, T., Németh, B. & Szabó, Cs.
Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]lentifruzsi@gmail.com)

The main aim of our study was to constrain the formation conditions of barite-calcite hydrothermal veins in the Boda Aleurolite Formation (Mecsek Mts., Hungary). Based on preliminary studies, the Boda Aleurolite, deposited under arid climate in a Permian lake [1], is thought to be the best candidate in Hungary for high level nuclear waste disposal [2]. The studied rock samples originate from the so-called ALPHA-1 prospect tunnel from depth of 1050 m, which was made to carry out in situ physical and chemical experiments and measurements on the aleurolite rocks.

To our study we collected the mostly veined aleurolite samples to better understand the mechanism of fracture filling, as well as to study fluid inclusions in the veins. Based on petrographic observations, an older and a younger fracture filling event can be distinguished. The earlier phase resulted in formation of barite, whereas during the later event crystallization of carbonate (calcite and dolomite) took place in the vein.

Primary fluid inclusions can be recognized in both barite and carbonates minerals. Barites contain tiny (<3 μm), two-phase, negative crystal-shaped fluid inclusions, whereas primary fluid inclusions in calcites also have two phases in room temperature and irregular shapes in sizes of 7-8 μm. We have also observed secondary fluid inclusions in calcites along healed fractures, however their small size (<3 μm) did not permit additional study on them.

Results of microthermometric measurements indicate that the fluid inclusions entrapped a low-salinity (3.2 to 4.3 m/m% NaCl) aqueous solution. This compositional range is characteristic of all identified fluid inclusion assemblages in the calcite veins of the studied sample. The similarity of trapped fluids may suggest that the hydrothermal parent fluid did not evolve significantly during the crystallization of the carbonates. The homogenization temperatures (minimum temperature of entrapment) measured in the inclusions fall between 105 and 107 °C. Based on microthermometric data and geobarometric assumptions, we have estimated the maximum of the formation temperature range at 177 °C.

The presence of the secondary fluid inclusions in calcite suggests past fracture renewal events in the veins. Considering that the fractures have had completely healed and that the volumetric portion and size (3-8 μm) of the fluid inclusions is insignificant compared to the solid hydrothermal phases, it can be suggested that the studied veins do not represent weakness zones or impose threat on safe radioactive waste storage.

[1] Árkai, P. et al. (2000) *Ac. Geol. Hung.*, **43**, 351-378. [2] Bárdossy, Gy. (1995) *Magy. Tudomány*, **8**, 935-942.

Traces of primary hydrocarbon migration in the outcrop of the fractured Jurassic Hosszúhetény Calcareous Marl Formation (SW Hungary)

Lukoczki, G.[1,2*] & Schubert, F.[2]
[1]Dept. of Geology, University of Pécs, Hungary ([*]lukoczki@gamma.ttk.pte.hu)
[2]Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Hungary

Latest researches revealed that certain part of the Hosszúhetény Calcareous Marl Formation (HCMF) contains mature organic matter [1]. Numerous calcite veins have been discovered in an outcrop of the HCMF near Pécsvárad (SW Hungary), which have an odour of bitumen, caused by petroleum inclusions. It proves that in the past the fracture system acted as a migration pathway for petroleum-bearing fluids.

The aims of the study were to determine the type of the organic matter in the marl and its maturation stage to verify whether the HCMF could serve as a source rock of the oil, which was trapped in fluid inclusions (FIs) of the vein filling calcite, as well as to study the inclusion fluids.

The relative ratio of the three main maceral types (liptinite, vitrinite, inertinite) was determined by visual kerogen analysis. The organic matter in the HCMF is composed mainly of liptinite of marine origin, but there are also vitrinite and ineritinite of terrestrial origin, therefore it can be established that the accumulation of the HCMF took place in a marine environment, which was relatively proximal to land.

The results obtained by vitrinite reflectance measurements (Ro%=0.688 and 0.791) and Rock-Eval Pyrolysis (RE) [1] show that the maturation state of the organic matter in the marl reached the oil window and oil has been generated. The studied part of HCMF was heated to a temperature of 106-117 °C at its deepest buried state, which was evaluated by the Vitrinite Reflectance Geothermometry (VRG) method [2].

Six pure calcite veins with different textural habits were distinguished in the studied outcrop. Two basic fluid inclusion assemblages (FIAs) were found in the calcites, which were suitable for microthermometry. Under UV-excitation numerous secondary FIs show an intense fluorescence referring to a hydrocarbon-bearing fluid infill. Visually three different fluorescence colours could be determined (yellowish blue, light blue and vivid blue). Nevertheless, the UV-fluorescence microspectroscopy does not show any difference between FIAs of yellowish blue and light blue fluorescence colours.

The temperature of the hydrocarbon-bearing fluid migration falls between 65 and 110 °C, which was evaluated using the homogenisation temperature (T_h) of the co-genetic aqueous fluid inclusions [3]. There are no significant differences in the T_h of the FIAs with different fluorescence colour. Thus microscale fractionation of the original hydrocarbon fluid during trapping could be responsible for the different fluorescence colours [4], therefore we suppose that they originate from the same hydrocarbon fluid.

Since the marl contains type II-III kerogen in sufficient amount for oil generation and it reached the oil window during the subsidence, it is likely that the HCMF has been the source rock of the hydrocarbon fluid trapped in petroleum inclusions. Biological marker analysis of the organic matter extract of the marl and the petroleum inclusion fluid would be necessary to make exact oil-source rock correlation.

Study of felsic granulite xenoliths from the Pannonian Basin

Németh, B.[1*], Koller, F.[2], Török, K.[3], Dégi, J.[1,4] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Dept. of Petrology and Geochemistry, Institute of Geography and Earth Sciences, Eötvös University, Budapest, Hungary ([*]bianca.nemeth@gmail.com)
[2]Dept. for Lithospheric Research, University of Vienna, Austria
[3]Eötvös Loránd Geophysical Institute of Hungary, Budapest, Hungary
[4]Metals Research Dept., Research Institute for Solid State Physics and Optics, Hungarian Academy of Sciences, Budapest, Hungary

The Pannonian Basin is well known due to its ultramafic mafic and felsic xenoliths hosted in late Tertiary alkaline basalts, where rock fragments from different depths of the lithosphere were studied. In this work we present petrography, mineral chemistry, geothermobarometry and fluid inclusion study of mid-crustal felsic granulite xenoliths from Beistein (Styrian Basin, SBVF) and compare the results to other xenoliths of similar origin from the Bakony-Balaton Highland Volcanic Field (BBHVF). Based on our studies, the felsic granulite xenoliths went through at least three evolutional stages. The characteristic mineral assemblage of the felsic granulites consists of Pl + Opx + Qtz ± Cpx ± Bt ± Grt ± Ksp. The accessories are: Zrn + Ilm + Mag + Ttn + Gr + Rt. The samples have granoblastic texture, but in several cases relic poikilitic microtexture was also observed. These textural features refer to a silicic magmatic precursor rock, which intruded into the middle crust. The cooling of the igneous body resulted in antiperthitic exsolution of former high temperature ternary feldspars. Another cooling and crystallization gave rise to formation of a felsic granulite. According to the data of mineral equilibrium and geothermobarometry, the studied xenoliths from Beistein were in equilibrium in the middle crust, in depth of about 20-28km similarly to those from the BBHVF. The first fluid invasion and entrapment was coeval with the emplacement and crystallization of the magmatic body at middle crustal level as it is witnessed by primary pure CO_2 inclusions in the relic magmatic minerals, like apatite and zircon. The second evolutionary stage of the magmatic body was connected to partial melting of biotite-bearing assemblages occurred in association with the trapping of CO_2 rich fluid. Biotite is found either in the rock matrix partially molten and surrounded with melt or as remnants in orthopyroxene. This second fluid event also resulted in primary fluid inclusions in the main rock-forming minerals such as Pl, Qtz and pyroxenes. The majority of the fluid is CO_2 and the presence of additional N_2, H_2S and CO was identified by Raman spectroscopy. This event happened in the lower crust and could be connected to partial melting of biotite-bearing assemblages in the granulite facies. The third step was the sampling the magmatic body by the basaltic melt, and then uplift of the xenoliths to the surface, which caused a temperature increase and a pressure decrease, thus, limited melting of the xenoliths. All xenoliths contain different amounts of melt patches with associated secondary fluid inclusions. This later generation of secondary fluid inclusions was mostly observed in the felsic minerals and the fluids could be associated with the host basalt, with the compound of mostly CO_2, but there are also presented N_2, H_2S and CO, as well.

Fluid inclusion study of upper mantle xenoliths from the Cameroon Volcanic Line

Pintér, Zs.[1*], Tene Djoukam, J.F.[2], Tchouankoue, J.P.[2] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]zsanett.pinter.hu@gmail.com)
[2]Dept. of Earth Sciences, University of Yaoundé I., Yaounde, Cameroon

We have studied upper mantle xenoliths from alkali basalts outcropped at Nyos and Barombi Lakes, which are situated along the Cameroon Volcanic Line. The main aim of this study is to find out whether upper mantle, containing plenty fluid inclusions, can be a potential source of the CO_2 that erupted from the Nyos Lake and killed about 2000 people and animals in 1986. Based on the results of previous study [1], the CO_2 gasses in the crater lake waters can be derived from the a degassing mantle. The studied peridotite xenoliths are spinel lherzolites (with protogranular and porphyroclastic texture) show similar lithology and mineral chemistry to the other xenoliths from the continental sector along the Cameroon Volcanic Line, and also to the average subcontinental lithospheric mantle.

Two generation of fluid inclusions can be distinguished in the Cameroon peridotitic xenoliths studied: an older and a younger one. The older generation fluid inclusions occur randomly in olivine and orthopyroxene in the Nyos peridotites. Fluid inclusions in this population have negative crystal shape with 50-80 μm average size and they are partly or completely decrepitated. The younger generations of fluid inclusions occur in all mantle silicates from both Barombi and Nyos xenoliths. They are trapped along healed fractures; however, they can also be seen in the neighborhood of the older decrepitated inclusions, in case of Nyos peridotites with size of 8-15 μm. Microthermometric measurements were carried out on this population of fluid inclusions. In these fluid inclusions for both Barombi and Nyos peridotites similar last melting temperatures were observed. In the Barombi xenoliths melting temperature is in the range of -57.9 and -56.6 °C, and in the Nyos samples it shows a very close range between -58.1 and -56.6 °C. The negative shift from the triple point of CO_2 (-56.6 °C) suggests presence of minor amount of other apolar component(s), for instance CH_4 and N_2 or H_2S [2] besides the common and major CO_2. Based on the density of CO_2 inclusions in pyroxenes, the estimated minimum trapping pressure conditions are between 8.4-9.8 kbar.

Raman microspectroscopy at room temperature indicates that beside the CO_2 a small amount of H_2S also occurs in some younger generation inclusions. This is in good accordance with the results of the observed low melting temperatures. Raman spectroscopy also reveals the presence of liquid H_2O as dissolved component in the CO_2-rich phase. Solid phases, namely carbonates, in the fluid inclusions were identified under polarized microscope.

Our results suggest that the CO_2 rich fluid inclusions, occurring both in the Barombi and Nyos upper mantle xenoliths, were trapped at lithospheric mantle conditions in the mantle silicates. Our study provides additional information on the composition of mantle fluids that can be indeed a potential source of volcanic hazards along CVL, especially in maar lakes such as Nyos.

Alkalic silica-undersaturated melts formed via interaction of peridotite with chloride-carbonate liquids: an experimental study

Safonov, O.
Institute of Experimental Mineralogy, Chernogolovka, Russia (oleg@iem.ac.ru)

Kamafugitic (SiO_2-undersaturated potassic) melts are believed to originate from peridotite source mixed with phlogopite-pyroxene-carbonate veins produced from the influx of alkalic fluids at 4-6 GPa [1]. Association of kamafugites with carbonatites [2] and fluid/melt inclusions in minerals of these rocks [3,4] suggest that evolution of such melts was accompanied by complex salt liquids enriched in K-Na carbonates and halides, S, P, etc., which are able to provoke liquid immiscibility [4].

In order to demonstrate the role of immiscibility [5] in generation of the kamafugite-like melts, experiments on interaction of a model peridotite $Fo_{63}En_{30}Prp_5Di_2$ with the $CaCO_3$+Na_2CO_3+KCl melt were performed at 1, 2 and 7 GPa. At 7 GPa, chloride-carbonate melt (L_{CC}) coexists with Fo, Grt, and KNCM-phase $(Na,K)_2Ca_4Mg_2Si_4O_{15}$ below 1460°C. Alkalic melt containing 32-34 wt. % of SiO_2, up to 28 wt. % of Na_2O+K_2O and 2-3 wt. % of Cl, immiscible with L_{CC}, appears at 1460°C. At 1-2 GPa such melt forms at 1100-1200°C via melting of the assemblage Fo+Cpx+Kls, generated from reaction of enstatite and pyrope constituents of the starting peridotite with the chloride-carbonate liquid: Prp+2En+[KCl+ Na_2CO_3+$CaCO_3$]=2Kls+7/3Fo+1/3Di+[2NaCl+4/3CO_2]. SiO_2 content of the melt increases (up to 45 wt. %), Cl and K_2O+Na_2O contents decrease (1.2 and ~16 wt. %, respectively) with decreasing pressure. De-carbonation (which is more active at low pressures) of the chloride-carbonate liquid produces CO_2-rich fluid.

Thus, immiscible KCl-rich liquid assists to a strong enrichment of the SiO_2-understurated melts in K_2O. Being formed within metasomatised peridotite in equilibrium with chloride-carbonate liquids, the melts loose Cl [6] during assent through the mantle preserving high K_2O content.

Carbonic and highly saline fluids in Precambrian deep-crustal metamorphism, southern peninsular India

Srikantappa, C.
DOS in Geology, University of Mysore, Manasagangotri, Mysore, India (srikantappa@googlemail.com)

Orthopyroxene bearing granitic - granodioritic - tonalitic, ortho-gneiss and para-gneiss of Precambrian age (3.3 to 2.5 Ga), termed as charnockitic-enderbitic granulites are well exposed in southern Peninsular India. Based on field relationship, petrography, mineral assemblage and geochemistry two major types of granulites are recorded in south India [1]: 1) Massive/banded charnockites (MBC) and 2) Incipient charnockite (IC). The MBC show regional granulite facies metamorphism with P-T (M1): 700 – 730 °C, 6 - 11 kbar. They show ITD and IBC P-T-t trajectories. In contrast, IC localities occur on a local scale, occupying low-land areas, confined to shear zones with mineral P-T (M2): ~ 650 - 700°C, ~ 6 kbar.

Deep-crustal fluids like CO_2, CO_2-H_2O and CO_2-CH_4-N_2 have been recorded in granulites from south India [2,3]. In this paper occurrence of halite bearing, highly saline fluids (up to 35 wt.% NaCl eqv.) coeval with carbonic fluids have been identified in granulites from the Dharwar craton (Fig. 1).

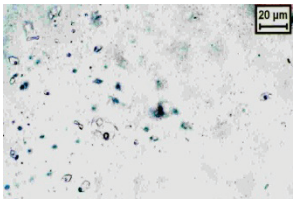

Fig. 1: Halite bearing fluids in south Indian granulites.

Different types of fluids in granulites is dependent on factors like lithology, mineral assemblage, protolith characters (ortho or para) and type of deformation. CO_2 and CO_2-H_2O fluids and, in some instances, hypersaline fluids appears to be the dominant fluids characteristic of massive granulites, derived from igneous precursors in contrast to CO_2, CO_2-CH_4-N_2 and N_2 bearing fluids which are common in granulites derived from sedimentary protoliths. High density CO_2 (1.10 to 1.14 g/cm^3) and CO_2-H_2O inclusions are common in minerals like garnet, plagioclase and quartz in MBC, indicating to their entrapment conditions at deeper crustal levels. High density carbonic inclusions (1.00 to 1.12 g/cc) have been found in many syn-metamorphic basic granulites. Lower density CO_2-fluids (0.90 to 0.95 g/cc) are common in IC. A combined micro-textural, mineral P-T, fluid evolution and the chronology of entrapment of fluids in MBC show synmetamorphic nature of CO_2 fluids [2], which exhibit an initial IBC path, followed by ITD path, suggesting an early collisional event followed by extensional tectonic regime for the evolution of most of these granulites.

The present study has shown occurrence of both high density carbonic and highly saline fluids in granulites from south India. This study brings into light importance of highly saline fluids in Precambrian deep-crustal metamorphism in south India in contrast to the earlier hypothesis of "Carbonic metamorphism" [2,3]. The source for these fluids appears to be the underplated basaltic/alkali basaltic magmas, suggesting addition of mantle derived fluids into lower crust, implying growth of the continental crust vertically. For the formation of incipient charnockites, "fluid release" model [4] has been proposed.

Significance of silicate melt inclusions in olivine and spinel phenocrysts in alkaline basalt from Pohang (South Korea)

Vetlényi, E.[1], Bartucz, D.[1], Németh, B.[1], Yang, K.[2] & Szabó, Cs.[1*]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]cszabo@elte.hu)
[2]Dept. of Geological Sciences, Pusan National University, Busan, South Korea

Silicate melt inclusions generally represent melt composition from at the time of entrapment. Therefore, silicate melt inclusions entrapped in minerals that crystallized at different stages of igneous evolution can preserve the composition of a continuously changing melt. In the approx. 2 million years old alkaline basalt at Pohang (South Korea) large amounts of silicate melt inclusions have been found enclosed in olivine and spinel phenocrysts. These inclusions provide unique opportunity to reconstruct the evolution path of the crystallizing mafic magma.

The studied alkaline basalt has porphyritic texture and contains phenocrysts of olivine (0.3-5.0 mm in size) with forsteritic (mg#=0.85-0.89) composition, Cr-bearing spinel (cr#=0.18-0.25) and anorthite-rich plagioclase. The groundmass also consists of microphenocrysts of olivine, clinopyroxene, spinel, plagioclase and glass.

Silicate melt inclusions as isolated inclusions are enclosed in the core of olivine and spinel phenocrysts. These inclusions usually have rounded or elongate shape with sizes ranging up to 150 microns in diameter. Both olivine-hosted and spinel-hosted silicate melt inclusions contain daughter minerals such as Ni-Fe-rich sulfide blebs, Al-Mg rich spinel, zoned clinopyroxene, and addition Na-K-rich residual glass, and empty bubble (Fig. 1). The composition of clinopyroxene daughter phases shows differences in function of the host minerals: clinopyroxenes of melt inclusions hosted in olivine have higher Ca content than those of spinel host. Hence, a somewhat different evolution of the silicate melt inclusions can be suggested in the different host minerals. Based on the preliminary results obtained from petrographic observations and geochemical analyses on phases of SMI, we assume that the SMI of olivine and spinel phenocrysts were entrapped at the very early stages of the crystallization process and their bulk compositions can be representative for the primary mafic magma.

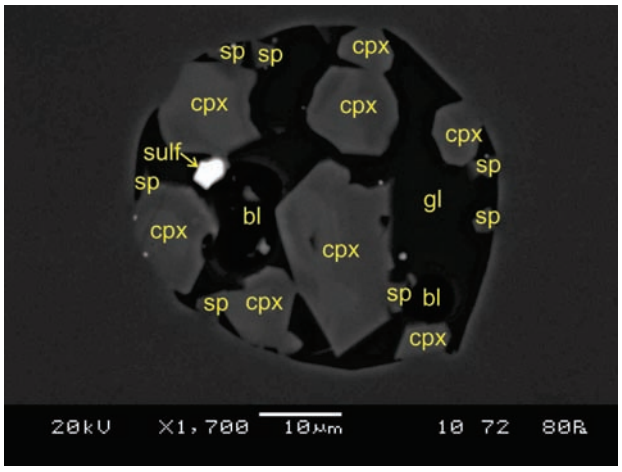

Fig. 1: BSE image of olivine-hosted silicate melt inclusion containing sulfide (sulf), spinel (sp), zoned clinopyroxene (cpx), glass (gl) and bubble (bl).

Deformation and metamorphism in the Mengku iron deposit, Southern Altaides, China: ore textures and fluid inclusions

Xu, J.H.[*], Lin, L.H., Wei, X.F., Shan, L.H., & Chu, H.X.
Resource Engineering Dept., University of Science and Technology, Beijing, China ([*]jiuhuaxu@ces.ustb.edu.cn)

The Mengku iron deposit, located at the south margin of Altaides, occurs in metamorphic volcanic-sedimentary rocks of the lower Devonian Kangbutiebao group. There has been a controversy on genesis of the deposit, such as volcanic-sedimentary, metamorphic and skarn [1-3]. Our research shows that the deposit has experienced a volcanic sedimentary, a metamorphic and a hydrothermal metasomatic mineralizing periods, based on field geology and ore textures (Fig. 1). The regional metamorphic mineralizing period consists of a disseminated-banded magnetite stage and a massive magnetite stage, which is important for iron mineralization. The hydrothermal metasomatic mineralizing period includes a calc-silicate metasomatic stage, a sulfide stage and a calcite-quartz vein stage. The vein copper mineralization is related to hydrothermal metasomatic mineralizing period.

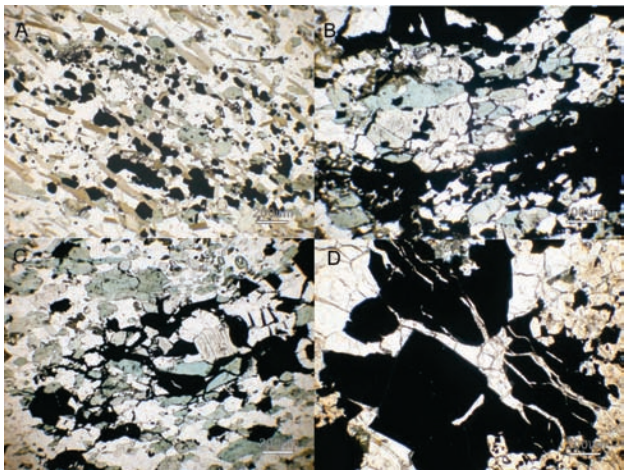

Fig. 1: Microphotos of ore textures of the Mengku iron deposit, Altay:

C- Pressure solution of magnetite in amphibolic leptynite, MK38B;
D- Abnormal heterogeneous garnet interpenetrating magnetite, MK43.

Fluid inclusion study shows that homogenization temperatures of fluid inclusions hosted in metamorphic vein quartz are 133-250°C and 265-337°C respectively, and the salinities are 3.87-10.61 % NaCl eq. The homogenization temperatures of fluid inclusions hosted in hydrothermal metasomatic quartz are 122-207°C and 222-337°C respectively, and the salinities are 22-23.6 % NaCl eq. The $\delta^{18}O$ values of magnetite are -2 ‰~1.28 ‰, which are similar to that of volcanic sedimentary – metamorphic deposits. It could be believed that the Mengku iron deposit was finally enriched during regional metamorphism and hydrothermal metasomatism from Late Devonian to Early Permian.

Group II ultramafic xenoliths from Jeju Island, South Korea: evidence for melt migration and secondary orthopyroxene formation

Yang, K.[1*], Szabó, Cs.[2] & Arai, S.[3]
[1]Dept. of Geological Sciences, Pusan National University, Busan, South Korea ([*]yangkyhe@pusan.ac.kr)
[2]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary
[3]Dept. of Earth Sciences, Kanazawa University, Kanazawa, Japan

Group II xenoliths, corresponding to lithology of wehrlite, olivine clinopyroxenite, olivine websterite and websterite in Pleisto-Holocene basalts from Jeju Island, South Korea, are reported in this study. Jeju Island (75×32 km) is located at the eastern margin of the Eurasian plate surrounded by the SW Japan arc to the east and Okinawa through of the Jeju-Taiwan back-arc system to the south, which is similar to the East Sea back-arc on the eastern part of the Korean peninsula. This area is particular for two distinct magmatism sites such as convergent plate margins where Pacific and Philippine plates are being subducted beneath the Eurasian Plate and divergent tectonic settings where intraplate magmatism is active [1]. The large grain sizes (1–5 mm), moderate mg# of olivines (79-82) and pyroxenes (77-83), and absence of metamorphic textural features indicate that the studied Group II xenoliths have igneous origin. Strikingly similar major element and trace element variations of constituent minerals between the studied in Group II xenoliths and the host basalt suggest that the xenoliths formed as magmatic cumulates crystallized from the host basaltic magma-related system emplaced at the Moho beneath Jeju Island prior to the onset of Pleisto-Holocene volcanic activity. Secondary orthopyroxenes with moderate mg# (77-83) and Cr contents (0.15-0.34 wt%), free of exsolution, are pervasive in the studied Type II xenoliths, having formed by reactions between cumulate olivine and evolved basaltic melt that migrated through solidified crystalline assemblages [2] (Fig. 1). The evolved basaltic melts producing secondary orthopyroxenes resulted from the underplating and fractionation of mafic magma.

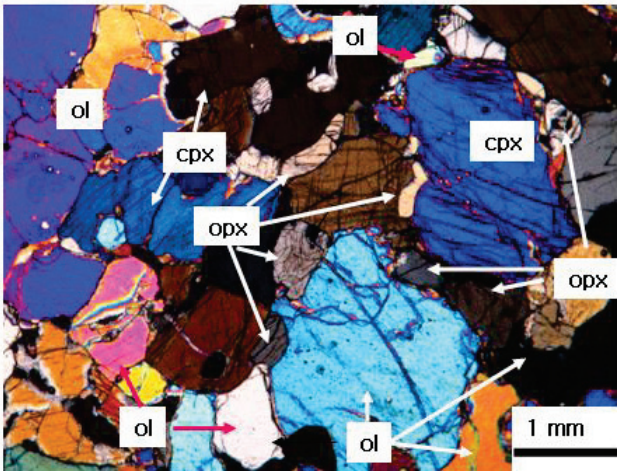

Fig. 1: Photomicrographs of Type II xenoliths from the Jeju Island showing secondary orthopyroxenes associated with olivines. ol=olivine, opx=orthopyroxene, cpx=clinopyroxene.

Fate of subducted continental margins

Cuthbert, S.J.
School of Science, University of the West of Scotland, Paisley, United Kingdom (simon.cuthbert@uws.ac.uk)

Substantial parts of ultra-high pressure (UHP) terrains probably represent subducted passive continental margins (PCM). This contribution reviews and synthesises research on processes operating in such systems and their implication for the wider Earth system. PCM sediments are large repositories of volatiles including hydrates, nitrogen species, carbonates and hydrocarbons. Sediments and upper/ mid-crustal basement are rich in incompatible elements and are fertile for melting. Lower crust may be more mafic and refractory. Juvenile rift-related mafic rocks also have the potential to generate substantial volumes of granitoid melts, especially if they have been hydrated. Exposed UHP terrains demonstrate the return of continental crust from mantle depths, show evidence for substantial fluxes of aqueous fluid, anatexis and, in entrained orogenic peridotites, metasomatism of mantle rocks by crust-derived C-O-H fluids. However, substantial bodies of continental material may never return to the surface as coherent masses of rock, but remain sequestered in the mantle where they melt or become entrained in the deeper mantle circulation. Hence during subduction, PCM's become partitioned by a range of mechanisms. Mechanical partitioning strips away weaker sediment and middle/upper crust, which circulate back up the subduction channel, while denser, stronger transitional pro-crust and lower crust may "stall" near the base of the lithosphere or be irreversibly subducted to join the global mantle circulation. Under certain conditions sediment and upper crustal basement may reach depths for UHPM. Further partitioning takes place by anatexis, which either aids stripping and exhumation of the more melt-prone rock-masses through mechanical softening, or separates melt from residuum so that melt escapes and is accreted to the upper plate leading to "undercrusting", late-orogenic magmatism and further refinement of the crust. Melt that traverses sections of mantle will interact with it causing metasomatism and refertilisation. Partitioning also takes place by solid-fluid and melt-fluid partitioning. Dehydration may take place both during subduction and exhumation, and fluxes between dehydrating and hydrating rock masses influence the internal fluid budget of the orogen (essential for eclogitisation and densification of mafic lithologies). Ascending granitic melts advect dissolved water to shallow levels, or even the atmosphere. Irreversible subduction of PCM sediment carries water plus nitrogen species to the deeper mantle. Decarbonation of voluminous PCM carbonates depends on thermal regime and may release a pulse of CO_2 to the atmosphere, but is limited in colder subduction zones hence transferring large volumes of CO_2 to the deep mantle. This may ultimately be mobilised by melting or dissolution to form fluid media for diamond formation.

Origin and metamorphic evolution of Grt-clinopyroxenite from the Sulu UHP terrane, China: evidence from microstructure and composition of mineral

Zhang, R.Y.[1,3*], Liou, J.G.[1], Xu, H.F.[2], Huberty, J.M.[2], Maki, K.[3] & Jahn, B.-M.[3]
[1]Dept. of Geological & Environmental Sciences, Stanford University, Stanford, CA, USA
[2]Dept. of Geosciences, University of Wisconsin – Madison, Madison, WI, USA
[3]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan
([*]ryzhang@earth.sinica.edu.tw)

The studied Grt-clinopyroxenite is unusual in widespread exsolution textures and transformation of initially coarse-grained mantle-derived rock to a fine-grained ultrahigh-pressure (UHP) metamorphic rock. The Grt-clinopyroxenites (Cpx + Grt + Ilm ± Ol) occur as lenses in a dunite body in the Sulu UHP terrane, eastern China. Two types of clinopyroxenite, Grt-poor (Grt < 5-10vol%) and Grt-rich (10-35vol%), are identified, and both contain rare, nearly initial coarse-grained (1-6 mm) and later recrystallized fine-grained (< 0.4 mm) clinopyroxenites. Some layers show porphyroblastic texture, and a few others contain megacrystic garnet of 2-12 cm in size. Coarse-grained Cpx and Cpx inclusions in megacrystic garnets contain numerous of oriented lamellae of Grt + Ilm/Mag ± Spl ± Amp. AEM and EBSD studies indicate that Ilm, Spl, and Amp lamellae have epitaxial relationship with host Cpx, and $[001]_{Grt}//[001]_{Cpx}$. This suggests that the lamellar phases were produced by solid-state exsolution. Fracture, kink band and wave extinction resulting from deformation are observed in the coarse-grained Cpx. The coarse-grained garnets and garnet inclusions in lamellae-bearing Cpx show that pyrope decrease with increasing grossular components from core ($alm_{16-20}sps_{0-2}prp_{36-54}grs_{22-44}$) to rim ($alm_{12-24}sps_{0-2}prp_{17-38}grs_{39-70}$). Fine-grained Grt in the matrix and Grt lamellae in Cpx are rich in grossular component (44-70%). This is similar to the rims of coarse-grained garnets. The lamellae-bearing Cpx contains Al_2O_3 (1.45-4.20 wt%) higher than matrix Cpx (0.59.6-1.20 wt%). Matrix Grt-Cpx yields P-T estimates of 5.2-6.6 at 850 ± 30 ^oC that lie in a high P/T regime. All the available data indicate that the Grt clinopyroxenite was derived from mantle, and the formation of UHP garnet clinopyroxenite with fine-grained granoblastic texture is attributed to multiple processes including exsolution and recrystallization of primary high-Al Cpx, deformation, and subduction-zone UHP metamorphism.

Polyphase oriented solid inclusions in Ti-rich pyropes from the Bohemian Massif peridotites: possible role of fluids in their origin

Bakun-Czubarow, N.[1*], Dobrzhinetskaya, L.[2], Jung, H.[3] & Kusy, D.[1]
[1]Institute of Geological Sciences, Polish Academy of Sciences, Warszawa, Poland ([*]nbakun@twarda.pan.pl)
[2]Institute of Geophysics and Planetary Physics, University of California at Riverside, CA, USA
[3]School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea

Within the Bohemian Massif there can be found garnet-bearing peridotites which preserved microtextural memory of ultradeep origin – UDO. The peridotites are Mg–Cr pyrope lherzolites, associated with garnet pyroxenite and/or eclogite layers. The rocks under consideration occur either as small boudins within felsic granulites in the Sowie Mountains Block (SMB) of Saxothuringian zone in the Polish West Sudetes, or within migmatitic gneisses of Kutna Hora (KH) complex of Moldanubian zone in Czech Republic. The peridotites in question display inequigranular texture with large (up to 12 mm in diameter) garnet porphyroblasts set in a fine-grained groundmass of olivine, pyroxenes, garnet, clinoamphibole and spinel. Some of the large garnet porhyroblasts have in the cores abundant oriented solid inclusions of rutile, ilmenite-geikielite solid solutions, orthopyroxene, ±clinopyroxene, ±olivine, ±spinel. Among solid inclusions found in cores of garnet porphyroblasts there can be distinguished mono- or two-phase topotaxial exsolutions of Rt, Ilm_{ss}, Opx, Ol precipitated during decompression and located mainly along {111} planes of the host garnets; metasomatic solid inclusions with crichtonite, phlogopite, magnesite, pentlandite as well as mysterious oriented polyphase inclusions with Rt, Ilm, Ol, Sp (Fig. 1). The precursor garnet for rich in topotaxial exsolutions garnet cores was not supersilicic but contained Ti-rich and Al-deficient molecules: $Ca_2Na(AlTi)Si_3O_{12}$ and $M_3(MgTi)Si_3O_{12}$ being indicators of UDO for garnets. On the basis of the results of EBSD studies of rutile needles in garnets from the SMB peridotites [1] the hypothesis can be put forward that decompressional exsolution of rutile needles from Ti-rich majoritic-like garnets was accompanied by simultaneous deformation of the host peridotites.

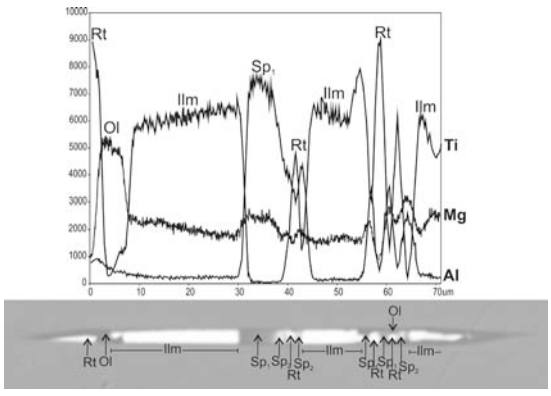

Fig. 1: Polyphase oriented inclusion in garnet core from Kutna Hora peridotite. The inclusion consists of Rt, Ilm, Ol, Sp_1 and Sp_2.

The oriented polyphase inclusions in UDO garnets are most likely the results of fluid interaction with solid phases at the grain boundaries of the previously exsolved inclusion. Further study is being carried to address fluid interaction with solids in nanoscale.

Ultramafic cumulates of oceanic mantle affinity in a continental subduction zone: UHP garnet peridotites from Pohorje (Eastern Alps, Slovenia)

De Hoog, J.C.M.[1,*], Janák, M.[2], Vrabec, M.[3] & Hattori, K.H.[4]
[1]School of Geosciences, The University of Edinburgh, United Kingdom ([*]ceesjan.dehoog@ed.ac.uk)
[2]Geological Institute, Slovak Academy of Sciences, Bratislava, Slovak Republic
[3]Dept. of Geology, University of Ljubljana, Slovenia
[4]Dept. of Earth Sciences, University of Ottawa, Canada

Rare UHP garnet peridotites have been reported from the Slovenska Bistrica Ultramafic Complex (SBUC) in the Pohorje Mts., NE Slovenia, Eastern Alps [1]. The SBUC is a strongly serpentinised remnant of oceanic mantle entrained within lower Central Austroalpine basement units during Eo-alpine intracontinental subduction in the Cretaceous [1,2]. Peak *P-T* conditions of the garnet peridotites reached up to 4 GPa and 900°C [1].

The UHP metamorphic assemblage of the garnet peridotites consists of olivine (Fo 87-90), Mg-rich (Py 65-67) and low-Cr (Cr_2O_3 <0.2 wt.%) garnet and low-Al orthopyroxene and diopside. Remnants of magmatic minerals include Al and Cr-rich Opx and Cpx, Ti-rich chromian spinel, ilmenite and apatite, but their primary compositions are seldom preserved. Low-TiO_2 (<0.3 wt.%) spinel with Cr# 0.1-0.5 is replaced or rimmed by metamorphic garnet, whereas TiO_2-rich spinel with higher Cr# is not. Two types of magmatic clinopyroxene can be recognised: (a) low-Ti (0.5±0.1 wt.% TiO_2) Cpx with LREE-depleted trace-element patterns that strongly resembles Cpx in primitive olivine-rich gabbros from an oceanic spreading ridge [3], and (b) high-Ti cpx (1.4±0.4 wt.% TiO_2) with strongly negative Eu anomalies and less depleted LREE, which indicates crystallisation from more fractionated melts than low-Ti Cpx. Both types of Cpx show strong HREE depletions towards the crystal rims probably due to partial re-equilibration with garnet during meta-morphism. Fine-grained metamorphic Cpx shows the strongest depletions in HREE (Lu_N<0.3) and has very low TiO_2 (<0.1 wt.%) which indicates equilibrium with TiO_2-poor (<0.1 wt.%) metamorphic garnet.

Bulk rock compositions comprise 28-33 wt.% MgO, 7-10 wt.% Al_2O_3, 3-8 wt.% CaO and 0.3-0.8 wt% Na_2O. They show nearly flat and subparallel REE patterns over a range of HREE contents (Lu_N=0.5-3) and commonly have positive Eu anomalies (Eu*/Eu 1.0-2.3). This suggests that the protoliths were olivine-rich gabbros with ca. 60% olivine, 25% An-rich plagioclase and 10% Cpx, and not refertilised mantle, which is supported by their low but fractionated PGE contents (0.1-0.2 ppb Ir, Pd/Ir=5-15). Trace-element patterns are very similar to those of Pohorje zoisite and kyanite eclogites of predominantly MORB affinity.

The geochemistry of the garnet peridotites and their association with the SBUC and eclogites indicates their oceanic lithosphere origin. This implies that ultramafic plagioclase-bearing cumulates, the protoliths of garnet peridotites, were incorporated into the continental crust during subduction and subsequently experienced UHP metamorphism.

Using garnet peridotite as tools to reconstruct paleo-geodynamic settings of fossil continental collision zones

Zhang, Cong[1,2*], Van Roermund, H.[2] & Zhang, Lifei[1]
[1]School of Earth and Space Sciences, Peking University, Beijing, China ([*]zhc@pku.edu.cn)
[2]Dept. of Earth Sciences, Structural Geology and Tectonics, Utrecht University, Utrecht, The Netherlands

Orogenic garnet peridotites (metamorphic rocks containing the characteristic HP garnet-olivine mineral assemblage) exposed in ancient orogenic belts may contain quantitative data regarding formation of subcontinental/subcratonic lithosphere, evolution of a lithospheric mantle wedge, incorporation of garnet peridotite into subducted continental crust, subsequent (ultra)high pressure metamorphism during ongoing continental subduction and final exhumation back to subcrustal levels. Allowing a more systematic way to investigate such variables in nature we propose here a simplified conceptual model that can be used to classify orogenic garnet peridotites. In addition to the "classic" mantle wedge- versus subduction zone garnet peridotites, the model subdivides mantle wedge garnet peridotites into four subtypes, called type A, B, C and D, equivalent to young/hot/dynamic- versus cold/old/static mantle in thick or thin garnet-olivine bearing mantle wedges.

We have chosen three well studied orogenic belts in Scandinavia (Scandinavian Caledonides) and China (Sulu-Dabie and North Qaidam orogen) to illustrate the applicability of the model. For garnet peridotites of the Scandinavian Caledonides, our conceptual model seems to fit well with geological observations and petrological, mineral-chemical and isotope characteristics of the orogenic garnet peridotites. Different types of mantle wedge garnet peridotite can be recognized when garnet peridotites of the WGR (type A =old, cold, thick, depleted mantle wedge- and/or subduction zone garnet peridotite) are compared to those in the Seve-, Lindås- and Tromsø Nappes (type C=old, cold, thin, depleted mantle overprinted by subduction zone garnet peridotite). Similar investigations on Chinese orogenic garnet peridotites appear to be more complicated except for the crustal origin of the Bixiling and Maowu subduction zone garnet peridotites in Dabieshan. Published models concerning the origin and evolution of the Zhimafang garnet peridotite in the Sulu terrane have two contrasting interpretations, 1) Type A=Old, cold, depleted (subcratonic) lithospheric mantle and 2) type B or D= hot, fertile, young upwelling asthenosphere. Recent evidence points towards the idea that the Xugou garnet peridotite also originates from the subcratonic lithospheric mantle underneath the Sino-Korean Craton (type A). There are also three contrasting interpretations for the origin of the Lüliangshan garnet peridotite in the North Qaidam orogenic belt: 1) type D = thin, hot, young & dynamic (Alaska type magmatic cumulate), 2) subduction zone type = serpentinised cumulates formed by dehydration of serpentinites during the subduction process and 3) type A = Archean fragments underneath a subcratonic lithosphere. It is clear from the results presented that our model is able to classify all garnet peridotites but in the case of the Chinese occurrences more detailed work is still needed before the final subtype of the model can be identified.

Assuming universal applicability of our model we conclude that the most important discriminative parameters in our model are: 1) The mean bulk temperature (T) that is operative in the mantle wedge at the onset of continental collision/subduction and 2) the thickness (P) of the lithosphere underneath the overriding plate during collisional. Finally it needs to be emphasized that also the age of melting, as well as the depth at which melting takes place (LP versus HP) are important parameters to be determined in garnet peridotites.

Garnet growth and dissolution in high-pressure metamorphic rocks; implication for multi-phase/multi-stage metamorphism in the Bohemian Massif

Faryad, S.W.[1*], Klápová, H.[1] & Jelínek, E.[2]
[1]Institute of Petrology and Structural Geology, Charles University, Prague, Czech Republic ([*]Faryad@natur.cuni.cz)
[2]Institute of Mineralogy, Geochemistry and Natural Resources, Charles University, Prague, Czech Republic

Garnet crystals with multi-stage growths in eclogites from two different units in Krušné Hory (Erzgebirge) and Mariánské Lázně Complex (western part of the Bohemian Massif) were studied to analyse chemical zoning in relation to a change of PT conditions during metamorphism and reactions with coexisting phases. In the Krušné Hory, garnet core was formed during blueschist facies stage and during the passage to eclogite facies stage it became unstable and formed atoll garnet structure which was interpreted as resulting from fluid infiltration and element exchange between the garnet core and matrix of the rock. The outstanding feature of the atoll garnet is its homogeneous central islands or peninsulas, which show composition similar to the rim-ring, implying growth under similar conditions. In addition, due to fluid access, the primary textures, mainly grain size, were also effective for the atoll garnet formation. Small grain fractions with thin rims were easily infiltrated by fluid, which used the short distance for element exchange between core and matrix. Both core and rim contain micro-veins that were used for compositional change due to fluid infiltration through the vein-channels. The core garnet was gradually dissolved and new garnet formed first island or peninsula and finally completely replaced the old core. Electron backscatter diffraction analyses show that the new garnet (II), including the outermost ring and islands or peninsulas in the core, have crystallographic orientations identical to that of the old garnet (I).

In the Mariánské Lázně Complex, core and rim of garnet were formed during different metamorphic events; the older core (garnet I) during amphibolite and younger rim (garnet II) during eclogite facies conditions. Garnet (II) may contain inclusions of Na-Ca amphibole and of omphacite. These two garnets have highly different composition: the core is rich in Mg and has lower Ca comparing with the surrounding garnet crystal. Both core and rim show different crystallographic orientation supporting their formation during different metamorphic events. Growth zoning is preserved in both core and surrounding crystals. Full multicomponent diffusion modelling of compositional zoning at the interface of amphibolite - eclogite facies garnets in conjunction with the retrieved P-T paths were used to evaluate average subduction / exhumation as well as heating / cooling rates during eclogite facies event. In addition to conventional geothermobarometry, pseudosection and garnet isopleths were used to estimate PT conditions for the early amphibolite facies and subsequent eclogite facies metamorphic events.

Tubular Mg-ferrite in magnesiowüstite inclusions in diamond from superdeep origin: control of Fe-valence by dislocation core structure

Wirth, R.[1], Dobrzhinetskaya, L.[2], Harte, B.[3] & Green, H.W.[2]
[1]German Research Centre for Geosciences GFZ, Potsdam, Germany ([*]wirth@gfz-potsdam.de)
[2]Dept. of Earth Sciences, University California at Riverside, USA
[3]University of Edinburgh, UK

Inclusions of ferropericlase and Mg-wüstite frequently occur as inclusions in diamond from the lower mantle. Under mantle conditions, diamond plus inclusion are regarded as a closed system. Therefore, the original oxygen activity f_o inside inclusions in diamond should have remained unchanged. Here, we report on TEM investigations on FIB-cut foils from Mg-wüstite inclusions in diamond enclosed in superdeep diamonds (Sao Luiz, Brazil) [1]. Along the inhomogeneously distributed dislocation lines in Mg-wüstite tubular structures of Mg-ferrite are observed. The tube-like structures are usually 70 - 150 nm in diameter and associated with "negative crystals" (50 nm in size) that are arranged along the original dislocation lines. Additionally, HREM imaging of the tube-like Mg-ferrite reveals nanometer-sized magnetite crystals 20 – 50 nm in size. The different phases have been identified by their chemical composition and electron diffraction or fast Fourier transforms from HREM images. Mg-wustite, Mg-ferrite and magnetite have identical crystallographic orientation. It is suggested that Mg-ferrite has formed under constant oxygen fugacity solid stateconditions by a solid state reaction:

$$(Mg, Fe)O \Rightarrow MgFe_2O_4 + \rho Mg_{vacancies} + Fe_3O_4$$
$$3Mg^{2+} \Rightarrow 2Fe^{3+} + 1\ Mg_{vacancy}$$

The atomic structure of a dislocation reveals that around the dislocation core the atomic positions are shifted. In the upper part of the dislocation (inserted half plane) above the dislocation line, the ions are compressed whereas below the dislocation line the atomic distances are slightly expanded. The effective ionic radius of Fe^{2+} in octahedral coordination is 0.078 nm and that of Mg^{2+} in octahedral coordination is 0.072 nm. Shifting the ions towards each other, then, at a certain distance, repulsive electrostatic forces will hinder further compression. In the compressed region of the dislocation core neighboring Fe^{2+} or Mg^{2+} ions would come to close to each other and repulsive forces are acting. These repulsive forces can be minimized by replacing Mg^{2+} by Fe^{3+}, which has a significantly smaller ionic radius (0.0645 nm). Replacing 3 Mg-ions by 2 Fe^{3+} plus 1 Mg vacancy makes the inter-atomic distances in the compressed part of the dislocation core more favorable because the ionic radius of Fe^{3+} (0.0645 nm) is smaller than that of $(Fe^{2+})^{VI}$ (0.078 nm) and $(Mg^{2+})^{VI}$ (0.072 nm). 3 Mg ions diffuse out of the core region into the bulk lattice and simultaneously 2 Fe ions diffuse into the dislocation core region leaving one Mg-position unoccupied thus creating one Mg-vacancy. The Mg-vacancies condense along the dislocation core forming negative nanocrystals. The observation that the tubes have approximately the same thickness of 70 nm can be explained by the size of the stress field around the dislocation core. The stress field around the dislocation core determines the width of the tubes.

[1] Harte, et al. (1999) in Fei, Y., Bertka, C.M & Mysen B. (eds.) *Mantle petrology: Field observation and high pressure experimentation: A Tribute to Francis R. (Joe) Boyd*. The Chemical Society, Sp. Publ., **6**, 125-153.

Synthesis of clinopyroxene from CNMAS system at P = 6-12 GPa and T = 900-1200°C

Dobrzhinetskaya, L.[1*], Zhao, S.T.[1,2], Nee, P.[1] & Green, H.[1]
[1]Dept. of Earth Sciences, University of California at Riverside, USA ([*]larissa@ucr.edu)
[2]China University of Geosciences, Wuhan, China

The publications of 1960-70s report that many eclogitic pyroxenes are characterized by non-stoichiometry, when sum of cations calculated per 6 oxygen atoms is <4, caused by the reaction: $CaAl(AlSi)O_6 + 3SiO_2\square \rightarrow \square\ Ca\square Al_2Si_4O_{12}$, where □ is a vacancy.

The reaction runs to the right by substitution of Si for Al in tetrahedral sites, displacing Al to M1 octahedral sites, where it is electrically balanced by a vacancy. The right side of the reaction has a smaller volume than the left, hence increasing pressure drives the reaction to the right. Day & Mulcahy [1] showed three possible ways of SiO_2-exsolution: (1) vacancy consumption in non-stoichiometric pyroxene; (2) dissolution of Ti-phases in pyroxene or garnet; (3) reactions between accessory phases and either pyroxene or garnet. We have conducted a series of anhydrous experiments in a Walker-style multianvil apparatus at P = 6, 8, 10, 12 GPa, and T = 900, 1000, 1100 and 1200 °C using powdered glass of the composition (wt%): SiO_2 = 58.29, Al_2O3 = 24.12, MgO = 5.44, CaO = 11.37, Na_2O = 0.78.

Our experiments demonstrate that at given bulk chemistry the Px with the largest CaEsk value is crystallized at P = 6 to 8 GPa at all temperature ranges; with increasing P up to 12 GPa and T up to 1200 °C the CaEsk component tends to decrease. Our data are in a good agreement with experiments by [2] because CaEsk component exhibits similar tendency, though the values of the CaEsk components are significantly different due to differences in the bulk chemistry chosen as starting materials. For example, Px synthesized from the starting material A toleiite at 10 GPa, 1200 °C contains CaEsk = 0.10 [2], whereas at similar conditions we have synthesized Px with CaEsk = 0.19. Our experiments showed that the nonstoichiometry of omphacite reaches a maximum between 5 and 8 GPa, followed by rapid decrease in CaEsk component when stishovite becomes stable in the assemblage and the pyroxene progressively dissolves into garnet, culminating in a garnetite at ca. 15 GPa. We conclude, that the CaEsk component can be responsible for SiO_2 lamellae exsolution formation in pyroxenes uplifted from depth not more than 180 km, and therefore decompressed from P = 6 – 8 GPa to ambient pressures.

[1] Day & Mulcahy (2007) *J. Metamorph. Geol.*, **25**, 35-70. [2] Irifune, T. et al. (1986) *Earth Planet. Sci. Lett.*, **77**, 245-256.

Lattice preferred orientation, water content, and seismic anisotropy of orthopyroxene

Jung Haemyeong*, Park Munjae, Jung Sejin & Lee Jaeseok
School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (*hjung@snu.ac.kr)

Lattice preferred orientation (LPO) and seismic anisotropy of orthopyroxene (enstatite) in mantle xenoliths from Spitsbergen, Svalbard, near the Arctic, are studied. LPOs of enstatite were determined using electron backscattered diffraction (EBSD). We found five types of LPOs of orthopyroxene and defined them as type-AC, -AB, -BA, -BC, and -ABC. Type-AC LPO of orthopyroxene is defined as (100) plane aligned sub-parallel to foliation and [001] axis aligned sub-parallel to lineation. Type-AB LPO is defined as (100) plane aligned sub-parallel to foliation and [010] axis aligned sub-parallel to lineation. Type-BA LPO is defined as (010) plane aligned sub-parallel to foliation and [100] axis aligned sub-parallel to lineation. Type-BC LPO is defined as (010) plane aligned sub-parallel to foliation and [001] axis aligned sub-parallel to lineation. Type-ABC LPO is defined as both (100) and (010) planes aligned sub-parallel to foliation and [001] axis aligned sub-parallel to lineation.

We report for the first time the type-AB and -BA LPO of orthopyroxene. LPO pattern has a correlation with the content of orthopyroxene in the specimen. FTIR study showed that type-AC LPO was observed mostly in the samples of enstatite with low water content. It is found that the strength of the LPO of enstatite decreases with increasing water content and has a correlation with the strength of the LPO of olivine: the stronger the LPO of enstatite, the stronger the LPO of olivine. Seismic anisotropy of enstatite was smaller than that of olivine in the same specimen.

Open system precipitation – a new way to explain crystallographically oriented precipitates/exsolutions in minerals from high-T/high-P rocks

Proyer, A.*, Krenn, K. & Hoinkes, G.
Institute of Earth Sciences, University of Graz, Austria
(*alexander.proyer@uni-graz.at)

The deep earth is where pressure and temperature have increased to an extent that substitutions considered rather exotic for "normal" crustal conditions become significant. The preservation of such exotic mineral compositions, directly or indirectly as precipitates/exsolutions, is an important criterion to derive prior extreme conditions of formation in ultrahigh-pressure and – to a lesser extent – ultrahigh-temperature rocks or regions.

The presence of crystallographically oriented inclusions in garnet (mainly rutile), in clinopyroxene (amphibole, quartz, Ti-minerals) and in titanite (mainly amphibole) from a high-grade metamorphic complex in the Rhodope mountains, where the presence of microdiamond indicates prior UHP conditions, cannot be explained by exsolution in a closed (intracrystalline) system. Hence we postulate that these precipitates form by an exsolution process at relatively high temperatures, where those components of an exotic high-P/T endmember with the slowest diffusion rates (Ti, Si, Al) can form precipitate minerals only because ions are to some extent exchanged with the rock matrix or a melt-phase in intergranular pore space. In other words, the host mineral is to some extent an open system where the exchange rates of ions with the matrix are a function of chemical potential gradients and diffusion rates. Example reactions would be:

For garnet: 2 $M_{2,5}TiAlSi_3O_{12}$ (grt) + 4 $M_3TiAl[AlSi_2]O_{12}$ (grt) + Si^{4+}= 5 $M_3Al_2Si_3O_{12}$ (grt) + 2 M^{2+} + 6 TiO_2 (ru);

For clinopyroxene: 6 $CaMgSi_2O_6$ (cpx) + 2 $CaAl_2SiO_6$ (cpx) + 1 $NaAlSi_2O_6$ (cpx) + 4 H^+ + 2 Mg^{2+} = 2 $Na_{0.5}Ca_2Mg_4Al[Al_{1.5}Si_{6.5}]O_{22}(OH)_2$ (amph) + 3 SiO_2 (qtz) + 4 Ca^{2+};

For titanite: 24 $CaAlSiO_4OH$ (tit) + 6 Si^{4+} + 20 Mg^{2+} + 5 Na^+ = 5 $NaCa_2Mg_4Al[Al_2Si_6]O_{22}(OH)_2$ (amph) + 14 H^+ + 9 Al^{3+} + 14 Ca^{2+}.

This apparently exotic exsolution mechanism is in fact to be expected in rocks where temperatures are high enough to reset bell shaped composition profiles – even in elements like Al – towards plateaus and where the absence or strongly reduced grain size of oriented inclusions near grain boundaries indicates (diffusional) material transport even of highly charged (slowly diffusing) ions out of the host crystals.

If this mechanism can be confirmed as valid and significant for high grade rocks in the future, the practice of calculating the composition of a precursor high grade mineral by broad-beam analysis or simple adding of exsolution and host mineral compositions must be considered imprecise and should be used with caution. It may also significantly affect the derivation of exchange vectors from metamorphic mineral compositions because any open system process "falsifies" the compositional record. More experimental work, including diffusion experiments, will clarify the significance and importance of open system behaviour in general and open system precipitation in particular.

Metamorphism and devolatalization in subduction zones

Perchuk, A.L.[1,2]
[1]Petrology Dept., Geological Faculty, Moscow State University, Moscow, Russia (alp@geol.msu.ru)
[2]Institute of Experimental Mineralogy, Chernogolovka, Russia

High pressure experiments, thermodynamic modeling and studies on (U)HP metamorphic rocks provide important knowledge on composition of fluid and net transfer reactions operated within the subducting slabs. Metamorphic fluids liberated from downgoing slabs are essential for metasomatic and magmatic processes in the overriding mantle as well as for the global element cycling in subduction zones. The contribution aims to overview the most poorly understood aspects of subduction zone process such as devolatalization, fluid escape from subducting slabs and its transfer to the mantle wedge, and to discuss a novel experimental method which allows studying these processes simultaneously in the high-gradient zone of piston-cylinder apparatus.

Experimental runs with glaucophane schist and olivine as analogs of crust and mantle, respectively, were carried at pressure up to 2.7 GPa. The temperature up to 1050°C at the top of the capsules was measured by the thermocouple whereas temperature up to ~700°C at the bottom of the capsules was quantified from the numerical modeling. The experiments demonstrate glaucophane and chlorite breakdown reactions in the schist and behavior of liberated liquid (supercritical fluid?). The liquid often migrates either through the grains or along the grain boundaries towards the high temperature olivine zone. Si-rich liquid reacts with the olivine and produce an orthopyroxene layer at the boundary between the olivine and the glaucophane schist. Pathways of liquid escape from the glaucophane schist are not identified in some domains, however presence of the orthopyroxene layer provides strong evidence that fluid can migrate in the schist without visible traces. Liquid migration above the orthopyroxene layer causes neither no changes in olivine composition nor its partial melting.

Subduction-related fluid activity in the Austroalpine Polinik complex: constraints from tourmaline-bearing eclogites

Hoinkes, G.[1*]**, Krenn, K.**[1]**, Konzett, J.**[2] **& Hauzenberger, C.A.**[1]
[1]Inst.of Earth Sciences, University of Graz, Austria (*georg.hoinkes@uni-graz.at)
[2]Inst. of Mineralogy and Petrography, University of Innsbruck, Austria

Tourmaline is a rare constituent in eclogites since boron contents are usually too low in mafic protoliths to stabilize tourmaline during metamorphism. Hence the occurrence of tourmaline in an eclogite of eo-Alpine age in the Austroalpine unit is an exceptional feature indicating metasomatic activity. These eclogites occur as boudins of a few tens of metres in diameter interlayered in pelitic gneisses and schists from the Texel area in the W to the Koralpe area in the E and mark an eo-Alpine collision zone appearing as Southern Limit of Alpine Metamorphism (SAM) within the Eastern Alps. The eclogite investigated belongs to the Polinik Complex, the northern part of the Kreuzeck Mountains between the Möll valley in the N and the Drau valley in the S in Upper-Carinthia. Textures imply that tourmaline occurs as mm-sized idiomorphic grains as part of the HP-assemblage comprising garnet, omphacite (Jd_{33-48}), Ca-amphibole, clinozoisite and quartz as major constituents. Additional minor or accessory constituents are phengite, rutile, titanite, apatite, zircon and K-feldspar. The calculation of a pseudosection for a phengite-bearing sample yields *P-T*-conditions of 1.6 GPa and 650°C. Tourmaline contains inclusions of omphacite, rutile, apatite and rarely K-feldspar and is typically intergrown with abundant small zircons of up to 100 μm in size. Chemically the tourmalines are schoerl-dravit solid solutions with unusually high TiO_2-contents of up to 3.4 wt%. Their trace element content is high in Sr (1288 – 3948 ppm), Pb (32 – 71 ppm) and Li (16 – 30 ppm) and low in Be (< 1 ppm). The zircons contain omphacite and rutile inclusions and have high U (264 – 419 ppm), Th (1.2 – 2.5 ppm) and Li (5.0 – 8.3 ppm) contents compared to a single very large zircon grain of 300x500 μm in size. Both zircon generations give similar U-Pb – SIMS ages of 86+1 and 109+2 Ma for the small generation and 90+9 Ma for the larger one. These ages are consistent with well documented ages of the eo-Alpine HP-metamorphism of the Austroalpine unit. Two main chemical systems of fluids are included in tourmaline: System 1 consists of H_2O-CH_4-N_2-NaCl-CO_2 with salinities of ca. 6 mass% NaCl, is restricted to tourmaline and occurs as single inclusions. System 2 comprising saline aqueous fluids of NaCl-$CaCl_2$-H_2O chemistry, are arranged along cracks in tourmaline and dominate in apatite and quartz with a wide range in salinities between 8 and 30 wt%. Independent of salinity, the fluids occur either as single, primary inclusions or along planes. Aqueous inclusions in quartz rarely contain calcite daughter crystals which may coexist with halite. Trace element contents of the aqueous fluids determined by SIMS result in high Sr-, Pb- and B-contents of up to 1081 ppm Sr, 16 ppm Pb and 372 ppm B and resemble the tourmaline composition. Calculated isochors of primary inclusions in tourmaline, apatite and quartz combined with petrologic thermobarometric estimates yield minimum pressures of 10 – 12 kbar. Since postentrapment leakage of fluid inclusions is common minimum *P-T* estimates point to formation of tourmaline, zircon, apatite and quartz at eclogite facies metamorphic conditions. Enrichment of HFSE-LILE – elements in zircon of eo-Alpine age are in agreement with a continental-derived fluid in course of a Cretaceous collision/subduction event within the Austroalpine lithosphere.

Tourmaline – an ideal geochemical recorder in UHP metamorphic rocks?

Marschall, H.R.
Dept. of Earth Sciences, University of Bristol, UK
(Horst.Marschall@bristol.ac.uk)

The extensive *P-T* stability and the high chemical variability of tourmaline (Tur) together with its common occurrence in metasediments proves its high potential for petrologic and (isotope) geochemical studies on fluid-rock interaction in subduction and collision-related rocks. Its occurrence in natural rocks combined with experimental data demonstrates that at least some members of the Tur group are stable in subducting slabs to a depth of at least 150 km, possibly even 250 km. Tur of the schorl-dravite solid-solution series with coesite inclusions has been discovered from the Erzgebirge and from the Western Alps, and is taken as unambiguous evidence for the crystallisation of Tur under UHP conditions.

(U)HPM rocks are the products of complex histories, and the occurrence of Tur in any given sample may be related to one or several of a number of different processes. The first aim in a petrologic or geochemical study involving Tur, therefore, has to be the identification of the Tur-forming process by petrographic or petrologic means. In general, Tur may be (1) a relic from the pre-metamorphic protolith (e.g., detrital grains), or (2) may have formed from B released from surrounding minerals during prograde metamorphism, or (3) may have formed during metasomatism at any stage of the *P-T* history. Metasomatic formation of Tur is a common mechanism and has been documented for (U)HP metamorphic rocks in a number of fossil subduction zones. These metasomatic Tur porphyroblasts form by reaction of silicates with incoming B-rich fluids or melts, in most cases during the decompression history of the rocks.

Inclusions of Tur in (U)HP phases, or of (U)HP phases in Tur are probably the best indicators for (U)HP stability and/or formation of Tur. Coesite found as inclusions in Tur can be recognised by Raman spectroscopy, which allows for rapid analyses of a large number of inclusions down to micrometer size.

Tourmaline is chemically highly variable, confronting us with the difficulty to decipher a highly relatively complex mineral system. On the other hand, it presents us with a geochemical recorder of unparalleled broad representation across half of the periodic table. Tur records the magmatic or metamorphic *P-T-X* evolution of its host rock by changing major element compositions, such as Mg/Fe and Ca/Na ratios. Recently, advancements have been made in the investigation of the thermodynamic properties of Tur towards a quantification of the metamorphic *P-T* history during its crystallisation. A wide range of isotope systems has been applied to Tur, including major (O, B, Si, H), minor and trace elements (Sr, Pb, Nd, Li) and both radiogenic and stable isotope systems. Fluid-rock interaction processes, magmatic-hydrothermal systems and ore-forming processes have been reconstructed this way.

Dating of tourmaline has been achieved using the K-Ar and Ar-Ar techniques, which show blocking temperatures in Tur in the same range as in amphibole. Pb-Pb and Sm-Nd dating has also been successfully applied to Proterozoic and Archean tourmaline. Therefore, it is in some cases even possible to directly link the wide range of geochemical signals documented in tourmaline to the ages of their formation.

Metasomatic hide and seek: origins of the Roberts Victor eclogites, South Africa

Huang, J-x[1,2*], Greau, Y.[1], Griffin, W.L.[1] & O'Reilly, S.Y.[1]
[1]GEMOC, Macquarie University, Sydney, Australia
([*]jhuang@els.mq.edu.au)
[2]School of Earth Sciences and Resources, China University of Geosciences, Beijing, China

Eclogite is an important minor constituent of subcontinental lithospheric mantle (SCLM) (1-3 vol%) and a clear picture of its origin will help us to understand the origin of the ancient SCLM. Extensive studies of these rocks have generated two contradictory hypotheses about their origin; one regards the eclogites as deep-seated magmatic rocks, while the other regards them as components of subducted oceanic slabs. Xenolithic eclogites from Roberts Victor kimberlite (South Africa) have been studied to constrain their origin.

The Roberts Victor eclogites can be divided into two types based on differences in microstructure and mineral composition. Type II eclogites have low Na in gnt and low K in cpx, while Type I has high values. Type II eclogites are generally fresh and show equilibrated microstructures. Rutile exsolution in gnt and cpx, and gnt exsolution in cpx, are only found in Type II. Type I eclogites, in contrast, are texturally not in equilibrium, and have many fluid inclusions. Only Type I eclogites contain diamond, graphite, sulfides and apparently-primary phlogopite.

All the minerals are homogeneous within each sample. Reconstructed whole-rock compositions show that Type I eclogites are richer in Mg, K, Rb, Sr, LREE and LILE than Type II. P-T estimates indicate Type II eclogites are distributed from 170-200 km depth, but Type I are strongly concentrated in a layer at 180-190 km depth, just beneath lithosphere-asthenosphere boundary. However the abundance of Type II is low, about 6-8% of Type I.

Sr, Nd and Hf isotopes of gnt and cpx were analyzed in clean small grains after acid-leaching. The Nd-Hf data for Type I eclogites define two-point isochron ages (Sm-Nd 100±21 Ma; Lu-Hf 133±17 Ma) that are identical to the kimberlite eruption age (128 Ma). Lu-Hf isochron ages for Type II eclogites (1354±9 Ma) may suggest a connection to the Namaqua-Natal Orogenic Belt to the south of Kaapvaal Craton. These differences suggest that Type II eclogites have retained their initial isotopic compositions whereas the isotopic systems of Type I eclogites were actively re-equilibrating at the time of kimberlite eruption. This is also consistent with the petrographic and mineralogical evidence of fluid metasomatism in Type I eclogites. Sr, Nd and Hf isotopic ratios at the time of kimberlite eruption also show marked differences between Type II and Type I; $^{87}Sr/^{86}Sr$ is 0.7060-0.7064 in Type I and 0.7013-0.7030 in Type II. O- isotope ratios are also different. Type II eclogites have $\delta^{18}O < 4.3‰$ and those of Type I have mantle values (ca 5.4) or higher.

These data and observations suggest that Type I eclogites were being actively metasomatized slightly prior the kimberlite eruption. Inter-element correlations suggest that the metasomatism was adding Mg, K, S, Rb, Sr, C (diamonds), LREE and LILE. Some samples (the present Type II eclogites) from the same depth range appear to have escaped this process and preserved their original characteristics.

The calculated fluid in equilibrium with Type I eclogitic gnt and cpx is LREE-enriched and shows trace-element patterns similar to those of fibrous diamonds and carbonatitic/kimberlitic melts. The Sr- and Nd-isotope values are also consistent with reaction between Type II eclogites and diamond forming fluid to form Type I eclogites. Type II eclogites therefore are the key samples for studying the origin of this eclogite suite, since they may represent the protoliths. Type I, in contrast, are heavily metasomatised rocks, and retain little evidence of their primary origin.

Chromian kyanite, chromian magnesiostaurolite and ruby in UHP eclogites from Pohorje (Eastern Alps) and Tromsø Nappe (Northern Scandinavian Caledonides)

Janák, M.[1*], Vrabec, M.[2], Krogh Ravna, E.[3], Kullerud, K.[3] & Hurai, V.[1]
[1]Geological Institute, Slovak Academy of Sciences, Bratislava, Slovakia ([*]marian.janak@savba.sk)
[2]Dept. of Geology, University of Ljubljana, Slovenia
[3]Dept. of Geology, University of Tromso, Norway

Chromian kyanite, magnesiostaurolite and ruby were found in eclogite associated with metaultramafic rocks (garnet peridotite, serpentinite) from Pohorje Mountains (Eastern Alps) and the Tromso Nappe (Northern Scandinavian Caledonides). At both localities eclogite is composed of primary Mg-rich garnet (X_{Mg} = 0.75-0.81), omphacite (Jd = 16-29 mol%) and kyanite with secondary amphibole (pargasite, magnesiohornblende) and zoisite, which are abundant in strongly retrogressed rocks. Chromian kyanite (Cr_2O_3 up to 14.2 wt%) of turquoise-blue colour contains inclusions of chromite (Cr* = 0.74-0.78), Cr-rich garnet (Cr_2O_3 = 2.0 wt%), omphacite (Cr_2O_3 = 0.5 wt%) and Cr-rich amphibole (Cr_2O_3 = 3.5 wt%). Chromian kyanite shows the highest Cr content near chromite. Rarely, a very Cr-rich chromian magnesiostaurolite (Cr_2O_3 = 8.8-15.0 wt%, X_{Mg} = 0.7-0.81) occurs as inclusions in Cr-rich domains of kyanite. Texturally different staurolite occurs in the retrogressed rocks with abundant amphibole and zoisite. This staurolite forms subhedral, up to 500 μm large crystals of blue-green colour, the composition is magnesian (X_{Mg} = 0.76-0.82) and Cr-rich (Cr_2O_3 = 5.4-8.5 wt %). Blue-green staurolite is associated with blue Cr-kyanite, brown Cr-spinel and pink Cr-corundum (ruby) which are surrounded by pargasitic amphibole. The ruby from Pohorje shows the highest chromium content (Cr_2O_3 = 12.4 wt%). Some kyanites are surrounded by coronas composed of sapphirine + corundum + Al-spinel + plagioclase assemblage. Sapphirine corresponds to 3:5:1 end-member with 1.7 wt% Cr_2O_3. Mg-chlorite, margarite and plagioclase are present in the most retrogressed domains. Chromium enrichment in kyanite, staurolite and corundum was controlled by substitution for Al in the octahedral sites. The highest Si content and almost absence of tetrahedrally coordinated Al was observed in the most Cr-enriched staurolite in primary assemblages of the Pohorje eclogite. Metamorphic peak-pressure conditions of the Pohorje eclogites reached >3 GPa at 800-850°C. Experimental studies demonstrate that magnesiostaurolite can be stable at such UHP conditions and chromium content in kyanite tends to increase with pressure. Formation of Cr-kyanite and chromian magnesiostaurolite is inferred by reactions involving Cr-spinel, during subduction and UHP metamorphism of the mantle-derived, Cr-rich magmatic protolith of eclogite. Formation of blue-green magnesiostaurolite, ruby and less chromian, Mg-rich spinel seems to be related to partial breakdown of Cr-kyanite, involving garnet and omphacite during decompression and exhumation of the eclogite. Lower *P-T* limits can be constrained by the stability of magnesiostaurolite at >1.2 GPa and 750°C in the system MgO-Al_2O_3-SiO_2-H_2O, however, chromium may shift the magnesiostaurolite stability field. The Cr-kyanite, chromian magnesiostaurolite and ruby reported here show chromium contents which are among the highest recorded in natural samples.

Mantle wedge convection and metasomatism: evidences from the Maowu mafic-ultramafic rocks in Dabieshan UHP terrane, eastern China

Chen Yi[*], Ye Kai, Guo Shun & Liu Jingbo
State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China ([*]chenyi@mail.iggcas.ac.cn)

The Maowu mafic–ultramafic body occurs in paragneisses in the Dabieshan ultrahigh-pressure (UHP) metamorphic terrane, eastern China. It is a lens (50x250 m^2) composed of millimeter- to centimeter-thick compositional layers, dominated by garnet orthopyroxenite and orthopyroxenite with minor dunite, harzburgite, garnet websterite and garnet clinopyroxenite. Previous researchers assumed that the protolith of the Maowu mafic-ultramafic body was a cumulate complex, fromed by fractional crystallization of a basaltic magma in the Yangtze Craton, which suffered by deep subduction and UHP metamorphism in the Triassic [1-5]. However, these rocks exhibit a sequence of symmetric layering ranging from Mg-rich to Mg-poor, Fe-, Al- and Ca-rich composition, and no rhythmic bandings have been found in the outcrops. The matrix orthopyroxene from the garnet websterite, garnet orthopyroxenite and orthopyroxenite have high NiO content and high Ni/Mg and Fe/Mn ratios, which is similar to that in olivine from dunite. The same is true for the relicts of fine-grained olivine and orthopyroxene in the core of matrix orthopyroxene in pyroxenites, which have composition similar to the matrix olivine and orthopyroxene in the dunite, respectively. These features indicate that the Maowu pyroxenites were derived by metasomatic interactions between refractory mantle wedge dunite and slab-derived silica-saturated fluid or hydrous melt.

The Maowu garnet orthopyroxenite preserves mineralogical and mineral chemical evidence for multistage metamorphism related to progressive mantle wedge convection during the Triassic subduction of oceanic and continental plates. Six stages of metamorphism are distinguished, based on detailed mineralogical and petrological studies: (I) High-T low-P metamorphism (~1.4 GPa, ~900 ^oC); (II) Low-T low-P metamorphism (1.3-1.7 GPa, 700-750 ^oC); (III) Low-T low-P metamorphism (2.1-2.5 GPa, 740-760 ^oC); (IV) UHP metamorphism (5.3-6.3 GPa, ~800 ^oC); (V) Early stage retrogression (< 3 GPa, > 750 ^oC); (VI) Late stage retrogression (< 2.3 GPa, < 670 ^oC). Mineral textures and compositions indicate that the Maowu garnet orthopyroxenite was derived by metasomatic interactions between precursor refractory dunite in the mantle wedge and slab-derived fluid. M1-M2 defines an isobaric cooling P-T path, implying that the protolith dunite convected from a hot depleted mantle wedge to the cold and wet mantle wedge corner and was metasomatized by oceanic slab-derived fluid rich in SiO_2, Al_2O_3, TiO_2, CaO, Na_2O, K_2O, FeO, P_2O_5, SO_2, BaO and Cl. M2-M4 defines an isothermal compression P-T path, suggesting that the rock subsequently convected from the shallow, cold and wet mantle wedge corner to deep mantle up to ~ 200 km depth and suffered HP-UHP metamorphism. Dehydration during subduction might have released fluid that migrated into the above hotter mantle wedge and resulted in partial melting and formation of arc magmatism. M4-M6 defines a retrograde P-T path during exhumation to the crustal level together with the UHP terrane and was continuously metasomatized by fluid derived from the country UHP crustal rocks.

The Triassic age of oceanic eclogites in the Dabie orogen: entrainment of oceanic fragments in the continental subduction

Cheng, H.[1*], DuFrane, S.A.[2], Vervoort, J.D.[2], Nakamura, E.[3], Li, Q.L.[4] & Zhou, Z.Y.[1]
[1]State Key Laboratory of Marine Geology, Tongji University, Shanghai, China ([*]oahgnehc@gmail.com)
[2]School of Earth and Environmental Sciences, Washington State University, Pullman, Washington, USA
[3]Institute for Study of the Earth's Interior, Okayama University, Tottori, Japan
[4]State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Low-temperature and high-pressure eclogites with an oceanic affinity in the western part of the Dabie orogen have been investigated with combined Lu–Hf and U–Pb geochronology. These eclogites formed over a range of temperatures of 482–565°C at 1.9–2.2 GPa. Three eclogites, which were sampled from the Gaoqiao country, yield Lu–Hf ages of 240.7 ± 1.2 Ma, 243.3 ± 4.1 Ma and 238.3 ± 1.2 Ma, with a corresponding lower-intercept U–Pb zircon age of 232 ± 26 Ma. Despite the well-preserved prograde major- and trace-element zoning in garnets, these Lu–Hf ages mostly reflect the high-pressure eclogite-facies metamorphism instead of representing the early phase of garnet growth due to the occurrence of omphacite inclusions from core to rim and the shell effect. An upper-intercept zircon U–Pb age of 765 ± 24 Ma is defined for the Gaoqiao eclogite, which is consistent with the weighted mean age of 768 ± 21 Ma for the country gneiss. However, the gneiss has not been subjected to successive high-pressure metamorphism. The new Triassic ages are likely an estimate of the involvement of oceanic fragments in the continental subduction (Fig. 1).

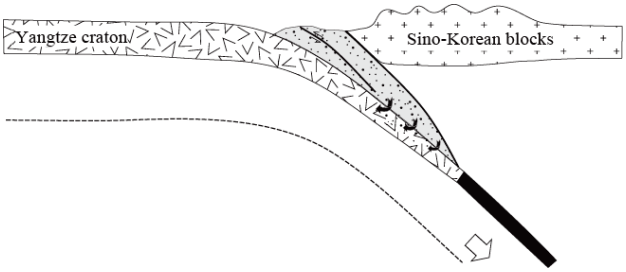

Fig. 1: Continental subduction started and oceanic subduction terminated. Some early oceanic fragments were probably entrained by the subducted continental crust.

Fluid-rock interaction and element mobilization in deep subduction zone: evidence from mass transfer calculation of UHP eclogite

Guo Shun*, Ye Kai, Chen Yi & Liu Jingbo
State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China (*guoshun@mail.iggcas.ac.cn)

In order to study the complex UHP fluid-rock interaction and element mobility involved in deep subduction zone, we calculated the mass transfers of eclogite profile towards the HP vein in Dabie UHP metamorphic belt, eastern China. The normalized Isocon diagram (Fig. 1) indicates various degrees of trace elements mass transfers which reflect their mobilities during the formation and precipitation of the fluid released from the host UHP eclogites. (1) The less mobile LILEs (U, Th, Pb and Sr) are dramatically scavenging from the elcogites towards the vein, indicating that they were released from the host eclogites during the vein formation and largely deposited in the vein during the fluid precipitation. (2) The REEs are also gradually scavenged towards the vein, however, they exhibit remarkably different mobility behaviors. The HREEs (from Gd to Yb) decrease gradually with the increase of their atomic number. In contrast the LREEs (from Ce to Gd) show gradual increase with increasing atomic number. This tendency is significantly inconsistent with the results of laboratory experiments [1], thus reveal the residual fluid after the precipitation of the HP vein carries significant LREEs back into the host eclogites. (3) The HFSEs (Nb, Ta, Zr and Hf) show low degree of reductions towards the vein in the host eclogites, indicating the HFSEs are also mobile, but their mobility is limited. (4) The water soluble LILEs (Cs, Rb, K and Ba) that are assumed to be most mobile, are however low in the vein and are gained in the eclogites a little away from the vein. This indicates that they were mainly dissolved in the residual fluid after the precipitation of the vein and were carried back into the host eclogites. The mobility of LREEs and water soluble LILEs in the residual fluid and their depositions in the host eclogites is assumed by the formation of later stage hydrous minerals such as epidote, barroisite, phengite and apatite in the host eclogites.

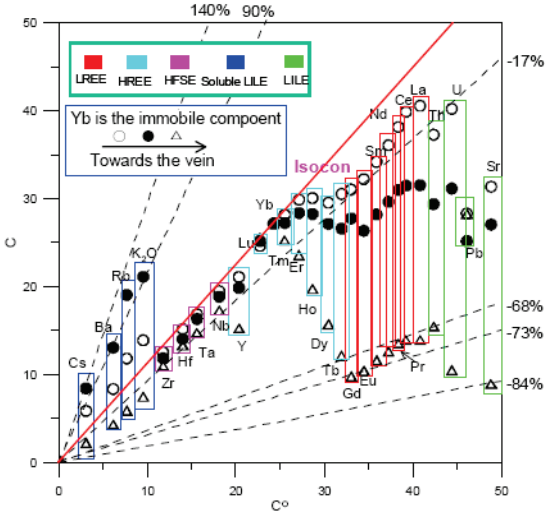

Fig. 1: A normalization Isocon diagram for mass transfer along profile from the vein towards the host eclogite in Dabieshan. The results of calculation using the method by [2] suggest that Yb is the immobile component due to its very low mobility in the fluid-rock interaction [1]. $\mathbf{c^o}$ is composition of eclogite far away from the vein and **c** is near to the vein. Ecolgite samples gradually closer to the vein are indicated by open circle, solid circle and triangle.

Lattice preferred orientation of olivine in garnet peridotites from Finsch, South Africa

Lee Jaeseok* & Jung Haemyeong
School of Earth and Environmental Sciences, Seoul National University, Seoul, South Korea (*shoo3680@snu.ac.kr)

Olivine is a major mineral in the upper mantle and plays an important role in deformation processes and seismic anisotropy. It has been known that water and stress influence lattice preferred orientation (LPO) of olivine [1,2]. In addition, recent experimental study at high pressure & high temperature showed that LPO of olivine can be changed due to pressure [3]. To understand the deformation processes in the deep upper mantle, garnet peridotites from Finsch, South Africa were studied. Lattice-preferred orientation (LPO) of olivine was determined by the electron back-scattered diffraction (EBSD) with CHANNEL 5 software. Water content of olivine was measured using the Nicolet 6700 FTIR with Continuum FTIR Microscope. Thermo Scientific DXR Raman Microscope was used to check the high pressure mineral phases.

Three samples showed that [001] axes of olivine are aligned subparallel to the lineation and [010] axes are aligned normal to the foliation, which is known as B-type LPO of olivine. The B-type LPO of olivine could be formed at the high stress condition with large amount of water [1,2]. However, there was no water observed inside of the olivine. Samples were dry. Study of Raman spectroscopy of specimens showed that some diamonds exist in garnet. We found peaks at the Raman shift wavenumbers of 1320cm^{-1} and 1322cm^{-1} which are known to be diamond peaks. These result suggest that the peridotite from Finsch, south Africa, orignated from a depth greater than ~120km (P ~ 4GPa), and the LPO of olivine was formed by high pressure. This is the first report of natural samples showing the type-B LPO of olivine most-likely induced by high pressure.

Tectonic exhumation rates of eclogite bodies from a Neoproterozoic subduction zone; Zambezi belt, Zambia

Mapani, B.S.[1*], Johnson, S.[2] & Tembo, F.[3]
[1]Geology Dept., University of Namibia, Windhoek, Namibia ([*]bmapani@unam.na)
[2]Tectonics Special Research Centre, Dept. of Earth and Geographical Sciences, University of Western Australia, Perth, Australia
[3]School of Mines, Dept. of Geology, The University of Zambia, Lusaka, Zambia

The Neoproterozoic to early Palaeozoic Gondwana supercontinent formed by the amalgamation of numerous cratonic blocks over an extended period of ca. 150 M.y. Although the post-collision configuration of Gondwana is relatively well constrained, the timing, order and nature of collisions leading to amalgamation are, in part, poorly understood. The African cratonic blocks form the core of the Gondwana supercontinent and thus determining the precise location and number of sutures and blocks, and the timing of their collisions are critical for understanding the supercontinents amalgamation. Neoproterozoic to Cambrian, i.e., Pan-African, tectono-magmatic activity in southern and eastern Africa formed the Damara-Lufilian-Zambezi (DLZ) and East African orogens, respectively. Evidence from the Lusaka eclogites and the Chongwe area of Zambia suggest a more complicated and perturbed exhumation history [1]. *PT* conditions in the Chongwe River area were based mainly on the whiteschist lithologies (10kbar at 700°C) [2]. Mafic eclogites that rest tectonically on the Congo Craton margin in southern Zambia, record maximum pressures of 26-28 kbar and have MORB-like geochemistries [2]. Isotopic mineral isochron ages between 659-595 Ma [3, 4] are interpreted as the time of eclogite-facies metamorphism and record the subduction and hence closure of the Zambezi Ocean. The very-high pressure-metamorphism and metasomatism recorded at ca. 570 Ma in the Chongwe River area and the various whiteschists marks the first contact between the Congo and Kalahari Cratons, or at least a promontory of one or other craton [1]. The formation of whiteschists and very-high-pressure rocks that comprise the Congo Craton margin indicate that it was subducted to at least 50km [1]. In this paper we outline the mineralogical, chemical and structural evidence that point to a staggered exhumation history during exhumation of the the subducted eclogitised gabbroic rocks.

Decompression and partial melting of subducted continental crust rocks: example from felsic high-*PT* granulites in the Bohemian Massif

Nahodilová, R.[1,2], Faryad, S.W.[1*] & Dolejš, D.[1]
[1]Inst. of Petrology and Structural Geology, Charles University, Prague, Czech Republic ([*]faryad@natur.cuni.cz)
[2]Czech Geological Survey, Prague, Czech Republic

Felsic granulites are closely associated in space and time with high-temperature eclogites and garnet peridotites in the Moldanubian and Saxothuringian zones of the Variscan orogen. Ultra-high pressure conditions for some mafic and ultramafic precursors were documented by the presence of coesite and microdiamonds (Saxothuringian) or were derived from phase equilibria and geothermobarometry (Moldanubian). Felsic granulites from the Kutná Hora complex in the Moldanubian zone consist of quartz, ternary feldspar, garnet, biotite, kyanite and rutile, and exhibit modal layering and discordant leucocratic veining. The layering is interpreted as evidence for partial melting along the exhumation path from the eclogite to granulite facies. Garnet grains show relatively high and constant Ca in their cores but in the rim, pyrope concentrations increase whereas those of grossular and almandine drop. In contrast, garnets from the leucocratic layers have comparably low Ca contents that further decrease towards the rim. Mineral assemblage and garnet chemical zoning constrain a prograde metamorphic path from 530 °C and 3.0-3.1 GPa through muscovite dehydration melting at 900 °C and 2.0-2.2 GPa to 850 °C and 1.4 GPa where the partial melt has crystallized. Phase formation and melt productivity were independently estimated by experiments in the piston-cylinder apparatus at 850-1100 °C and 1.7-2.1 GPa. The partial melt was produced by the dehydration melting: muscovite + omphacite + quartz = melt + K-feldspar + kyanite. The melt fraction was controlled by the whole-rock H_2O budget present throughout the eclogite facies, estimated to be 0.21 wt. % H_2O and accommodated by shifting the equilibrium: phengite + quartz = K-feldspar + kyanite + H_2O. Minimum water solubilities in silicic melts predict the bulk fertility to 2.8-4.2 wt. % melt during decompression but the actual melt fraction varied by as much as 28 wt. % on centimeter scale due to deformation-enhanced melt redistribution. The melt accumulation was probably controlled by shear instabilities and strain accommodation within foliation-parallel sites, eventually leading to the formation of modal layering. The presence of partial melt was responsible for attaining equilibrium during decompression at 850-900 °C, thus eliminating any potential relics of precursor high-pressure phases such as phengite or omphacite. In contrast, adjacent mafic granulites and eclogites, which apparently share the same metamorphic path but have not undergone partial melting, often preserve relics or inclusions of eclogite-facies mineral assemblages. The presence of partially molten domains of felsic granulites in the Variscan orogenic continental root probably exerts major rheological control on the incorporation and immersion of lenses and boudins of mafic granulites, eclogites and garnet-bearing ultramafics and their common extrusion *via* an exhumation channel to the middle continental crust.

Mössbauer spectroscopy studies of valence state of iron in a Tibetan chromite containing high-pressure mineral inclusions

Ruskov, T.[1*], Spirov, I.[1], Georgieva, M.[2], Yamamoto, S.[3], Green, H.[4], McCammon, C.[5] & Dobrzhinetskaya, L.[4]
[1]Institute for Nuclear Research and Nuclear Energy, Sofia, Bulgaria ([*]ruskov@inrne.bas.bg)
[2]University of Sofia, Bulgaria
[3]Tokyo Institute of Technology, Tokyo, Japan
[4]University of California, Riverside CA, USA

The Mössbauer spectroscopy studies show that chromites from massive ore are characterized by $Fe^{3+}/\Sigma Fe = 0.42$, and chromites from nodular and disseminated ores contain $Fe^{3+}/\Sigma Fe = 0.22$, all are from a Tibetan ophiolite. The massive ores record traces of ultrahigh pressure minerals: diamond, exsolution lamellae of coesite and diopside in chromite, inclusions of metal-nitrides, SiC and Fe^0 [1,2], the latter indicate a strongly reducing environment [3]. In contrast, chromites from nodular and disseminated ores contain abundant low-pressure OH-bearing mineral inclusions whose formation requires a more oxidizing environment. The high value of $Fe^{3+}/\Sigma Fe$ in the "reduced" massive ores is explained by stabilization of Fe^{3+} in a high-pressure polymorph of spinel deep in the upper mantle through a mechanism such as charge coupled substitution, or creation of oxygen vacancies, accompanied by Fe disproportionation to balance charge.

We suggest that the massive chromitite and their host peridotite were transported in the solid state from a highly reduced deep mantle (>300km) to an ocean spreading center. In this shallow environment they partially reacted with their host peridotite in the presence of hydrous melt, yielding the nodular and disseminated chromitite ores as proposed previously. Given that the high pressure highly-reduced mineral assemblage within the Tibetan massive chromitite is not unique, similar examinations of chromitites worldwide and high-pressure experiments on reduced Cr-rich systems should help to decipher further the missing history of the deep mantle processes that are involved in their formation.

Preservation of prograde high-pressure assemblages and textures in granulites from the Rychleby Mts., Bohemian Massif

Schlöglová, K.[*], Faryad, S.W., Dolejš, D. & Klápová, H.
Institute of Petrology and Structural Geology, Charles University, Prague, Czech Republic ([*]schloglo@gmail.com)

Mafic and felsic granulites in the Rychleby Mts. (Czech Republic and Poland) represent an high- to ultrahigh- pressure crustal segment exhumed along the eastern margin of the Bohemian Massif. These occurrences are related to the granulites and eclogites of the Sówie Góry Mts. which contain pseudomorphs after coesite [1]. Their metamorphic history can provide valuable insight into burial mechanisms of pre-Variscan crust and its exhumation during the Variscan orogeny. Mafic granulite varieties are composed of omphacite, garnet, kyanite and rutile. Garnet grains are zoned with composition ranging from Py18Gr36 in the core to Py30Gr24 in the rim, and host inclusions of omphacite and phengite; kyanite was found in the matrix only. Omphacite with 23-25 mol. % jadeite component is frequently replaced by symplectitic overgrowths of diopside, amphibole and plagioclase whereas biotite and ilmenite are secondary phases. Felsic granulites contain ternary feldspar, garnet, kyanite and quartz, with minor amounts of biotite and plagioclase formed during decompression and retrogression. Large garnet grains preserve compositional zoning, which spans Py01Gr31 in the core to Py18Gr25 in the rim. Inclusions of phengite in garnet contain up to 5.4 wt. % TiO_2 and were partially replaced by biotite. The phase assemblages of granulites and eclogites in this area reveal decompression path from high- to ultra-high pressure and high-temperature conditions - 1.8-3.0 GPa and 850-950 °C [1-4]. In addition to information gained from garnet compositional zoning and mineral inclusions, the presence of titaniferous phengite documents maximum temperatures that were reached at the transition from eclogite to granulite facies, and were accompanied by high-pressure partial melting. This scenario provides new insights into exhumation mechanisms of mafic and felsic high-pressure precursors from the continental root to the orogenic middle crust

Elasticity of serpentine: first principles investigation

Tsuchiya Jun[1*], Tsuchiya Taku[2], Usui Yusuke[2] & Katayama Ikuo[3]
[1]Senior Research Fellow Center, Ehime University, Ehime, Japan ([*]junt@sci.ehime-u.ac.jp)
[2]Geodynamics Research Center, Ehime University, Ehime, Japan
[3]Dept. of Earth and Planetary Science Systems, Hiroshima University, Hiroshima, Japan

Serpentine is formed by reaction between peridotite and water which is released from hydrous mineral in subducting slab under pressure. Partially serpentinized peridotite may be a significant reservoir for water in the subducted cold slab and is considered to play an important role in subduction zone processes such as generation of arc magmatism. Precise determination of elastic properties of serpentine is essential for estimating the degree of serpentinization, and is important for investigating the transporting processes of water into deep Earth interior. Several studies on the degree of serpentinization have been reported so far based on limited experimental data on elasticity of serpentine. Here we investigate by first principles calculation, the detailed structures and elastic properties of lizardite and antigorite which are lower and higher temperature polymorphs of serpentine up to 10 GPa at 2 GPa interval, and discuss the difference of compression mechanism and elasticity between these polymorphs.

Our calculations are based on density functional theory within generalized gradient approximation for exchange correlation functional. We calculated the crystal structure and elasticity of antigorite m=16 polysome which contains 273 atoms in primitive cell. We found the bulk modulus of antigorite and lizardite are almost same at ambient pressure, but they show significant difference at high pressure conditions. On the other hand, antigorite always has a few % larger shear modulus than lizardite presumably because of corrugated layer structure of antigorite. Combining the data from the present ab initio calculations, latest high-pressure deformation experiments with the lattice preferred orientation of serpentine and seismological observations for the velocity and anisotropy structures of subduction zones, we analyzed the degree of serpentinization and possible water content in subducting slabs.

The "Chessboard" classification scheme of mineral deposits-geology and mineralogy from aluminium to zirconium

Dill, H.G.
Bundesanstalt für Geowissenschaften und Rohstoffe, Hannover, Germany (dill@bgr.de)

Economic geology is a "*mixtum compositum*" of all geoscientific disciplines focused on one goal, finding new mineral deposits and enhancing their exploitation. The keystones of this "*mixtum compositum*" are geology and mineralogy whose studies are focused around the emplacement of the ore body and the development of its minerals and rocks. In the present study, mineralogy and geology act as x- and y-coordinates of a classification chart of mineral resources called the "chessboard" ("spreadsheet") classification scheme. Magmatic and sedimentary lithologies together with tectonic structures (1-D / pipes, 2-D/ veins) are plotted along the x-axis in the header of the diagram representing the columns in this chart diagram. 63 commodity groups, encompassing minerals and elements are plotted along the y-axis, forming the lines of the spreadsheet. These commodities are subjected to a tripartite subdivision into ore minerals, industrial minerals and gemstones/ ornamental stones.

Further information on the various types of mineral deposits, as to the major ore and gangue minerals, current models and mode of formation or when and in which geodynamic setting these deposits mainly formed throughout the geological past may be obtained from the text by simply using the code of each deposit in the chart. This code can be created by combining the commodity (lines) shown by numbers plus lower caps with the host rocks or structure (columns) given by capital letters.

Each commodity has a small preface on the mineralogy and chemistry and ends up with an outlook into its final use and the supply situation of the raw material on a global basis, which may be updated by the user through a direct link to databases available on the internet, e.g., the database of the US Geological Survey. The internal subdivision of each commodity section corresponds to the common host rock lithologies (magmatic, sedimentary, metamorphic) and structures. Cross sections and images illustrate the common ore types of each commodity. Ore is given priority over the minerals. The minerals are listed by their chemical composition and may be viewed by the reader by clicking on-line the pertinent databases, where the "showroom" varieties, seldom found in a mine, are on display.

A metallogenetic-geodynamic overview is given at the bottom of each column in the spreadsheet describing the geodynamic models put forward by the various researchers for all the deposits pertaining to a certain clan of lithology or structure. This classical or conservative view of metallotects related to the common plate tectonic settings is supplemented by an approach taken for the first time for such a number of deposits, using the concepts of sequence stratigraphy. The relationship supergene-hypogene and syngenetic-epigenetic has been the topic of many studies for ages but to keep them as separate entities is often unworkable in practice, especially in so-called epithermal or near-surface/shallow deposits. Vein-type and stratiform ore bodies are generally handled also very differently. To get these different structural elements (space) and various mineralizing processes (time) together and to allow for a forward modeling in exploration, architectural elements of sequence stratigraphy are adapted to mineral resources. Deposits are geological bodies which need accommodation space created by the environment of formation and the tectonic/geodynamic setting through time. They are controlled by horizontal to subhorizontal reference planes and/or vertical structures. Prerequisites for the deposits to evolve are thermal and/or mechanical gradients.

Major metallogenic provinces and epochs of Mexico: a review and new perspectives

Camprubí, A.
Instituto de Geología, Universidad Nacional Autónoma de México, México D.F., Mexico (camprubitaga@gmail.com)

Epithermal, porphyry, skarn, MVT, VMS, SEDEX, and IOCG deposits are the most outstanding types in Mexico. Such deposits are distributed in various metallogenic provinces that grossly mimic the distribution of major geological provinces and events. Most ore deposits in Mexico are associated with two major metallogenic domains: (1) the Pacific convergent margin and the resulting magmatism since the Jurassic, or (2) the evolution and migration of basinal brines, and diagenesis in the Gulf of Mexico basin, that formed after the breakup of Pangea. Other events like the opening of the Gulf of California have also associated other types of ore deposits. This paper is based on the typological analysis and the compilation of geochronological data of over 200 deposits.

Prejurassic deposits are relatively scarce: Ti-bearing anortosites, rare-element pegmatites (Proterozoic) and chromitites (obducted during the Ordovician) in S Mexico, barite SEDEX deposits in Sonora (Devonian), and several metalliferous mafic-ultramafic complexes in W Mexico (Paleozoic to middle Jurassic). Since the Jurassic epithermal, porphyry, skarn, VMS, IOCG "clan", rhyolite-hosted Sn and U-Au deposits, as well as other minor types formed along the Pacific margin. The metallogenic epochs associated with Pacific magmatism can be sketched as follows:

1. Middle Jurassic to Early Cretaceous in SW Mexico: mostly VMS in volcanosedimentary series;
2. Cretaceous in SW Mexico and the Pacific margin: mostly deposits in oceanic-crust or island-arc ultramafic-mafic complexes;
3. Paleocene to Early Eocene in NW Mexico and the Pacific margin: porphyry, deposits; also skarn and IOCG deposits;
4. Early Eocene to Late Eocene in NW and central Mexico: skarn and epithermal deposits;
5. Oligocene, elsewhere: mostly epithermal; several Sn and skarn deposits;
6. Final Oligocene to Early Miocene in SW and central Mexico: epithermal;
7. Middle Miocene to Present: several hypogenic and supergenic types.

The Eastern Mexican Alkaline Province deserves to be mentioned as a special case in the Pacific domain: it formed southeastwards and contains IOCG, carbonatite, agpaitic complex, porphyry, skarn and epithermal deposits, usually telescoped or overprinted.

The evolution of the Gulf of Mexico since the Late Jurassic, besides the vast majority of oil and gas fields in the country, generated important and world-class MVT, SEDEX, and red-bed Cu-U deposits all along the basin. Also, the opening of the Gulf of California since the Miocene generated several shallow SEDEX deposits during the early stages of crustal spreading, and recent VMS deposits.

See details at https://www.e-sga.org/index.php?id=1284.

Yanshanian (J-K) magmatism and metallogenesis in Taihang Mt region (China)

Dong Guochen[1,2*], Mo Xuanxue[1,2], Li Shengrong[1,2] & Qu Kai[1]
[1]China University of Geosciences, Beijing, China
([*]donggc@cugb.edu.cn)
[2]State Key Laboratory of Geological Processes and Mineral Resources, CUGB, Beijing, China;

Taihang Mt area as a part of Yanshanian orogenic belt lies in the middle part of North China Craton. It is characterized that Mesozoic intensive magmatism and related mineral deposits such as copper, molybdenum, gold, sliver, iron, lead, zinc etc. so it was named as a Yanshanian Au-Mo-Pb-Zn-Ag-Cu-Fe metallogenic belt in East China. Since Mesozoic, the orogenic belt is controlled by an intra-continental orogenic process, and Mesozoic granitic magmatism, related mineralization are the result of the processes. It was found that the middle Jurassic to early Cretaceous granitic intrusion and related mineralization widely distributed in the area and the ore deposits mainly formed during late Jurassic to early Cretaceous. The Cretaceous deposits distribute along a few NE trending fault belts. Geochemical and isotopic data proved that the ore deposits are controlled by Mesozoic granitic magmatism, and Mesozoic orogenic process. All ore-forming are related to the origin and evolution of granites.

Based on detail field investigation and former works, the authors marked clearly the location of granitic intrusion and its mineralization, established a series of Mesozoic granitic magmatism and related mineral deposits. Then geochemical and isotopic ages data were dealt with for both intrusive rocks and related ore deposits. The evidences show that magma differentiation and related metallization were formed as one continuous process. The magmatism in the process consists of temporal series from diorite → granodiorite → monzonite →granite→ lueco-granite, while the metallization is from Pb-Zn, Fe-Cu, Fe-Au, → Fe, Cu-Ag→Mo, Au, Ag → Pb-Zn, Cu. The geochemical signatures of the magma intrusions were characterized by a high K and $Mg^{\#}$ (locally), highly fractionated REE patterns (with minor Eu anomalies), high Sr-Ba abundances, and enriched Sr-Nd isotopic compositions, which were probably related to originate from both enriched mantle-derived mass and crustal materials. On the basis of the available data, magmatism and related mineralization during the early, peak and late orogenic episodes (J_2-K_1) were studied. The magma source, the division for metallogenic systems, and origin of the mineralization also discussed as a focal point in this paper.

Mineralogical mapping and its significance in Jinqingding gold-quartz lode of Jiaodong peninsula, east margin of North China Craton

Li Shengrong[*], Zhang Xiubao & Chen Haiyan
State Key laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China
([*]lisr@cugb.edu.cn)

Jinqingding gold-quartz lode is located in the center of Muping-Rushan gold belt within the Kunyushan monzonitic granite, the eastern margin of the North China Craton in Jiaodong peninsula, Shandong Province. The gold-quartz lode extends and plunges northeastly for > 900m along the Jiangjunshi fault, and dips steeply with angle of 75-85° for > 1100m towards southeast. The lode is pyrite-rich with gold reserves greater than 50 tonnes. Although more than 10 tunnels and 40 exploring holes had been completed, the gold enrichment regularity was not revealed and margin of the orebody had not been clearly delineated before 1991. Having conducted numerical processing, 10 mineralogical parameters were adopted for mapping the pyrite-rich gold-quartz lode. For the case of quartz, the parameters include integral intensity (R) of natural thermoluminescence, distribution density (Nf) of fluid inclusions, homogenization temperature (T) of fluid inclusions, infrared optical density of CO_2 (DCO_2), infrared optical density of H_2O (DH_2O), DCO_2/ DH_2O, and the number of structural zones (Nz). For pyrite, the parameters include crystallomorphological ballotage score (Y), percentage of thermoelectric conduction P-type of pyrite (P%), and average thermoelectric coefficient value (α). Beside the first author's work, Yang L.X. (1993) selected another 2 parameters for pyrite, namely the a0 value of the cell and the infrared spectral peak value (υs-s). The maps with T and Nz as parameters show mainly the flowing tracks of the ore-forming fluid, namely one major stream and 2 branches flowing upwards from northeast down to southwest upper. The frontier of the flowing fluid found at around –200m level have pulsated many times. The areas with small variation gradient at about –300m and –500m levels were stable metallogenic domains and suitable for gold to precipitate forming thick and rich gold ore sectors (pay sectors). This conclusion matches with the known high value areas of the gold grade contours. Other maps, in different precision, indicate the controlling of NE and SW plunged fracture systems to the major orebody and the pay sectors respectively. It is interesting that the pay sectors tend to 'float' in the major orebody and plunged southwest. It means that the ore-forming fluid not only flowed towards southwest upper in the main stream and 2 branches, but also flowed towards northeast upper in the southwest plunged fracture system. Based on these considerations, combined with other geological studies, the authors concluded that the area between exploration lines 17 and 19, and at the levels of –200m and –500m, should be payable for further exploration by tunnels, although previous drilling (more than 5 holes) had 'proved' to be hopeless. It is also revealed that the pay sectors tend to occur repeatedly along the lode plunge and the gold mineralization intensity decreases from the level of –200m to –700m. Later tunnel and drilling exploration had given abundant return and more evidences for the above mentioned regularity of gold enrichment.

Identification of bauxite deposits with the aid of remote sensing techniques (case studies)

Komlóssy, G.
Geo-Kom Geological Exploration Ltd., Budapest, Hungary
(geokom@mail.datanet.hu)

In recent years companies interested in developing their bauxite–alumina industries are in competition to find new bauxite sources. Although, in the past decade, huge deposits have already been explored and developed, there is now greater pressure to operate even more efficiently and a continuing need for additional ore reserves.

During the past decade the author, with co-operation of his GIS, has applied remote sensing techniques in identification of laterite bauxite deposits. The method elaborated with co-operation of the Remote Sensing Division of the Ministry of Agriculture (Budapest – Hungary) has been proven to be useful in delineation of prospect areas to serve different targets:

(1) establishing of further prospects in the vicinity of formerly discovered occurrences, deposits;

(2) identification of new deposits in promising bauxite districts.

The methods applied are basically Shuttle Radar (SRTM) and Thematic Mapping (TM) techniques with different channel combinations and also complex terrain model analysis for a special case. The method is fitted to the given bauxite geological conditions (geology, geomorphology, altitude, relative elevation, etc.) which vary at different places. Since no standardisation can be introduced, the technical process should be elaborated for each target area. The basis of the procedure, (where possible) is the investigation of the already discovered deposits (explored bauxite contours - actual data) from which the prognostic chart (forecast) can be made. Reliability of the Land-Sat maps needs checking at site, and calibration and modification of the procedure to be done accordingly.

The author in his contribution gives an overview on his experiences (both successes and failures) achieved in India (East Coast), Indochina (Laos, Cambodia and Vietnam) Indonesia (West Kalimantan), West Africa (Guinea Bissau, Guinea, Ghana), Guiana Shield (Venezuela, Guyana and Suriname) and Brazil. The interpretation, in some cases, has proved to be fairly exact, so that even a resource estimate in hypothetical category is possible. In other cases their reliability is much less, and no more than delineation of prospect areas can be indicated with acceptable probabilities. Investigation of the hydrogeological (leaching) condition of the parent rock is essential. Field checking, measuring the bias with GPS, is important.

Mineralizations of Tantalum and Niobium in Vichada and Guainía, eastern part of Colombia

Cramer, T.[*], Bonilla Pérez, A., Amaya Perea, Z., Franco Victoria, J.A. & Iregui Ramírez, I.
Dept. of Geosciences, Universidad Nacional de Colombia, Bogotá, Colombia ([*]thcramer@unal.edu.co)

At the end of 2009, the Colombian public opinion was surprised by news about the presence of "Coltán", mineralizations of Tantalum and Niobium in the Amazonas and Orinoco region of Colombia, in spite of an informal exploitation during years. Our group has been working with samples, which we had recollected in the last two years in Matraca and other places in the Colombian rainforest [1].

The main Ta-Nb-occurrences are alluvial concentrations of "black sands" produced by tropical weathering, transport and depositation in old and recent riverbeds. The placer grains (Fig. 1) are accompanied by normally smaller magnetite, hematite and titanite grains. The chemical element composition of the heavier minerals (D > 4,5g/cm^3), determined by means of a recently acquired Bruker Tracer V-III XRF instrument, is highly variable and sometimes exceeds 50% Ta, 20% Nb, the rest being mainly Fe and Ti. Mn is nearly never present, indicating that the minerals are not tantalite/columbite sensu strictu. In some cases, cassiterite with tantalium (Sn 90-99%, Ta 0-9%) predominates in the black sands.

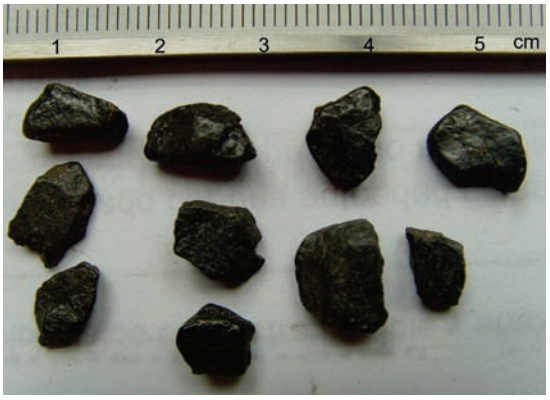

Fig. 1: Grains of alluvial Ta- and Nb-minerals.

Table 1: Average mineral composition of the pegmatitic dykes

Normalized minerals	*%*
Quartz	37
Albite	35
Microcline	28
Biotite, Fe-poor	2
Sericite	1

In some parts of the difficult-to-access area, pegmatitic dykes and lenses are present, which are assumed to be the primary enrichment sources of the Ta-, Nb- and Sn- mineralizations, although we did not find them in the samples. The visible unweathered micas are Fe-poor biotites, and microscopically in the feldspars quartz and altered sericite inclusions can be observed.

The results are preliminar, but indicate the presence of larger economically exploitable Ta-, Nb- (Sn-, Ti?) mineralizations in the Colombian area of the ancient South American Guayana-Shield, which until now is poorly understood. Hopefully, they will contribute to estimulate more detailed mineralogical, geochemical, isotopic and geological research activities, which do not exclude social and environmental aspects.

REE and their relevance to the development of the Kupferschiefer copper deposit in Poland

Sawlowicz, Z.
Institute of Geological Sciences, Jagiellonian University, Krakow, Poland (zbigniew.sawlowicz@uj.edu.pl)

Over hundred samples, representing different ore sections which contain carbonate-rich shales (Kupferschiefer) and hanging-wall dolomites (Z1 Werra) have been collected in different mines of the Lubin-Glogow mining district, mainly near the contact (transitional zone) between the copper-mineralized zone and secondarily oxidized (Rote Fäule-RF) zone. In general, the Polish Kupferschiefer shales are enriched in MREE in comparison to NASC. In a typical copper-rich section the REE amounts and patterns depend on lithologies, being generally similar in shales and dolomite. ΣREE vary among sandstones, shales and dolomites (average 73, 143 and 85 ppm, respectively), probably reflecting their clay contents.

The REE patterns of shales from the mineralized Cu-zone are generally convex (MREE enriched) and have negative Eu anomalies. However, in a section with Cu-, Zn- and Pb- shales the REE pattern of Pb-bearing shales shows a positive Eu anomaly, in contrast to other shales and overlying dolomite. More oxidizing conditions of deposition can be assumed for Pb-shales, as was also suggested by a study of Ph/Pr ratios of organic matter [1].

No significant differences between REE distributions in transitional and oxidized zones have been observed. Their REE patterns are more convex and are much higher (av. 247ppm) than those in the mineralized zone and they do not show Eu anomalies. The strongly convex pattern may suggest either enrichment in MREE or relative depletion in LREE due to localized precipitation of light REE minerals, both in shales and in the uppermost part of the sandstones**.** Sandstones have strongly convex REE patterns with positive Eu and negative Gd anomalies and depletion in LREE and enrichment in MREE relative to HREE. The REE patterns of shale and dolomite are similar and rather flat, with strong negative Eu anomalies, and a small positive Gd anomaly in the case of shales.

Two unusual sections, one Cu-rich and one Cu-lean (partly oxidized), comprising three shale beds interbedded with dolomites have been compared. Generally ΣREE contents are similar in these two sections. Also similar are contents of REE between beds in both sections, which decrease significantly upwards (from 157-171 ppm to 54-60 ppm). The REE patterns of the lowermost beds (directly overlying sandstones) are ramp-like, with LREE enrichments. The upper beds have concave REE patterns. Comparison between sections shows generally stronger negative Eu and positive Gd anomalies in the highly-mineralized section.

There is a highly significant positive relationship between Cu and∑REE contents in Cu -rich shales and slightly less significant for their concentration in oxidized and transitional shales.

The observed differences in REE contents cannot be provenance dependent but have been caused by diagenetic processes, possibly related to the ore mineralization and the oxidation. Europium anomalies, generally reflecting different Eh conditions in the deposit, can be eliminated by the prolonged oxidation. Strong enrichment of the RF zones in REE may result from their desorption from large volumes of oxidizing, including mineralizing, solutions which probably emerged from the underlying molasse lithologies into the Rote Fäule areas. Higher contents of REE in the lowermost shales suggest upward movement of solutions from the underlying sandstones also far away from the RF areas.

Genetic and age relationship of base metal mineralization along the Periadriatic-Balaton Lineament system on the basis of radiogenic isotope studies

Benko, Zs.[1*], Molnar, F.[1], Billström, K.[2], Pecskay, Z.[3] & Lespinasse, M.[4]
[1]Dept. of Mineralogy, Eötvös Lorand University, Budapest, Hungary ([*]benko.zsolt@ttmk.nyme.hu)
[2]Laboratory of Isotope Geology, Natural History Museum, Stockholm, Sweden
[3]Institute of Nuclear Research, Hungarian Academy of Sciences (ATOMKI), Debrecen, Hungary
[4]UMR CNRS 7566 G2R; University HP-Nancy 1, Nancy, France

The Late-Palaeozoic granite intrusion of the Velence Mts. (W-Hungary) and the Early-Palaeozoic metasedimentary block of the Koszar-hegy are located along the Periadriatic-Balaton Lineament System which is a major fault between the Southern and Eastern Alps as well as between the ALCAPA and Tisa Megaunits of the Pannonian basin. Both Palaeozoic blocks are hosts of quartz-galena±sphalerite±fluorite vein type mineralization. According to the most accepted theory, formation of the base metal sulphide veins of the Velence Mts. can be related to a hydrothermal system developed by the cooling host granite. However, several fluid inclusion data and radiometric age dates suggest that the formation of the veins cannot be simply derived from the granite. In case of the Koszár-hegy mineralization, Carboniferous, Triassic and Palaeogene ages were also put forward but no direct evidences confirmed these theories.

In order to determine the source rocks, and indirectly the age of mineralization, detailed radiogenic isotope analysis (Pb-Sr-Nd) have been carried out on galena, sphalerite, fluorite, calcite and on the potential source rocks (Early-Palaeozoic schist, Carboniferous granite, Permian sandstone, Oligocene andesite).

Results have proven that the mineralization hosted by the granite cannot be derived from a single source rock (e.g. from the granite) and the Oligocene andesite certainly couldn't be the source rock of lead for the ore minerals. The remaining potential source rocks are the Carboniferous granite and different Early-Palaeozoic metamorphic-metasedimentary rock types. Isotope data of the two localities show a limited variation indicating a similar source rock and age for the two occurrences. Comparing the new isotope data with data of the Triassic Alpean-type carbonate-hosted stratiform-stratabound Pb-Zn mineralizations and their source rocks located along the Periadriatic Lineament system in the Eastern and Southern Alps, the similarities are obvious. Fluid inclusion properties and ore paragenesis are also similar, and therefore a common origin of these ore mineralization is suggested. This conclusion, however, isn't surprising in light of the Alp-Carpathian geodynamics: by the time of the Triassic both investigated localities were located in their original position, e.g. in the region of the Alpean deposits. Their displacement took place by the time of the Late-Palaeogene - Early Neogene. According to our model, veins in the Velence Mts. granite and in the Early-Paleozoic carbonate at the Koszar-hegy represent deeper zones of the shallow level Alpean type carbonate hosted Pb-Zn deposits. The shallow, carbonate hosted stratiform level of the studied mineralization, however, had been eroded or sheared down from its base due to the Alpean orogenesis.

Styles and stages of the Rudabánya base metal mineralizations, Hungary

Földessy, J.[1*], Németh, N.[1], Kristály, F.[1], Zajzon, N.[1], Kupi, L.[1], Majoros, P.[2] & Gerges, A.[2]
[1]Institute of Mineralogy and Geology, University of Miskolc, Hungary ([*]foldfj uni-miskolc.hu)
[2]Rotaqua KFT, Hungary

Rudabánya, an iron ore mine closed in 1986, lies in NE-Hungary, in a region which was traditional host of mining (ores, lignite, brown coal, non-metallics.

Its annual iron ore production reached a pick of around 1 million tonne/year in the 1970s. In the last active years copper ore was found in small orebodies and mined.

Its new exploration has started in 2007 after careful geological remodelling of the deposit, and verifying its potential for base metals. The deposit is hosted in a major shear zone, formed in Triassic dolomites and siltstones, the NNE-SSW Darnó zone. A major porphyry and skarn copper mineralization, Recsk, lies along the same zone, some 80 km SSW from Rudabánya. The iron ore is dominantly siderite origined from the metasomatic alteration of dolomites, with extensive limonites in the oxidized cap. The base metal ores are partly stratiform in sediments, partly superimposed and younger than the siderite mineralization.

In the 2600 previous drillhole logs there are numerous indications of base metal ores. Copper mineralization was also known from the surface as supergene enrichment. The existence of low grade Pb mineralization was also known, but the Zn mineralization has been discovered recently and considered to be widespread through different lithologies and alteration zones. At least four major stages of ore mineralization have affected the host lithologies, from the Triassic until the Paleogene.

The new geological model has been tested on the field by detailed re-mapping of surface outcrops, partial revision of acccessible underground workings, surface geochemistry, trenching and shallow drillholes. All these methods have supported the geological model and allowed to discover a major multi-stage ore occurence, yet to be explored in detail.

Fig. 1: Position of the Rudabanya mineralization in the Carpathian belt.

Mineral assemblages of Cu-Sn-sulfides as indicators of HS-IS transition in epithermal environments

Kovalenker, V.A.[*] & Plotinskaya, O.Yu.
Institute of Ore Geology, Petrography, Mineralogy, and Geochemistry RAS Moscow, Russia ([*]kva@igem.ru)

Ores of numerous epithermal deposits referred to HS type, e.g., Akturpak, Kairagach, Kochbulak (Kurama Mountains, Middle Tien Shan), Bereznyakovskoe (South Urals), Lahoca, Chelopech, Elshica, Radka (Carpathian-Balkan region), El-Indio (Ands), Ozernovskoe (Kamchatka) etc., contain large group of minerals, with Cu, Sn and S as major components, and with variable amounts of Fe, As, Sb, Mo, V, Ge. This group includes both well known (e.g. stannite, këserite, stannoidite, mawsonite, colusite, hemusite), and recently discovered minerals (mohite, kuramite, nekrasovite, vinciennite, chatkalite), as well as several unnamed phases.

The Kochbulak gold deposit (Middle Tien Shan) was chosen as a key example to reveal spatial and temporal peculiarities of Cu-Sn sulfides distribution within an HS epithermal system. The earliest mineralization of the Kochbulak deposit is represented by pipe-like ore bodies. At shallow levels of these bodies kuramite Cu_3SnS_4 and mohite Cu_2SnS_3 occur in assemblage with goldfieldite, enargite, famatinite, alunite, diaspore, pyrophyllite (typical minerals for HS environment), and with native gold (~ 900‰) and Au ditellurides. At deeper levels as well as at neighboring Akturpak and Kairagach deposits Cu-Sn-sulphides are represented by mawsonite $Cu_6Fe_2SnS_8$, chatkalite $Cu_6FeSn_2S_8$, stannoidite $Cu_8Fe_3Sn_2S_{12}$, nekrasovite $Cu_{26}V_2Sn_6S_{32}$, and by few unnamed phases ($Cu_{10}Fe_3Sn_3S_{12}$, $Cu_{10}Fe_2Sn_4S_{12}$, $Cu_{11}Fe_2Sn_3S_{16}$). They coexist with tetrahedrite-tennantite, chalcopyrite, electrum (~ 800-860‰), Au-Ag-tellurides and sericite. Vein bodies of the Kochbulak deposit represent later mineralizing stage. Hemusite Cu_6MoSnS_8 and stannite-këserite $Cu_2(Zn,Fe)SnS_4$ associate here with electrum (500-650‰), petzite, and hessite.

Mineral assemblages listed above evidence an evolution from high to low oxidized environment and from high to low sulfidation state of the fluids: from the formation of enargite (famatinite) (As^{5+}, Sb^{5+}), goldfieldite (Te^{4+}) and high Cu minerals of the Cu-Fe-Sn-S system to stability of tetrahedrite-tennantite (Sb^{3+}, As^{3+}) and chalcopyrite. The transition to lower sulfidation state is accompanied by pH increase: from alunite, diaspore, and pyrophyllite to sericite.

Thus, the data obtained allow considering Cu-Sn-sulphides as indicators of HS to IS transitional zones.

Geochemistry of indium-bearing sphalerite from Toyoha polymetallic deposit, Japan

Shimizu, T.* & Morishita, Y.
Geological Survey of Japan, AIST, Tsukuba, Japan
(*t.shimizu@aist.go.jp)

Sphalerite (ZnS) is an economically important indium-bearing mineral, as indium is mainly produced from zinc concentrates for high technology applications (e.g., Liquid Crystal Display). Our study presents electron microprobe analyses and fluid inclusion study of indium-bearing sphalerite to decipher the chemical environment of indium mineralization. Toyoha was one of the largest xenothermal Zn-Pb-Ag-Cu-Sn-In deposits in Japan. Indium mineralization occurs southeast of the deposit. The ore veins locally contained more than 1000g/t In. Indium-bearing minerals are typically indium-bearing sphalerite and unnamed Zn-In mineral ($CuZn_2InS_4$) with lesser stannite, kesterite, roquesite, sakuraiite and chalcopyrite [1].

The inspection of X-ray and optical microscopes shows that indium-bearing sphalerite occurs as crustiform bands with the maximum thickness of 2mm. Its color varies from black (opaque) to dark-red (translucent) in thin sections. The crustiform bands show invisible oscillatory variation in In, Sn, Cu, Ag and Fe contents. The metal concentrations in sphalerite vary: 0.06-3.63 atom.% In, 0.00-1.67 atom.% Sn, 0.22-3.55 atom.% Cu, 0.00-1.21 atom.% Ag and 2.98-6.22 atom.% Fe. These data show that Cu+Ag and In+Sn are close to 1:1 in atomic proportions; the compositions of indium-bearing sphalerite can be expressed as $(Cu, Ag)_x(Zn, Fe)_{(4-2x)}(In, Sn)_xS_4$, where x is between 0 and 0.29. Near-infrared and visible light microthermometry was applied to fluid inclusions in indium-bearing sphalerite with U.S.G.S gas flow heating/freezing stage. Primary liquid-rich fluid inclusions occur along growth bands of which indium and iron contents are 0.17-0.70 and 3.00-3.96 atom.%, respectively. Homogenization temperatures (Th) range between 281 and 288°C. Assuming that pressure correction can be neglected, the obtained Th represents formation temperature of indium-bearing sphalerite. The consistent Th are lower than mineral equilibrium temperature (350-400°C) among polymetallic sulfides [2], but they are close to the highest value of Th range (150-300°C) from quartz and transparent sphalerite that were not contemporaneous with the indium mineralization [2]. Our obtained Th (281-288°C) are within a range of calculated closure temperatures (290±30°C) of indium-bearing sphalerite from Grandchamp polymetallic vein deposit, Loire, France [3] and measured precipitation temperatures of In, Cu and Zn (280-350°C) of an active hydrothermal vent in the Southern Lau Basin, SW-Pacific [4]. These temperature comparisons suggest that the range of our obtained Th (281-288°C) represents a minimum indium-precipitation temperature at Toyoha. The similarity of the minimum indium-precipitation temperatures between 260 and 290°C among different ore deposits suggests that a careful comparison of Th combined with chemical analyses of sphalerite enables us to distinguish between indium-enriched and barren zones of the deposits. This attempt of distinction may be useful for indium exploration.

Considering the pyrite-sphalerite assemblage, FeS (6.0-8.0 mol%) in sphalerite, sulfur fugacities of indium mineralization were calculated as a range between $10^{-11.4}$ and $10^{-10.8}$ atm using Th from the indium-bearing sphalerite (281-288°C). This sulfur fugacities-temperatures relationship corresponds to an intermediate sulfidation state [5].

Micro- and nanomineral assemblages are indicators of typification and searching for gold

Koneev, R.I.
Dept. of Mineralogy and Geochemistry, Faculty of Geology, National University of Uzbekistan, Tashkent, Uzbekistan
(rkoneev@yahoo.com)

The appearance of new directions – nanomineralogy and nanogeochemistry created conditions for new approaches to research, classification, exploration, evaluation of gold ore deposits. It is available now the systematization of the deposits on the basis of direct signs – peculiarities of gold and elements, defining its metallogeny (Au, Ag, Te, Se, Bi, Sb, As, Hg) and not on indirect indicators – quartz, carbonate, sericite, adularia, kaolin.

Long-term research on gold and gold-silver deposits of Uzbekistan (Muruntau, Daugyztau, Charmitan, Kochbulak, Kyzylalmasay and others) determined that independently from host rocks they all were formed by standard row of geochemical paragenesis: /Au-W/Au-As/Au-Te/Au-Ag/Au-Sb/Au-Hg/. Certain nanoassemblages of minerals, micro- and nanominerals are appropriate for each parageneses:

Au-W – nanogold, scheelite, wolframite, tungstenite, molybdenite, cassiterite;

Au-As – nanogold, arsenopyrite, pyrite, loellingite, gersdorffite, cobaltite;

Au-Te – maldonite, calaverite, hedleyite, tsumoite, petzite, hessite, tetradymite, kawazulite, altaite, tellurantimony, golfieldite, annivite;

Au-Ag – electrum, custelite, freibergite, stephanite, polybasite, pyrargyrite, prustite, acantite, naumannite, aguilarite, servellite;

Au-Sb – aurostibite, antimonite, boulangerite, zinkenite, jamesonite, gudmundite, meneghinite, andorite, owyheeite, eucairite;

Au-Hg – Au amalgam, kongsbergite, cinnabar, realgar, schwatzite, tiemannite, crookesite.

Depending on geodynamical position, depth of formation, vertical and lateral zoning, erosion cut the industrial resource of the deposit is determined by 2-4 paragenesis. For instance, Muruntau – /Au-W/Au-As/Au-Te/, Charmitan – /Au-W/Au-As/Au-Te/Au-Sb/, Kochbulak – /Au-As/Au-Te/. Au-As arsenopyrite-pyrite mineralization is developed on all deposits and all subsequent ones are combined with it. /Au-As/+/Au-Hg/ form the Karlyn-type. The form of elements changes with the depth. Bi tellurides form on hypoabyssal levels (Muruntau), on epithermal – Au, Ag, Pb, Sb, Hg (Kochbulak). The presence or absence of separate parageneses determines type, erosion cut, perspectives and scales of the object. The more and various the composition of micro- and nanoassemblages of gold is, the more the deposit is.

Mass loss in chromite and ferritchromite formation during metamorphism of chromite ores in the Golyamo Kamenyane serpentinite massif (Eastern Rhodopes, Bulgaria)

Gervilla, F.[1*], Kerestedjian, T.[2], González-Jiménez, J.M.[1], Sergeeva, I.[2] & Hadjiev, A.[2]
[1]Dept. of Mineralogy & Petrology, University of Granada, Spain ([*]gervilla@ugr.es)
[2]Geological Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria

The Golyamo Kamenyane massif is a portion of a metaophiolite, located in the Upper high-grade unit of the metamorphic basement of Eastern Rhodopes [1]. The regional-scale tectonic setting is dominated by two late Alpine metamorphic core complexes, (Kesebir-Kardamos and the Biala Reka-Kechros) domes [2], flanking the considered metaophiolite. The massif mainly consists of serpentinized dunites and harzburgites, containing several chromitite pods and asbestos veins. Serpentinites also contain rodingite layers in their upper part and are topped by metagabbros.

Chromite from chromitites can be classified into three textural groups: i) zoned chromite; ii) porous chromite, and iii) homogeneous chromite. Zoned chromite shows unaltered, Al-rich cores with unit cell size (according to Guinier powder diffraction data) of 8.26(3) Å and Cr#[Cr/(Cr+Al)]=0.50-0.60, Mg#[Mg/(Mg+Fe^{2+})]=0.60-0.70 and $Fe^{3+}/(Fe^{3+}+Fe^{2+})$=0.20-0.30, surrounded by porous chromite, having cell size of 8.33(2) Å, $Fe^{3+}/(Fe^{3+}+Fe^{2+})$<0.20 and values of the Cr# and Mg# evolving from 0.60 to 0.90 and 0.60 to 0.47 from core to rim, respectively. Porous chromite has a relatively homogeneous composition varying within the following ranges: $Fe^{3+}/(Fe^{3+}+Fe^{2+})$=0.20-0.52, Cr#=0.92-0.97 and Mg#=0.35-0.48. Its unit cell sizes also vary in the range 8.35(1)-8.36(1) Å. Most pores are filled with clinochlore. Homogeneous chromite has $Fe^{3+}/(Fe^{3+}+Fe^{2+})$=0.55-0.65, Cr#>0.96, Mg#=0.32-0.20 and cell size of 8.38(1) Å.

Zoned chromite is the most abundant and can be interpreted as the result of reaction between the primitive, Al-rich chromite (+H_2O) and either olivine or antigorite, during an early metamorphic stage. This reaction forms Cr-rich chromite (and clinochlore) by progressive loss of Al_2O_3 and, at lesser extent MgO and Fe_2O_3, with no addition of FeO. Change in chromite takes place with less than 1% increase of specific volume, insufficient to compensate the mass loss. The reaction can progress until the primitive core is completely consumed, giving rise to the porous chromite.

During a later stage, oxidizing metamorphic fluids percolated through the pores of chromite, supplying Fe_2O_3 and FeO to form ferritchromite, dissolving clinochlore, eliminating the porous texture and promoting chromite recrystallization. In fact, the Fe-richest ferritchromite tends to exhibit euhedral habit or polygonal texture.

Modification of chromite to ferritchromit in the Archaean Nuggihalli Schist belt, Western Dharwar Craton (southern India)

Mukherjee, R.[1] & Mondal, S.K.[1,2*]
[1]Dept. of Geological Sciences, Jadavpur University, Kolkata, India
[2]NordCEE, Geological Museum, Natural History Museum of Denmark, University of Copenhagen, Denmark
([*]skmondal@snm.ku.dk)

Reflected light and scanning electron microscopic (SEM) study of chromites in the Archaean Nuggihalli Schist belt, Western Dharwar Craton, southern India, reveals a compositionally zoned character of the grains. In the Nuggihalli chromitite deposits ferritchromit is identified as relatively higher reflectant rims around the chromite, vestiges of which occur as dark rounded islands at the centre. Sometimes, ferritchromit occurs along fractures and as patches within the grain. Detailed electron probe micro-analysis (EPMA) shows a compositional change in the chromite where cations like Cr (core 9.32%; rim 8.68%) Al (core 4.81%; rim 0.81%) and Mg (core 2.12%; rim 0.93 %) are lost from the core and consequently substituted by cations like Fe^{3+} (core 1.6%; rim 5.85%), Ti (core 0.05%; rim 0.15%), Mn (core 0.16%; rim 0.24%) and Ni (core 0.004%; rim 0.03%) towards the ferritchromit rim. This type of zoning is attributed to differences in cation mobility during diffusion. Among the cations that diffuse out of the grain Al has the highest mobility relative to Cr and Mg, while for the cations that enter the grain Fe^{3+} has the greatest mobility relative to Ti, Mn and Ni.

Formation of ferritchromit is most intense in accessory chromite within serpentinite and in chromite within silicate-rich chromitite such that some of the chromite grains are completely replaced by ferritchromit composition. Zoning is no longer optically discernible in these grains, which appear homogeneous. Compositional profiling of these grains show substitution of only Cr by Fe^{3+} with progressive alteration. The cores of completely altered grains are reset as understood from their much lower Cr (9.29%), Al (4.80%) and Mg (2.11%) values compared to the unaltered chromites (Cr 12.74%; Al 3.27%; Mg 4.66%) in massive chromitite.

In the chromite compositional space ferritchromit formation is represented by a trend of extreme Al loss ((Cr/(Cr+Al) cation ratio ~ 0.98) and strong enrichment of Fe^{3+} in the chromite grains. The former is explained by the formation of secondary chlorites and the latter is explained by the prevalence of oxidation conditions during alteration. Low temperature hydrothermal alteration during serpentinization was responsible for the formation of ferritchromit in Nuggihalli. This is understood from the specific occurrence of ferritchromit around grain boundaries and fractures, as these are the usual pathways for fluid interactions. Although the chemistry of ferritchromit remains largely uniform in different types of occurrences, the intensity of alteration varies greatly between them and also between different deposits, indicating a heterogeneous nature of alteration and probable involvement of fluids. Complete alteration of the grains to ferritchromit and modification of the chromite core is explained by later metamorphism of the rocks because of consequent increase in the capacity for cation diffusion.

Sulfur isotope constraints for a dynamic magmatic sulfide ore deposition model in the sill-like South Kawishiwi Intrusion of the Duluth Complex, Minnesota, USA

Molnár, F.[1*], Peterson, D.[2], Arehart, G.B.[3], Poulson, S.[3] & Hauck, S.A.[4]
[1]Eötvös Loránd University, Budapest, Hungary
([*]molnar@abyss.elte.hu)
[2]Duluth Metals Ltd., Minnesota, USA
[3]University of Nevada, Reno, Nevada, USA
[4]Natural Resources Research Institute, University of Minnesota, USA

The 1.1 Ga old Duluth Complex (DC) is the second largest mafic intrusion on Earth and probably contains the largest undeveloped magmatic Cu-Ni-(Co)-PGE ore resource [1]. The troctolitic sill-like South Kawishiwi Intrusion (SKI) of the DC currently hosts three major magmatic sulfide deposits: the Spruce Road deposit (529 Mt, 0.43% Cu, 0.15% Ni); the Nokomis deposit (449 Mt, 0.63% Cu, 0.2% Ni, 0.6 g/t Pt+Pd+Au); and the Birch Lake deposit (195 Mt, 0.53% Cu, 0.16% Ni, 0.93 g/t Pt+Pd+Au). These deposits are located along the contact of the SKI and the monzonitic Giant Range Batholith (GRB) of Archean age in the footwall. The basal mineralized zone (BMZ) of the SKI is highly heterogeneous: rock compositions range from norite to melatroctolite-troctolite-anorthosite-olivine gabbro with fine- to coarse-grained ortho- and adcumulate and pegmatitic textures. The BMZ contains assimilated inclusions of GRB, BIF and metapelite. Charnokitisation of GRB is espe-cially strong along the major conduits of the parent melts of SKI. The BMZ hosts fractionated ore in the forms of inter-cumulus patches of chalcopyrite, cubanite, pentlandite and pyrr-hotite with local semi-massive, replacive, less-fractionated ore with pyrrhotite, pentlandite and chalcopyrite along the immedi-ate contact. Disseminated ores in the footwall have replacive-infiltration texture with enrichment of chalcopyrite and bornite away from the contact. The highest sulfur isotope compositions (from +5 to +12‰ $\delta^{34}S$) of sulfides and whole rock samples occur along the contact, with a systematic gradual decrease in $\delta^{34}S$ to around 0‰ upward within the BMZ. Ore in the footwall and in association with footwall inclusions is also characterized by the heavy sulfur isotope signature. Another aspect of spatial distribution in the $\delta^{34}S$ values in footwall ores is that more positive values occur under the northern and southern parts of SKI (Spruce Road and Birch Lake deposits) in comparison to the central part (Nokomis Deposit). This distribution is largely coincident with occurrences of 'confined' (metal enrichment at the top of BMZ) and 'open' (metal enrichment at the bottom of BMZ) style of distribution of metals in the SKI and thus confirms that the footwall/SKI interaction had an important role in defining styles of mineralization. Observations support a dynamic model for ore deposition consisting of early accumulation of magmatic sulfides from the mantle-derived and metal-laden mafic melts along the contact and in the footwall due to custal sulfur assimilation and assimilation of some parts of the more SiO_2 and alkali rich footwall rocks, followed by superimposed sulfur isotope exchange between the early stage ores and later pulses of sulfur-undersaturated melts moving above the early stage sulfide mineralisation. This model offers keys for understanding the Cu- and PGE-enriched nature of ores in the BMZ, and suggests that re-mobilized volatile sulfur was included in the ore-forming processes.

Mineralization in the Kamsdorf ore field, Thuringian Basin, Germany

Brey, M.[*] & Majzlan, J.
Institut für Geowissenschaften, Friedrich-Schiller-Universität, Jena, Germany ([*]Maria.Brey@uni-jena.de)

The Thuringian sedimentary basin is a series of Upper Permian and Triassic strata (Zechstein, followed by Buntsandstein, Muschelkalk, and Keuper). The Tertiary tectonic activity uplifted the marginal portions of the today's basin where the pre-Permian rock complexes are exposed [1].

In our work, we concentrate on the mineralization of fissures in and around the Thuringian Basin. For this purpose, samples were taken in Kamsdorf, situated at the SE-Zechstein fringe at the interface between the basin and the uplifted horst (*Thüringer Schiefergebirge*). Hydrothermal veins and lenses pervade the Rotliegendes up to the Zechstein [2] (Lower to Upper Permian) and are either vertical or horizontal. The mineralization consists mostly of barite, calcite, and dolomite (Ca/(Ca+Mg)~0.52 to 0.59), and locally quartz. The primary fluid inclusions in barite are biphasic (liquid > vapour).

The ores were analysed by means of reflected-light microscopy, X-ray diffraction, and the electron microprobe. The principal ore mineral is tetrahedrite, with 2.1 to 4.0 Sb apfu. In some analyses, the arsenic component dominates (Sb/(Sb+As)<0.5 to 0.39). The fahlores are zinc-rich and silver-poor, with these concentrations: Cu 33.4 to 39.5 at%, Fe 0.32 to 3.2 at%, Ag 0.4 to 0.7 at%, Hg 1.3 to 1.5 at%, and Zn 3.4 to 8.5 at%). Furthermore, we found siderite, chalcopyrite, pyrite, arsenopyrite, Co sulfarsenides, subordinate sphalerite, galena, and secondary minerals such as malachite, covellite, goethite, and cerussite.

The paragenesis of the ore minerals and the fluid inclusions are used here as indicators of the chemical composition and the physical properties of the hydraulic fluid system that circulated in the Thuringian Basin during the Mesozoic.

Metamanganolites of Ural (Russia): mineralogy and genesis

Brusnitsyn, A.I.[1] & Zhukov, I.G.[2*]
[1]Faculty of Geology, St. Petersburg State University, St. Petersburg, Russia
[2]Institute of Mineralogy, Ural Division, Russian Academy of Sciences, Miass, Russia ([*]igorzhukov2009@yandex.ru)

We use "metamanganolite" term to describe metamorphic rocks of sedimentary or hydrothermal-sedimentary genesis, with different mineral composition. The study on these rocks, using as example the Ural manganese deposits (Kyzyl-Tash, Faizulino, Bikkulovo, Kozhaevo, Urazovo, Malosedelnikovo, Kurganovo, Borodulino, Parnok, etc.) has shown that:

1. More than 60 mineral species are known in manganese ores. They form three types of mineral assemblages: (a) assemblage of the main volume of orebodies formed during low-grade regional metamorphism, (b) assemblage of segregated and metasomatic veinlets that fill the systems of late tectonic fractures, and (c) assemblage of near-surface supergene minerals. The most part of minerals are metamorphic silicates.

2. During regional metamorphism of Mn-bearing sediments, the character of metamorphic assemblages and chemical composition of minerals were controlled by petrogenic elements (Mn, Fe, Ca, Mg, Al, and Si) ratio and organic matter (OM) distribution therein, dissolution of which regulated carbon dioxide and oxygen balance in pore solution. OM-bearing sediments were replaced by oxide-carbonate-silicate rocks mostly composed of Mn^{2+} silicates and carbonates (tephroite, pyroxmangite, rhodonite, rodochrosite, etc.), andradite, quartz, hematite, and hausmannite; and OM-free sediments were transformed into oxide-silicate rocks with predominant braunite (silicate of Mn^{3+}) and quartz.

3. Crystallization of Mn silicates is possible at the early stages of metamorphism at T≈ 200 –260 °C and P= 2–3 kbar. Caryopilite and hydrosilicates (friedelite, bementite, parsettensite, etc.) are typical minerals of low-temperature metamorphic Mn rocks. Presence of Mn-Si gel in primary sediments is a favorable condition of low-temperature crystallization of silicates (rhodonite, pyroxmangite, tephroite, etc.). Transformation of Mn-Si gel during increase in temperature occurs as follows: gel→ neotocite → caryopilite + quartz → caryopilite + pyroxmangite (±rhodonite) + tephroite → pyroxmangite (±rhodonite) + tephroite. Replacement of caryopilite by pyroxmangite (±rhodonite) with tephroite takes place at a temperature interval of the prehnite-pumpellyite facies. Thus, there are low-temperature caryopilite and high-temperature tephroite-pyroxmangite (±rhodonite) facies, PT-boundaries between which correspond to zeolite (prehnite-pumpellyite and greenstone) and deeper facies, respectively.

4. Assemblages of Mn silicates are stable at low concentration of carbon dioxide in pore solution. Insignificant increase in its molar share leads to replacement of silicates by assemblage of rhodochrosite+quartz, which is stable in the whole PT-interval of regional metamorphism.

Ti-rich Cr-spinel and Ni-Fe-Cu sulphides from the Hamutenha basic-ultrabasic intrusion (Cunene anorthosite complex, Angola)

Campeny, M.[1*], Proenza, J.[1], Torró, L.[1], Villanova, C.[1], Castillo, M.[1], Gonçalves, O.A.[2] & Melgarejo, J.C.[1]
[1]Dept. Cristal·lografia, Mineralogia i Dipòsits Minerals, Universitat de Barcelona, Catalunya, Spain ([*]markcamp100@hotmail.com)
[2]Depto. de Geologia, Universidade Agostinho Neto, Luanda, Angola

The Cunene complex is a large group of gabbro-anorthosite intrusions that covers an area of 15.000 km^2 between southern part of Angola and northern Namibia. Although ultrabasic rocks have not been found to data in the main anorthositic intrusion of the Cunene complex, a great number of small basic-ultrabasic bodies appear close to the west margin of the main intrusion.

This work is based in one of these Cunene associated basic-ultrabasic-intrusions outcropping close to the Hamutenha village, and especially on the study of its Ti-rich Cr-spinel and Ni-Fe-Cu sulphides associated mineralization. Both appear as a disseminated mineralization included in the olivine and clinopyroxene grains from the dunites and olivinic gabbros situated at the centre part of the intrusion.

The Ti contents of the Cr-spinel of Hamutenha are very high, even up to 15.66 % of TiO_2, with an average value of 5.17%. On the other hand, the Cr-spinel contains abundant exsolutions of ilmenite lamellae. The ratio Cr_2O_3/Al_2O_3 in Cr-spinel presents a positive correlation. This is an atypical behaviour, because the typical tholeiitic magmas that generate this kind of intrusions use to display a negative correlation.

These aspects suggest that the parental magma of Hamutenha was relatively rich in Ti, and had a similar composition as the estimated magma for Mount Ayliff intrusion (Karoo Igneous Province, South Africa [1]; and Jinbaoshan (SW China [2]) and Xinjie (SW China [3]) intrusions in which appear associated mineralizations of Fe-Ti-Cr and Pt-Pd sulphides.

Although Ni-Cu ore deposits are currently explored in the Cunene complex, in the Hamutenha intrusion Ni-Fe-Cu sulphides have been found only as accessory minerals disseminated in dunites and olivine gabbros. The sulphides occur as interstitial grains, in inframillimetric size. Primary sulphides are pentlandite, chalcopyrite and pyrrhotite. The secondary association is complex, and consists of thiospinels, heazlewoodite (Ni_3S_2), godlevskite ($(Ni,Fe)_7S_6$) and putoranite ($Cu_{16-18}(Fe,Ni)_{18-19}S_{32}$).

Cu-U-V stratabound deposits in red beds in the Catalan Pyrenees: structure and mineralogy

Castillo, M.[*], Torró, L., Campeny, M., Villanova, C., Tauler, E. & Melgarejo, J.C.
Dept. of Cristallography, Mineralogy and Ore Deposits, University of Barcelona, Spain ([*]montgarricastillo@gmail.com)

The Eureka mining group (La Plana de Mont-Ros, Pyrenees, Catalonia) has one of the best outcrops of Cu-U-V stratabound deposits in red-beds of Western Europe. The deposit was mined in surface trenches and underground galleries. This has allowed an accurate mineralogical and textural study of this deposit, which can be used as a model to explain the relationships between Cu-U-V minerals during precipitation of primary mineralization and supergenic stages.

The deposit is hosted by Lower Triassic detritic series, which are arranged approximately in an E-W direction, and were deformed during the Alpine Orogeny.

Field mapping and a study of the mineral assemblages, with the petrographic microscope, SEM-BSE-EDS and EMPA, have enabled to distinguish three mineralization stages:

1. Stratabound mineralization: this concentrates the main part of the stock. It is directly related to centimetric coal levels interbedded with greenish greywackes and conglomerates. This reducing trap caused the precipitation of redox sensitive elements (U, V, Cu, Sb, Bi, Ag, As, Se, Ni and Co) from a fluid with low S activity. Ores comprise native metals (silver, bismuth), pyrite, sphalerite, galena, Cu sulphides (djurleite, digenite, anilite), Ni-Co sulphoarsenides (gersdorffite, cobaltite), sulphosalts (wittichenite, tetraedrite, tennantite), selenides (chlausthalite and aguilarite) and uraninite. These ore minerals are found as a late cement of the detritic rocks, and replace an early calcitic cement. The general sequence starts with pyrite, which is replaced by copper sulphides, Ni-Co sulphoarsenides and sulphosalts. The matrix of the greywackes is made up of roscoelite and V-rich illite.

2. Vein mineralization: during the alpine compression, Cu remobilization took place and generated mm-sized veins filling small joints with chalcopyrite and bornite, along with quartz and ankerite.

3. Supergenic mineralization: oxidized minerals associated with supergenic alteration, like sulphates (brochantite), arsenates (zeunerite, erythrite, chenevixite), vanadates (carnotite, tyuyamunite, sengierite), carbonates (malachite, azurite), selenites (demesmaekerite and haynesite), and phosphates (torbernite) appear as crusts and efflorescences on the surface of the outcrop, as pseudomorphs or filling small cracks. On the other hand, leaching of the ores by ground waters produces the precipitation of a suite of recently-formed carbonates (cejkaite, andersonite) and sulphates (zippeite, uranopilite) in the galleries. Hence, these minerals fix the uranium again.

This study shows that acid fluids generated by alteration of sulphides can produce the leaching of U and RSE. Vanadates, arsenates and phosphates fix U in the supergene zone; the remaining U can be remobilized and reprecipitated, forming crusts of U carbonates on the mine walls. These observations could be considered in the management of radioactive waste products.

Formation and mineral chemistry of a Zn-Pb skarn from the Gageok mine, South Korea

Choi Bu Kap[1,2], Choi Seon-Gyu[2*], Seo Jieun[2], Kim Tae Hyung[1], Kang Heung Seok[1], Lee Sangbong[2], Koo Minho[2], Yoo In Kol[3] & Jung Yeon Ho[1]
[1]Korea Resources Corporation, Seoul, Republic of Korea
[2]Dept. of Earth and Environmental Sciences, Korea University, Seoul, Republic of Korea ([*]seongyu@korea.ac.kr)
[3]Korea Alumina Co., Ltd., Mokpo, Republic of Korea

The Gageok skarn deposit, located at the eastern edge of the Taebaeksan Basin, South Korea, is the result of the intrusion of the Cretaceous granitic pluton into the Paleozoic calcareous rocks. The subvolcanic intrusion ranges in composition from quartz monzonite to granite porphyry with numerous dikes having I-type, calc-alkaline and weakly peraluminous characteristics. Both endoskarn and exoskarn are developed at the Gageok Zn–(Pb) deposit, with more exoskarn than endoskarn. The alteration of the subvolcanic rocks began with very weak disseminated diopsidic pyroxene, epidote, actinolite, and titanite. Epidote skarn zones were formed as endoskarn during the intrusive phase. The clinopyroxene skarn, clinopyroxene- garnet skarn and garnet skarn developed as exoskarn from the calcareous wall rocks and the pluton, respectively, prior to mineralization. Garnets and pyroxenes show a wide range of variation in composition. Early pyroxene is diopsidic whereas pyroxene in distal/late veinlets is hedenbergitic containing varying amounts of johannesenitic. Similarly, garnet and pyroxene become more Mn-rich with paragenetic sequence. Some zoned garnets from a vein skarn display a prominent increase in Mn content (22.9 wt. % MnO). Sphalerite precipitated after pyroxene and garnet in exoskarn. Zn sulfide precipitated together with pyrrhotite in proximal locations, associated with prograde garnet+pyroxene+rhodonite and retrograde quartz+amphibole+calcite+chlorite. Based on the geological, mineralogical, petrological and fluid inclusiondata, an integrated fluid evolution model (involving magmatic and meteoric fluids) is developed to explain the geological and fluid controls on Zn-Pb-skarn mineralization associated with granite porphyry.

Origin of stibnite-bearing hydrothermal veins in the Tatric superunit, Western Carpathians

Chovan, M.[1*], Hurai, V.[2], Lüders, V.[3], Prochaska, W.[4] & Balogh, K.[5]
[1]Dept of Mineralogy and Petrology, Comenius University, Bratislava, Slovakia ([*]chovan@fns.uniba.sk)
[2]Geological Institute, Slovak Academy of Sciences, Bratislava, Slovakia
[3]Helmholtz Centre GFZ, Potsdam, Germany
[4]Dept. of Geosciences, Montanuniversität Leoben, Austria
[5]Institute of Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary

Variscan basement of Western Carpathians contains most important resources of antimony in Europe. Magurka and Dúbrava in the Nízke Tatry Mts. and Pezinok in the Malé Karpaty Mts. were the largest Sb deposits within Tatric tectonic unit. Stibnite-bearing hydrothermal veins crosscut the Tatric basement, which consists predominantly of medium-to-high grade metasedimentary and metavolcanic rocks intruded by large Variscan granitoid plutons. Variscan brittle and ductile deformation structures are generally well-preserved. $^{40}Ar/^{39}Ar$ data on muscovite from mylonitised orthogneisses point to a Late Palaeozoic tectonothermal activity at 330 Ma (about 300 Ma using K/Ar method), and an Alpine overprint at 80-100 Ma.

The sulphidic vein mineralizations can be subdivided into three stages: 1. quartz – pyrite/arsenopyrite (sometimes Au-bearing) – gold. 2. quartz – Fe-dolomite – stibnite – pyrite accompanied by minor berthierite, native antimony, and Sb-oxides. Later but in places also earlier is the sphalerite – Pb-Sb sulphosalt sub-stage. 3. quartz – carbonate – barite – tetrahedrite. Chlorite, muscovite and carbonate-illite alteration zones have been distinguished around the Sb-bearing veins. Crystallization of high temperature arsenopyrite - pyrite - gold assemblage was triggered by influx of low-salinity CO_2-rich aqueous fluids of magmatic or metamorphic origin. Mesothermal quartz-sulphidic (stibnite, berthierite, zinkenite, sphalerite, tetrahedrite) assemblages have precipitated from NaCl–KCl aqueous solutions, representing mostly deep-circulating heated meteoric waters.

Stibnite from quartz-carbonate veins of the Nízke Tatry Mts. precipitated from medium temperature (~150-200°C) and moderately saline fluids (12-16 wt. % NaCl eq.). Recrystallisation of the early stibnite and crystallisation of the superimposed, fine-grained stibnite occurred at similar temperatures in the presence of low salinity (1-5 wt. % NaCl eq.) aqueous solutions. Significant compositional and density differences exist between the ore- and gangue-precipitating fluids. Crush-leach and microthermometry data corroborate combined sources of water in the stibnite-precipitating fluid. Increased concentrations of bromine, $CaCl_2$ and sulphate and oxygen isotope ratios in Fe-dolomite are diagnostic of a basinal fluid component derived primarily from seawater, whereas carbon isotopes suggest a ^{13}C-depleted CO_2 derived from organic matter in low-grade sediments. The $^{207}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ ratios indicate a crustal origin of lead in stibnite and the associated sulphosalts. The high temperature pyrite – arsenopyrite - gold assemblage may be genetically linked to the evolution of the late Variscan granitoids and retrograde metamorphism within ~300 Ma old shear zones. Crystallization of stibnite, sfalerite and Pb-Sb sulfosalts was probably connected with Jurassic continental rifting dated at 210-170 Ma using K/Ar method applied to illite from alteration zones. Sulphide mineralization was recrystallized during the Alpine (Cretaceous) orogenic cycle.

Provenance analysis of gold and associated heavy minerals in the Black Reef Formation, South Africa, using geochemical fingerprints

Fuchs, S.[1,2*] & Gauert, C.D.K.[1]
[1]Dept. of Geology, University of the Free State, Bloemfontein, South Africa
[2]Institute of Mineralogy, Crystallography and Materials Science, University of Leipzig, Germany
([*]sfuchs@uni-leipzig.de)

The Black Reef Formation (BR), a thin, but laterally extensive unit of primarily conglomerates and quarzites at the base of the Transvaal Supergroup contains erratical gold at economic grade confined to regional areas. Highest gold grades are exploited in the West and East Rand area on top of underlying Witwatersrand Reefs. BR gold however occurs also outside of the Witwatersrand Basin in the eastern Mpumalanga and Limpopo Provinces, e.g. Kaapsehoop, in close contact to greenstone units. Platinum, Osmium and Iridium as well as Uranium-bearing minerals have been reported in association with gold in the BR mainly from BR exposures east of Klerksdorp [1]. Although most economic BR Au mineralization occurs at localities within the Witwatersrand Basin, a large number of Au occurrences are found in RR overlying Ventersdorp and Swaziland Supergroup strata; therefore, the reworking of Au placers of the prominent Wits Reefs such as the Ventersdorp Contact Reef the BR cannot be regarded as the only one source of gold within the BR.

Current geochemical fingerprinting attempts of BR Au and associated heavy minerals using Electron Microprobe, LA-ICP-MS, and NanoSims give an indication about a genetic relationship between the several Au deposits and their different underlying rocks. Constantinescu et. al [2] and McCandless et. al [3] successfully used indicator trace elements as such as Sb, Sn, As, Ru, Rh, Pd, Te, Ta, Os, Ir, (+Au, Ag, Cu) to characterize different gold deposits.

Average Ag contents in free gold from the East Rand determined by EMPA are high (14.8wt%, n=20), Hg contents low (on average 0.51 wt%); trace concentrations of S, Fe, Ni, Cu, As, Th, U and Cd in decreasing order were detected possibly because of micro-inclusions. The pyrite mineral chemistry shows minor As, Pb and traces of Ni and Cu, cobaltite contains minor Pb, gersdorffite Sb, and sphalerite shows minor Cu, Cd, and traces of Au and Pb. U-bearing phases such as Uraninite show minor Pb and Th and detectable trace amounts of S, Fe, Bi, As, Cd, Ag, Sb and In. The value of these trace elements for genetic and provenance interpretations still has to be assessed.

Investigation of detrital gold, gold in hydrocarbons and invisible gold in sulphides by LA-ICP-MS trace element of various BR sections is ongoing. In combination with NanoSims analyses for the visualization of invisible gold in pyrites, Ag-Au zoning in detrital gold grains the information could be relevant to determine possible gold sources, transport mechanisms, and depositional conditions. Finally it may allow to develop a holistic genetic model of the Au mineralization in the Black Reef Formation.

The chemical and structural characterization of garnierite minerals from several Caribbean lateritic mineralizations shows that this group of minerals is formed by intimate intermixings of three main Mg-Ni phyllosilicate solid solutions: serpentine-népouite, kerolite-pimelite and sepiolite-falcondoite [1-5]

The published experimental solubility constants for Mg end-members and the calculated constants for pure Ni end – members are used to calculate Lippmann diagrams for the three solid solutions, on the assumption that they are ideal. With the help of these diagrams, it is proposed that congruent dissolution of Ni-poor primary serpentine followed by equilibrium precipitation of Ni richer secondary phyllosilicates is an efficient mechanism of Ni supergene enrichment along the lateritic profile. The stability fields of the solid solutions are represented using [log $a_{SiO2(aq)}$, log (a_{Mg2+} + a_{Ni2+})/a_{H+}^2)] diagrams (Fig. 1). These, combined with Lippmann diagrams [6] give an almost complete chemical characterization of the solution and the precipitating phase(s) in equilibrium. The temporal and spatial succession of hydrous Mg-Ni phyllosilicates often encountered in Ni lateritic deposits is explained by the low mobility of silica [7] and the increase in its activity.

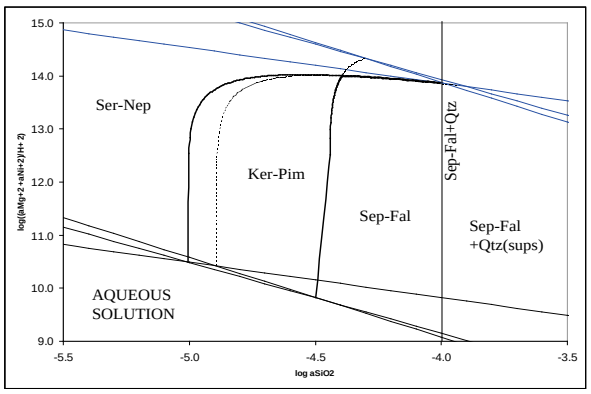

Fig. 1: Fields corresponding to the three solid solutions and boundaries: Ser-Nep+Ker-Pim; Ker-Pim+Sep-Fal and Ser-Nep+Sep-Fal. Dashed lines are metaestable extensions of these equilibria. Vertical line at log($a_{SiO2(aq)}$) = -4 gives equilibrium between quartz+Sep-Fal.

Mineralogical and geochemical characteristics of W>Sn quartz veins from Murçós (Northeastern Portugal)

Gomes, M.E.P[1,4*], Antunes, I.M.R.H.[2,4], Neiva, A.M.R.[3,4] & Teixeira, R.J.S.[1,4]
[1]Dept of Geology, UTAD, Vila Real, Portugal
([*]mgomes@utad.pt)
[2]Polytechnic Institute of Castelo Branco, Castelo Branco, Portugal
[3]Dept. of Earth Sciences, University of Coimbra, Portugal
[4]Geoscience Centre, University of Coimbra, Portugal

The Murçós mining area is located at the Galiza-Trás-os-Montes Zone, northeastern Portugal. The hydrothermal W>Sn quartz veins from Murçós cut Silurian schists and a Variscan biotite granite. The mineralization is of stockwork type and the veins fill mainly N40-50 ºW fractures that are probably related to the dextral shear zone which deformed the biotite granite. The exploitation of scheelite and cassiterite took mainly place at the surface in four open pit areas between 1948 and 1976 and 335 tons of W and 150 tons of Sn were produced [1].

The W>Sn quartz veins contain quartz, muscovite, tourmaline, scheelite, cassiterite, wolframite, arsenopyrite, pyrite, sphalerite, chalcopyrite, galena, native bismuth, rare pyrrhotite and stannite. Late minerals such as marcasite, bismuthinite, joseite, matildite, anglesite, zavaritskite, scorodite and roosveltite also occur. Tourmaline is subhedral and chemically zoned. There is an increase in Fe/(Fe+Mg) and Ti content and a decrease in Al content from core to rim. Scheelite is anhedral, light coloured with a typical blue fluorescence and irregularly zoned. Cassiterite is subhedral and usually zoned, with slightly pleochroic darker zones alternating with lighter zones. The darker and lighter zones have a similar chemical composition and contain inclusions of rutile and rare ilmenite. However, the darker zones of some crystals are richer in Ti than the lighter zones. Wolframite has a homogeneous composition and is enriched in the hubnerite component. Arsenopyrite is the most common sulphide. The richest euhedral arsenopyrite is in equilibrium with pyrrhotite and the subhedral arsenopyrite contains inclusions of bismuth, bismuthinite and matildite. Arsenopyrite is replaced by pyrite, scorodite and roosveltite. In general, pyrite occurs as fracturated euhedral to subhedral crystals. The sphalerite is anhedral associated with arsenopyrite and quartz. Chalcopyrite has an homogeneous composition and occurs included in subhedral arsenopyrite and as blebs aligned in sphalerite. Galena is homogeneous with Ag and Bi up to 1.5 wt% and 3.5 wt%, respectively. Galena has many exsolutions of bismuthinite and matildite which show ortogonal alignments. The coexisting suhbedral arsenopyrite and sphalerite have 31,9 wt% As and 18 mole% FeS, respectively, and give estimated temperature above 425ºC [3]. Pyrrhotite is monoclinic and probably resulted from the inversion of hexagonal pyrrhotite at about 248ºC [2]. Veinlets of quartz containing anhedral stannite and individual grains consisting of 75% Au + 20 % Pd + 5 % Ag fill fractures in arsenopyrite.

Aggregates of secondary phases of bismuthinite, joseite, zavaritskite and roosveltite occur around bismuth and fill fractures in subhedral arsenopyrite. Scorodite occurs as an alteration product of arsenopyrite. Anglesite is the alteration product of galena crystals.

[1] SIORMINP (2009) http://e-geo.ineti.pt/bds/ocorrencias/.[2] Scott, S.D. & Kissin, S.A. (1973) *Econ. Geol.*, **68**, 475-479. [3] Scott, S.D. (1983) *Mineral. Mag.*, **47**, 427-435.

Textural and mineralogical constraints in chromite sand enrichment by shaking tables at Brieville plant (Madagascar)

Grieco, G., Pedrotti, M.[*], Merlini, A. & Pileri, D.
Dipto. di Scienze della Terra "A. Desio", Università degli Studi di Milano, Milan, Italy ([*]maria.pedrotti@unimi.it)

Textural and mineralogical characters of ore together with technical parameters of enrichment plants strongly affect efficiency of chromite sand concentration with shaking tables. Such parameters were studied at Brieville gravity enrichment plant that works chromite ore from different mines within Andriamena district (Madagascar).

Ore is a massive to densely disseminated chromitite hosted by a peridotitic and pyroxenitic rock. Gangue mineralogy is very rich, comprising ortho and clinopyroxene, tremolitic to edenitic amphibole, phlogopite, chlorite, talc and minor pentlandite, pyrrhotite, ilmenite, rutile and dolomite.

Ore is firstly crushed and sieved to a grain size below 2.5 mm, and then it is hydroclassified and sent to shaking tables. As a result of hydroclassification different tables receive sand of decreasing grain size.

Mineralogy, chemistry and granulometry show that hydroclassification operates a pre-selection of chromite sand and as a consequence tables are fed with sands different not only for grain size but also for mineralogy and chemistry.

Separation of grains in a shaking table occurs due to contrasts in specific weight, grain size and, to a minor extent, grain shape. Specific weight contrast between grains for a given grain size distribution of sand depends on density and degree of liberation of phases [1]. At Brieville the degree of liberation of chromite was assessed for each table and for each grain size. Results show that the degree of liberation depends on the relation between crystal size distribution of chromite in the rock and grain size of sand. For grain size above 300 μm, the degree of liberation is low enough to considerably reduce enrichment efficiency of tables working at such grain sizes.

Increase of sorting from feeding sand to concentrate confirms that shaking tables separate grains also according to grain size and low sorting of feeding sand suggests sieving as a more efficient technique to select sand to be sent to shaking tables rather than hydroclassification.

Results of mineralogical distribution suggest that gangue minerals behave in different ways according to their density and habit, showing differential enrichments due to pre-selection operated by hydroclassification and to selection operated by gravity separation through shaking tables.

At Brieville the main parameter affecting efficiency of shaking tables is the degree of liberation of chromite. As a result the table working the coarsest grain size is able to enrich Cr_2O_3 content of feeding sand by only 5.14 wt%, against an enrichment of 20.26 wt% for the table working the finest grain size. This result is disguised by the Cr_2O_3 pre-enrichment of the coarser sand operated by hydroclassification as the combination of the two processes gives a concentrate sand similar in Cr_2O_3 content for all the tables.

In general results show that a detailed mineralogical and textural study of the ore can provide useful information to get the highest efficiency of the plant through an appropriate choice of crushing degree and shaking table settings and by substitution of hydroclassfiers with sieves.

Two genetic types of secondary native gold in epithermal gold-telluride deposits of the Far East of Russia

Ivanov, V.V.
FIGI FEB RAS, Vladivostok, Russia (dom101@mail.ru)

Native gold in ores of hydrothermal deposits of precious metals is frequently rated as typically hydrothermal mineral. It is known at the same time that a part of native gold in some deposits is secondary, i.e. a product of decomposition of the primary minerals of gold, specifically of gold tellurides. There are recognized two types of such secondary (newly formed) native gold: hypergenic and hypogenic gold, which have been found in the epithermal deposits located in various volcanic belts of the Russian Far East.

Hypergenic native gold - Secondary gold as a product of oxidation and full decomposition of various gold tellurides during hypergenic processes has long been known for a number of the world deposits. Brownish-earthy gold of lacy structure has a name of "mustard" gold in some countries. Such high-fineness gold cannot always be unambiguously considered the end product of the gold-rich tellurides minerals decomposition. In our case, a characteristic is given for the hypergenic newly formed gold presented in the partly oxidized samples of gold telluride ores from the Svetloye and Amy high-sulphidation epithermal gold deposits of the Alalindinskoye ore field (Priokhotye region). The gold is represented by very fine grains within the ortho-paragenetic assemblage of primary and secondary minerals of tellurium and other chemical elements. The author revealed in these ores also rare oxycompounds of gold and other metals concerning to Au – (Ag) – Cu − (As) – Fe – Te − O system.

Hypogenic native gold - It is a poorly-known type of newly formed native gold which was formed through the solid-phase thermal decomposition of Au-Ag tellurides. The author has proved the existence of such genetic (metamorphogenic) type of gold when carrying out the geological-mineralogical investigations of locally thermally metamorphosed adular-quartz ores in Priamurye and Kamchatka regions. The experimental modelling of hupogenic secondary gold growth through petzite thermal decomposition has been done (Fig. 1).

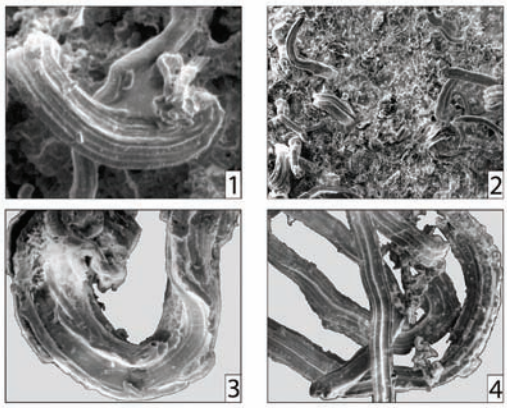

Fig. 1: Secondary high-fineness gold: 1, 2 – native-grown crystals; 3, 4 – crystals on secondary hessite surface experimentally grown throug petzite thermal decomposition.

Such authigenic gold formed "in situ" is characterized: in the case of the crystallization strained conditions by a specific root-limbate type of separations in hessite, and in the case of free growth conditions – by thread -like forms of individuals (whiskers of a pressure) with ribbed-grooved surface and different degree of twisting (for example, helical type).

REE distribution and mineralogy in a Palaeoproterozoic apatite-iron oxide deposit: Grängesberg, Bergslagen, Sweden

Jonsson, E.[1*], Persson Nilsson, K.[1], Högdahl, K.[2], Troll, V.R.[2] & Hallberg, A.[1]
[1]Geological Survey of Sweden, Uppsala, Sweden
([*]erik.jonsson@sgu.se)
[2]Dept. of Geosciences, Uppsala University, Uppsala, Sweden

The apatite-iron oxide deposits of the Grängesberg District (GD; past production 152 Mt of ore @ 58% Fe and 0.81% P) are situated in the Palaeoproterozoic Bergslagen ore province in central Sweden. The deposits have historically been compared to those of the Kiruna type, and were more recently suggested to be related to the IOCG-clan of deposits [1].

The GD Fe oxide ores range from magnetite to hematite-dominated, variably rich in apatite-(CaF). This mostly occurs as banded, fine-grained aggregates, and was recrystallised together with ores and metavolcanic host rocks during c. 1.85-1.80 Ga regional lower amphibolite facies metamorphism.

In the ores, REEs are mainly hosted as trace contents in the granular apatite, which is typically high in Y, Ce, La and Nd, but are also present in monazite, allanite and epidote, as well as in REE-fluorocarbonate(s). The host rocks exhibit REE patterns similar to the apatites, the major GD ore types and alteration assemblages (Fig. 1), linking the apatite-iron oxide ore to the (formation of the) host rocks.

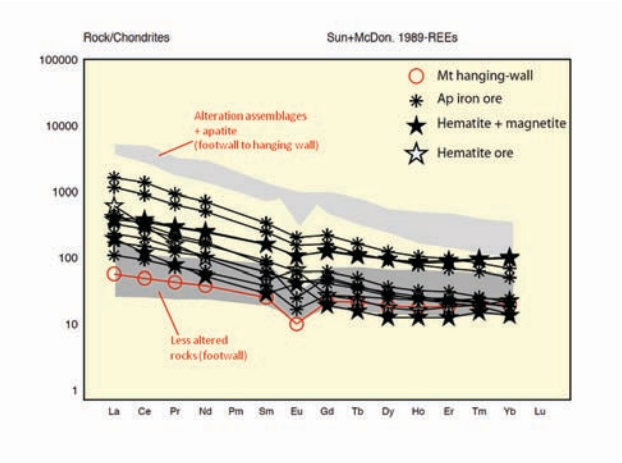

Fig. 1: Chondrite-normalised REE patterns för apatite (Ap), Fe oxide ores (Mt = magnetite) and host rocks at Grängesberg.

In relation to Kiruna ore apatites [2], the Grängesberg samples lack both the very abundant monazite inclusions and the patchy REE distribution. Instead, the recrystallised apatite often exhibits strong intra-grain REE zoning, with slightly depleted outer rims, intermediate REE-rich (Y>Ce≥La,Nd) rims, and REE-poor cores. Monazite occurring along apatite grain boundaries exhibits Ce≥La>Nd, in part mimicking the apatite LREE distribution. The last REE-phase to form, synchysite-(Ce), exhibits Ce≥La>Nd, and occurs in pockets in apatite and calcite. This assemblage indicates the presence of a late-stage carbonaceous fluid.

The systematic relation between zoned REE patterns and granoblastic grain shape in apatite indicates that this is a consequence of regional metamorphism, driving an REE mobilisation process which was variably arrested in different grains. Mobilisation of REEs from the apatite led to formation of intergranular monazite ± allanite, and finally, REE-fluorocarbonates.

Identification of uranium and vanadium minerals in black shale, South Korea

Kang, S.A.[1], Kim, Y.J.[1], Jung, S.Y.[2], Shin, J.K.[2] & Lee, Y.J.[1*]
[1]Dept. of Earth and Environmental Science, Korea University, Seoul, Korea ([*]youngjlee@korea.ac.kr)
[2]Uranium Exploration Team, Korea Resources Corporation, Seoul, Korea

Uranium, which is rich in metalliferous black slates of Okcheon Metamorphic Belt in South Korea, has been the subject of interest in mineral resources because of its potential roles in energy industries. Identification of mineral species has been played an important role in controlling mineral processing and extraction of metals such as uranium and vanadium in mine exploration and development. Despite the importance of uranium and vanadium minerals in the black slates, the identification of these minerals is still not clearly understood and verified. Moreover, no direct observation and confirmation of these minerals in the slates have been provided.

Systematic studies, combined conventional experiments with electron probe micro-analyzer (EPMA) methods have been used to evaluate uranium and vanadium minerals in the black slate. Results show that concentrations of these minerals increase with increasing total organic carbon contents. However, the relation between the concentration of uranium and that of vanadium is inversely proportional; the concentration of uranium increases with decreasing that of vanadium whereas the concentration of vanadium increases with decreasing that of uranium. EPMA results show that the primary minerals for uranium are uraninite ($(U^{4+}_{1-x-z}U^{6+}_{x}M^{2+}_{z})O_{2+x-z}$) and brannerite ($(U,Ca,Y,Ce)(Ti,Fe)_2O_6$). These minerals are aggregated with round shape. EPMA also shows that vanadium-bearing minerals contain high concentrations of Al, Si, Ca, Ti, suggesting that the main mineral is muscovite. This result is good agreement with microscopic observation, showing that greenish muscovite is frequently observed. No differences for vanadium concentrations on muscovite are observed by a point or an area microanalysis in EPMA, indicating that vanadium is in the structure of muscovite rather than found as a single mineral. In addition, Ba is also detected in K-feldspar where Ba is substituted for K of the feldspar in samples showing high concentrations of uranium. Our results suggest that the primary minerals of uranium in the black slate would be formed by the reduction of uranium due to reducing agents such as H_2S, CH_4, and Fe^{2+} or organic matters.

Micromineral composition of deposits of Zarmitan gold ore zone

Koneev, R.I. & Khalmatov, E.A.[*]
Dept. of Mineralogy and Geochemistry, Faculty of Geology, National University of Uzbekistan, Tashkent, Uzbekistan
([*]e_khalmatov@yahoo.com)

The Zarmitan gold ore zone is located on the South side of the Northern Nuratau range. It bowingly stretches from the south-east exocontact to the south-west side of the Koshrabad intrusion and relates to junction of the sub-latitudinal Karaulkhana-Zarmitan fault zone with hidden, abyssal, sub-meridional Zirabulak-Koshrabad fault. The Zarmitan gold ore zone consists of (from the south to the west) the Charmitan, the Urtalik and the Guzhumsay deposits. The Charmitan is located within the slates, sandstones and aleurolites (siltstone) of the Djazbulak suite (S_1) and endocontact of granosyenites of the Koshrabad intrusion (C_3-P_1); the Guzhumsai is nearly entirely located in the granosyenites.

Researche of ores from the Charmitan and the Guzhumsay deposits showed that the compositions of ores are practically identical, in spite of different host rocks. Geochemical numbers of elements accumulation intensity calculated concerning clarkes in the Earth crust coincided:

Charmitan – As-Te-Bi-Au-Sb-Ag-Se-Pb-W-Hg-Mo-Pd-Sn-Co-Zn; Guzhumsay – As-Te-Bi-Au-Se-Sb-Ag-Pb-W-Hg-Sn-Pd-Mo-Cu-Zn.

The ores from both deposits were formed by standard set of mineral associations, typical for gold ore deposits of Uzbekistan: 1. Scheelite – molybdenite (Au-W); 2. Gold-arsenopyrite – pyrite (Au-As); 3. Gold – telluride – selenide – polymetallic (Au-Te); 4. Electrum – selenide – polysulfidic (Au-Ag); 5. Gold – silver – antimonite – sulfoantimonite. Au-Hg association with cinnabar is not established. Au-As, Au-Te, Au-Ag and Au-Sb associations determine industrial productivity. In macromineral composition presence, development of the certain productive associations is clearly registered by micromineral composition.

Au-As association is characterized by presence of thin gold, loellingite, pyrrhotite, gersdorffite inclusions and mineral microparagenesises of consequent associations in arsenopyrite, pyrite and quartz.

Au-Te differs by development of bismuthic compounds – maldonite, bismuthinite, chorobetsuite, kobellite and tellurides – hedleyite, tsumoite, pilsenite, sulfotsumoite, joseite, calaverite, petzite and others. This association is the most typical for the Charmitan deposit.

Au-Ag mineralization is represented by electrum, kustelite, acanthite, freibergite, pyrargyrite, stephanite and other Ag sulfo-salts.

Au-Sb association is widely presented, especially on the Guzhumsayi deposit – aurostibite, boulangerite, jamesonite, zinkenite, gudmundtite, owyheeite, andorite and others.

Very original microparagenesises (nanoassemblages) are formed by combination of associations. Micromineralogical analysis allows completer determination of specific associations'development, estimation of the level of erosional cut and conditions of formation. Longer and more diverse list of minerals is, larger the scale of mineralization. The Guzhumsay deposit had being formed in less deep conditions than the Charmitan deposit, and both of them compose extensive ore-bearing zone pitching to the east.

Banded Iron Formation deposits from the Tiris region (Western Sahara): structure, mineralogy and textures

Lehbib, S.[1*], Arribas, A.[2] & Melgarejo, J.C.[1]
[1]Dept. Cristal·lografia, Mineralogia i Dipòsits Minerals, Universitat de Barcelona, Catalunya, Spain
([*]slehbib@yahoo.es)
[2]Escuela Técnica Superior de Ingenieros de Minas, Madrid, Spain

Many important showings of iron oxide deposits have been reported since the 1950's in the Tiris region, SE of Western Sahara. These deposits are located in the same Precambrian belt which hosts the world-class iron deposits of Quidiat Iyil in Mauritania, which are close to the border with Western Sahara. Unfortunately, the iron deposits of Western Sahara have not been characterized until the present, mainly because of the political conflicts in the area. Hence, the occurrence of these outcrops in Western Sahara defines new and interesting metallogenetic targets. Therefore, the aim of this work is to provide new data on the mineralogy of the main deposits, as well as their textures, paragenesis and origin.

Most of these deposits have been intensively deformed, in particular, by folds at macro, meso and micro-scale. On the other hand, most of these deposits have been affected by medium to high-grade regional metamorphism, and coarse-grained textures have been widely developed. This aspect could favour the benefit of the ores.

According to the age of the deposits, three main groups can be established:

1) Southern group. It is found in the Jneifisat zone, and it is hosted by the migmatitic units of the Lower Archaean. They are affected by high grade regional metamorphism, and all display a lepidoblastic texture. Magnetite can reach up to 35% modal of the rock. The rest is made up of quartz, which occurs in small bands or metamorphic rods.

2) Central group. These deposits are hosted in the highest part of the Archaean series, comprising paragneiss, metabasites and some marble beds, metamorphosed in amphibolite facies. The most important deposit of this type is found at El Farfarat, NW of Miyec, although there are many other mineralized units in different levels of the series. Some noticeable outcrops can be distinguished in Galb Leazib, Galb Fula and several outcrops in the vicinity of Miyec. The thickness of these BIF can vary a lot, being less than 3 m in all cases. These deposits have a modal content of magnetite which is slightly higher than the above mentioned, up to 50%; the content in quartz ranges from 30 to 50%. However, some outcrops can consist of massive magnetite, as in Galb Fula (more than 75 %), accompanied by small amounts of quartz and siderite. Other minerals, as siderite and grunerite, may appear in small amounts, as in Galb Leazib or Galb Laana. All these minerals have been formed by medium-grade regional metamorphism.

3) Northern group. These deposits are interbedded with Eburnean volcanosedimentary series. These BIF are the thickest in Western Sahara (more than 10 m in some points). In addition, they are massive, as in the Bu Daira Ranges, and the content in magnetite may reach 75% in volume. However, although the texture is also lepidoblastic, the fine grained textures (in the range 500 μm-1 mm) are not as suitable for the benefit of the ore as in the above-mentioned cases. Quartz is the only gangue mineral found there up to date.

In all these deposits, magnetite has been partially replaced on surface by fine-grained supergenic hematite.

The potential for magmatic metal sources in the Iberian Pyrite Belt

Marques, A.F.A.[1,2*], Scott, S.D.[1], Relvas, J.M.R.S.[2], Rosa, C.[3] & Guillong, M.[4]
[1]Dept. of Geology, University of Toronto, Toronto, Canada
([*]marques@geology.utoronto.ca)
[2]CREMINER (LA-ISR), University of Lisbon, Portugal
[3]LNEG, Alfragide, Portugal
[4]ETH, Zürich, Switzerland (present address CODES, Australia)

The Iberian Pyrite Belt (IPB), located in southern Portugal and Spain, hosts several giant volcanic-hosted massive sulfide (VHMS) deposits within a bimodal - siliciclastic volcanic-sedimentary succession of Late Devonian to Lower Carboniferous age [1]. Felsic volcanic centres display a complex architecture of lava domes, pyroclastic units and intrusions defining lava cryptodome pumice cone volcanoes [2]. Although current knowledge indicates that the direct contribution of metals of magmatic origin may have not been predominant in typical IPB deposits [3], the exceptional nature of the ores in some giant VMS deposits are best explained by a magmatic – hydrothermal model [3,4]. Volcanic successions in the Neves Corvo and Serra Branca areas are mineralized and Neves Corvo is a world-class giant high Cu and Sn grade VHMS deposit [1,3]. Conversely, Albernoa quartz-feldspar-phyric volcanics have no known sulfide mineralization or ore-related hydrothermal activity. Exposed melt inclusions hosted in quartz phenocrysts in felsic rocks from these three distinct volcanic centres were analysed by SEM/EDX [5] and LA-ICP-MS. EDX showed that melt inclusions present in Albernoa samples contained metallic precipitates with Sn, Cu, Cl and S suggesting that the magmatic source beneath the volcanic centre had high contents in these elements. LA-ICP-MS analyses on the unexposed melt inclusions determined the bulk composition. Quantification of element concentrations followed Halter et al's [6] methodology in which mass ratio was determined using whole rock differentiation trends. In clear contrast with their host rock compositions, melt inclusions from Serra Branca and one Albernoa sample showed higher concentrations of mafic-related elements (e.g. FeO, MgO, Co, Ni, Cu and Zn) and low Na_2O. The remaining rhyolite and rhyodacite rocks from Albernoa have melt inclusions with a composition similar to those of their hosts. The high-silica melt inclusions found in the Neves Corvo samples are depleted in Cu and have low Sn (12 ppm Sn). Sn concentrations are higher in the melt inclusions than in their host rocks. Serra Branca and Albernoa melt inclusions can contain up to 35 ppm Sn, much higher than in melt inclusions from Neves Corvo. Preliminary results of contrasting concentrations in particular elements observed in the melt inclusions and their host rocks suggest mixing of magmas. On the other hand, it is puzzling to observe that higher concentrations of ore-metals (e.g. Cu, Sn) are found in melt inclusions hosted in volcanic rocks from volcanic centres without known mineralization and not in the Neves Corvo volcanic rocks. On-going research should provide additional arguments for this discussion. Nevertheless, these observations have strong implications for the understanding of the pre-eruptive processes that occurred beneath the IPB volcanic centres and the on the evaluation of the role of magmatic-hydrothermal processes in the formation of high-grade Cu (±Sn) mineralization in this remarkable province.

Vent chimneys of Devonian black smokers in Rudniy Altay

Maslennikov, V.V.[1], Zhukov, I.G.[1*], Maslennikova, S.P.[1] & Simonov, V.A.[2]
[1]Institute of Mineralogy, Ural Division, Russian Academy of Sciences, Miass, Russia ([*]igorzhukov2009@yandex.ru)
[2]Institute of Geology and Mineralogy, Siberian Division, Russian Academy of Science, Novosibirsk, Russia

The occurrences of well-preserved ancient black smoker chimneys in VHMS deposits are rare [1-3]. Last years the Devonian massive sulphide deposits at Rudniy Altay (Nikolayevskoe, Artemyevskoe, Zarechenskoe) have yielded a number of very well-preserved sulfide vent chimneys. The VHMS deposits were formed in ensialic island arc basin in to anoxic to suboxic environments. This district comprises bimodal felsic (Altay subtype Kuroko type) classes of VHMS deposits hosted by black shales in dacites and rhiolites.

Three main chimney types are classified by the principal chemistry: 1) Cu-Fe-Zn-rich (in Nikolayevskoe deposits); 2) Zn-Cu-Ba-rich (in all mentioned deposits); 3) Ba-Fe-rich (Artemyevskoe); 4) Ba-rich (Zarechenskoe).

In general, the mineralogical zonation shown by various ancient chimneys is broadly comparable with those studied in modern black or gray smoker chimneys, with the exception of the lack of evidence for the former initial chimney shell of anhydrite or silica. In the Cu-Fe-Zn-rich chimneys, the pyrite in the outer walls (zone A) is represented by primary colloform, and fine varieties as well as pseudomorphs, probably after hexagonal pyrrhotite. In the inner parts of outer walls of the chimneys, the colloform and fine pyrite were partly replaced by marcasite and euhedral pyrite in association with sphalerite and chalcopyrite. The chimneys with sphalerite and barite outer wall were found, too. The inner walls (zone B) of the chimneys were always formed of coarse subhedral chalcopyrite, which sometimes demonstrates textures of relict intermediate solid solution copper-iron or copper-zinc sulfide phases (ISS). The enargite and fahlores are wide spread. The axial conduit zones (zone C) of some chimneys were consequently filled with sphalerite, pyrite, marcasite quartz and/or barite. In the Zn-Cu-Ba-rich, the outer wall is, commonly, sphalerite of barite sphalerite with minor euhedral pyrite. In Ba-Fe-rich chimneys, the outer wall is composed of framboidal or collloform pyrite. The pyrite-arsenipyrite-fahlore-galena-gold and bismuth assemblages have been revealed in the chimneys. The axial conduits were filled with barite and minor sphalerite and galena. In fragments of Ba-rich chimneys, concentric barite zones contain dissemenated galena, sphalerite, fahlores and native gold. The all chimneys canbe ranged from black smokere to gray and white smokers with increasing of sphalerite and barite. The significants of gold-galena-fahlore assemblage increase in the range. The mineralogical zonation may be interpreted in terms of zoned formation temperatures and redox conditions across the chimney wall during formation.

Genetic study of the primary hydrothermal mineralization in Špania Dolina and Ľubietová ore districts (Slovakia, Western Carpathians)

Michňová, J.[*] & Ozdín, D.
Dept. of Mineralogy and Petrology, Comenius University, Bratislava, Slovakia ([*]michnova@fns.uniba.sk)

Sulphidic and carbonate veins were from the Middle Ages the main sources of metals in the area of today`s Slovakia.

Older works dealing with the topic of hydrothermal carbonate-quartz-sulphide mineralization were focused mainly on mineralogical study, while from the half of 20th century more complex investigations including detailed geochemistry and genetic study of these systems were done.

These work was focused on two Cu abandoned deposits; first of them of known origin - hydrothermal Cu mineralization at Ľubietová deposit, which occurs in metamorphic crystalline rocks of Veporic Unit and originated during Alpine tectono-metamorphic events as many others siderite-sulphidic veins in Tatric and Veporic units. The second one Špania Dolina deposit is situated in sedimentary rocks of Permian age and some features indicated (according to older works) affinity to sedimentary copper deposits (e.g. Novoveská Huta deposit).

New results from our investigation show, that on both localites studied, mineralization has been developed in three stages:

1. siderite (carbonate) stage, 2. stage of Alpine mineralization and 3. – sulphidic stage. The 4. stage represented by Ca-carbonates was identified only at Špania Dolina.

Fluid inclusion study indicates, that minerals from siderite and sulphidic stage of mineralization in Špania Dolina precipitated from medium temperature (~120 – 314 °C) and moderately saline (~ 10 – 23 wt. % NaCl eq.) H_2O - NaCl fluids, which contain small amount of $FeCl_2$ and $MgCl_2$.

Minerals from stage of Alpine paragenesis and sulphidic stage of mineralization in Ľubietová precipitated from medium temperature (156 – 330 °C) and low to moderately saline (~ 3 – 20 wt. % NaCl eq.) H_2O - NaCl and H_2O - CO_2 0 NaCl fluids with small amount of $MgCl_2$ and $FeCl_2$. That means that fluids were influenced by metamorphic source.

Average temperature of the origin of Alpine paragenesis calculated using chlorite thermometry is 320°C and age of mineralization according to monazite dating is 92 ± 11 Ma (Upper Cretaceous tectono-metamorphic origin).

Isotopic study of secondary barite and primary sulphates of barite-celestine group shows different composition of isotopes S and O. Isotopic study in case of primary sulphates suggest, that their origin was influenced by Permian evaporates and in case of secondary barite juvenile fluids were most important.

C and O isotope data of carbonates from the siderite stage indicate mixing of fluids from various sources, but the most important were crustal fluid solutions.

All obtained results suggest, that mineralization at both studied localities have the same character of hydrothermal deposit, that „Cu – sulphidic mineralization“ in permian sedimentary rocks is analogue of sulphidic stage at siderite-sulphidic veins in crystalline rocks and differences in structures were caused just by different character of host rocks.

Giant quartz orebodies: structural, mineralogical and geochemical evolution

Moroni, M.*, Zucali, M., Tiboni, Ch. & Leoni, F.
Dipto. di Scienze della Terra "A. Desio", Università degli Studi di Milano, Milan, Italy (*marilena.moroni@unimi.it)

Quartz veins are frequent but giant quartz-only orebodies, mostly mined for metallurgy and ceramic industry, are not so common and their origin and mechanisms of emplacemen are not completely understood (e.g., see [1] for a geological-structural model). At the location of Sondalo, in the Central Alpine Belt (Northern Italy), a huge orebody of pure quartz is emplaced in high-grade continental basement of the Austroalpine Languard-Campo Nappe. The orebody, currently extensively mined and in development, is open ended at depth. It has never been studied. The orebody is irregularly tubular-shaped, and is in direct, brecciated to faulted contact with basement migmatites, garnet-biotite-sillimanite gneisses and amphibolites as well as with a Permian gabbro intrusion (Sondalo Gabbro) emplaced in the basement. The orebody consists of extremely hard, highly deformed, varicoloured (white, light pink, grey, black) quartz. Muscovite and tourmaline are the rare but coarser accessory minerals near the margins of the body, although sub-micrometric accessory phases variably disseminated throughout the body were observed. Fluid inclusions are locally abundant.

3D meso- and micro-structural relationships between orebody and basement and thermo-barometric estimates suggest emplacement of the quartz intrusion later than Permian but before Alpine convergence, at T >750°C and P ≈ 0.7 Gpa. However unusual, coarse skeletal biotite and orthopyroxene intergrowths in reaction rims of breccia fragments also suggest a remarkably high thermal regime of the quartz emplacement, at T > 670°C (biotite-opx thermometer). During the emplacement widespread brittle deformation occurred likely associated with hydrofracturing mechanisms. Quartz also bears evidences of intense plastic deformation with localized annealing, in addition to widespread mm- to cm-spaced late-stage fracturing. At the mesoscale highly strained portions of the orebody may show impressive colour variations from pure white to black.

Selected trace elements, Al, B, Ba, Fe, Ge, P, Ti were analyzed for evaluating colour variations and provenance of quartz based on mechanisms of Si replacement in the quartz lattice in pegmatite-like contexts (see [2,3]). The trace element composition of the Sondalo quartz revealed unusually high values of Si-substituting Ge, P Ti and Al contents and related ratios relative to pegmatite-related quartz, as well as high contents in Ba. Trace elements show roughly zoned, coherent distribution patterns and show some relationships with colour variations. Coupled Ba and Ti enrichments may also cope the occurrence of phases like benitoite (revealed only in XRD patterns) among the submicrometric accessory phases. Coupling of structural and geochemical mineralogical investigations of orebody and wall rock may give additional clues on the still poorly understood nature, mechanisms of formation and emplacement of huge quartz-only bodies in orogens.

Au-Bi-Te mineralization of the Myutenbay deposit (the Muruntau ore field, Uzbekistan)

Mun, Yu.S.
Dept. of Mineralogy and Geochemistry, Faculty of Geology, National University of Uzbekistan, Tashkent, Uzbekistan (ju.moon@yahoo.com)

The Myutenbay deposit is located in the Kyzylkumsky region. It is a south-eastern flank of the Muruntau deposit. It is localized in the block of Besapan suite schists (O_2-S_1*bs*) dropped relatively the Muruntau deposit and it is separated from it by sublatitudinal South Fault. The main productive mineralization is a gold-pyrite-arsenopyrite with fine dispersed nanogold and Ni-Co minerals – gersdorffite, pentlandite, ulmanite, Ni-loellingite, gold-tellurium-selenide-polymetallic with bismuth sulfides (bismuthinite, ikunilite), sulpho-salts (gustavite, kobellite, sakharovaite, pavonite, treasurite, galenobismutite), tellirides (hedleyite, tsumoite, pilsenite, tellurobismuthite), sulpho-tellurides (sulphotsumoite, joseite A, B, tetradymite, ingodite), seleno-tellurides (kawazulite), as well as maldonite, Ag-maldonite, native bismuth. On composition bismuth compounds are nonstoichiometric and they form transitional compounds of different homologous series and very often enriched in selenium, from 1 to 8 %.

Previous research (as it was on the Muruntau) determined the high indicated role of Bi, but it was marked that tellurides and selenides in the ores of the Myutenbay were not found. However, our research showed that tellurides and other Bi compounds have very wide abundance and are mainly segrerated in micro- and even nanoforms within arsenopyrite, pyrite and quartz forming close intergrowths (nanoassemblages or microparageneses) with gold, probably with maldonite, native Bi.

Mineral-geochemical research of gold ore deposits of Uzbekistan showed that on gold deposits proper (Au:Ag – 10:1-1:10) Au-As and Au-Te mineral associations of geochemical parageneses are constantly present. But Au-Te mineralization in the deposits of Kyzylkumsky and Nuratinsky ore districts is mainly represented by bismuth tellurides, sulphotellurides, selenides and sulpho-salts, and in Kuraminsky region by various tellurides of Au, Ag, Pb, Sb, Hg and Bi selenides. It is connected with that fact that the deposits of the Kyzylkumsky and Nuratinsky regions were formed in hypabyssal hypomesothermal conditions and in the Kuramninsky region in epithermal ones.

Geochemical rows of the elements accumulation intensity within the ores calculated on the basis of concentration coefficients that were calculated relatively clarks of elements in the Earth crust show that on the Myutenbay and Murunatau deposits following elements are accumulated with gold:

Muruntau – Bi-As-Te-Au-Se-Pd-W-Ag-Sb-Mo-Hg-Pb-Cu-Pt-Sn; Myutenbay – As-Te-Bi-Au-Se-Sb-W-Ag-Hg-Pd-Mo-Cu-Pb-Sn-Ni.

It should be also mentioned that Au, Bi, Te, As concentrations are thousands of units, and the rest elements are hundreds-tens units.

Thereby, Au-Bi-Te mineralization, together with Au-As one is the most important during formation of gold deposits in hypabyssal conditions.

Mineralogy of Sn-Nb-Ta-W(-Au) mineralizations in the Musha-Ntunga, Bugarura-Kuluti and Rwinkwavu mineral districts, south-eastern Rwanda

Ngaruye, J.C.[1,2*] & Gauert, C.D.K.[2]
[1]Rwanda Geology and Mines Authority (OGMR), Kigali, Rwanda ([*]jclaudengar@yahoo.fr)
[2]Dept. of Geology, University of the Free State, RSA

The cassiterite – wolframite - columbite/tantalite and gold mineralisation in Rwanda belong to the Kibaran metallogenic province which extends over an area of 1500*400 km from Katanga in southern DRC to south-western Uganda in the north-east. An approximate age of 1380 Ma were determined by several workers for the G1-3 granites, an age of 980+/-10 Ma for the G4 granites, the columbite mineralisation at 965+/-5 Ma, and cassiterite in mineralized quartz veins of Burundi at 951+/-18 Ma [1]. Intrusive orogenic S-type granites are supposed to function as the heat source for the mineralizing fluids [2].

Motivation for the study is a renewed economic interest in those commodities and the intention to strengthen the mining industry and exploration in Rwanda. Eastern Rwandan deposits in particular require modern mineralogical and geochemical investigations which are lacking to date.

Both primary and secondary mineralizations do exist: a) Cassiterite-ferberite-quartz veins and b) mineralization in pegmatite represent the first type of mineralization while the second consists of alluvial and/or eluvial cassiterite, wolframite, 'coltan' and gold placers.

Fig. 1: W-Sn-Nb-Ta-Au deposit map of Rwanda (OGMR, 2006).

SEM-W/EDX analyses of ore minerals reveal Mn-Ta-Fe-bearing ferberite, Mn-Sn-W-Fe-bearing columbite-tantalite, Fe-Ti-W-bearing cassiterite, and F-rich biotite; therefore, in combination with the co-occurrence of tourmaline we infer pegmatitic to pneumatolytic conditions during mineral deposition.

Copper potential resources in ophiolites of Albania and new possibilities of their development

Onuzi, K.[*], Bakallbash, J., Deda, T. & Kaza, Gj.
Geosciences Institute, IGJEO, Tirana, Albania
([*]onuzikujtim@yahoo.com)

This contribution presents a brief description of Albanian copper mining and processing industry, in the past and the trends of its future development.

In the four main minerals of Albania, chromites, copper, iron-nickel and coal, the copper seizes the second important place. The copper ores started to be mined and processed before the Second World War in Mirdita Region (central north of Albania). Later on, this region became the most important centre of copper mining and processing industry. Through an extensive programmer of exploration carried out in the past, new copper-bearing areas were found and were put into operation, but some of them had been ineffective.

After the year of 1990, under the conditions of Free Market Economy, the reevaluations for every mine and deposit were carried out, trending so to put into operation only the effective mines and deposits. By this way, there already started closing the ineffective mines, restructuring the effective ones and planning to open new deposits, applying new technologies in drifting, mining and processing.

Besides others, this contribution aims to show to the domestic and particularly to the foreign investors the real copper potential of Albania and new possibilities to attract their investments.

Copper deposits are localized in the ophiolites of Albanides, mainly in the upper and middle part of their sequence. From the regional aspect, the most important region of their occurrence is that of Central Mirdita. Based on the the geological conditions of position in the sequence of ophiolites, morphology, mineral and substantial composition, genesis, etc., four types of copper deposits are distinguished: 1. Hydrothermal - metasomatic and volcano - sedimentary deposits (Munella, Qafe-Bari, Gurth, Rruga e Rinise); 2. Volcanogene - hydrothermal - metasomatic vein deposits (Tuc, Spac, Derven, Paluce); 3. Volcano - sedimentary deposits (Gjegjan, Palaj, Karme, Rubik); 4. Vein-massive metasomatic sulphide deposits (Kurbnesh, Golaj, Thirre, Nikoliq). The geological reserves of all Albanian copper deposits are about 53 million tones and mine able reserves are about 27 million tones.

The activity of mining in all regions of Albania is carried out through 6 enterprises, with about 20 mines, which are included in the Copper Corporation-Albbaker. Before 1990 in the copper industry, about 7000 employees have been employed, most of them in the mining sector. Annual production of the copper ore has been, for a period more than 10 years, about 1 to 1.2 million tones of a grade averagely 1,3 to 1,4% Cu Together with the copper was produced a small amount of pyrite ore. Mining methods used in the copper mines are generally those of sublevel caving, as high-productivity methods, but with losses about 20 % and dilution 18 %.

Based on existing situation of copper industry, the development of this branch is foreseen to be supported from reconstruction of the existing objects, in order to improve the technology, as well as the construction of new mines, beneficiation plants and smelters. It is indispensable, that the development of such industry must be orientated through the production of cathodes copper and the production of wire and cables of high quality, as well as their export in the world market. To realize such objective, it will be planned a general invested program which consists on the implementation of a technical-economical study based on the actual situation and foreseen investments.

Mineralogical and genetical study of primary hydrothermal siderite-quartz-sulphidic veins hosted by Tatric and Veporic unit (Western Carpathians, Slovakia)

Ozdín, D.
Dept. of Mineralogy and Petrology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovak Republic
(ozdin@fns.uniba.sk)

Fe-carbonate-quartz-sulphidic mineralizations are the most abundant ones in Slovakian Carpathians, where occur in cca thousand localities. These veins occurs in the Tatric and Veporic Unit mainly in high metamorphic Palaeozoic rocks (gneisses) or in Permian sedimentary rocks (greywacke, arcose, conglomerate), in the Vysoké Tatry Mts. and Slovenské rudohorie Mts. are more frequently also in Palaeozoic granitoides. Hydrothermal veins form mainly carbonate lenses on mylonitized (cataclased) vein zones in crystalline basement. Their length is from some meters to 2.5 km (e. g. Vyšná Boca deposit), thickeness up to 6 m, mostly SW-NE to W-E direction and very steep slope toward S. Mineralizations form in sedimentary rock usually thin veinlets of sulphides with quartz or it is disseminated in rocks. More abundant are brecciated and cockarded (siderite, quartz), banded (barite), disseminated (sulphides) and drusy (minerals of Alpine-type veins) textures. Alteration processes represented only silicification and pyritization. Characteristic succession scheme for this type mineralization has 3 stages: 1. Fe-carbonates → 2. alpine paragenese → 3. quartz-sulphides. Predominant carbonates first stage are siderite/magnesite and carbonates dolomite-ankerite series. We can to observe space zonality in Slovakian occurrences from SE to NW: Mg-carbonates (almost chemical pure magnesite)→ Fe -Mg carbonates (transition members between magnesite and siderite and dolomite/ankerite)→ Fe -carbonates (predominantly siderite)→ Ca -carbonates (calcite, dolomite with low isomorphism Mg→Fe). On base leached of fluid inclusions formation temperature of siderite were 298 °C (Vyšná Boca) and 310 °C (Jedľové Kostoľany). An isotope study of siderite has provided the following data: ~$\delta^{18}O_{SMOW}$ +13-17‰ and $\delta^{13}C_{PDB}$ -3 to -5‰. Ankerite contains two-phased fluid inclusions (FI) (water solution of NaCl and vapour) with homogenization temperature (Th) from ~170 to 250°C and salinity 17-27 wt% $NaCl_{eq}$. Second stage is abundant mainly in Veporic Unit and at Pezinok in Malé Karpaty Mts. and Vysoké Tatry Mts. in Tatric unit. In this stage are following mineral assemblages: Aa. quartz-tourmaline-albite (two-phase FI in tourmaline: Th ~120-230°C, ice-melting temperature (Tm) -2 to -11°C, salinity 3-14 wt% $NaCl_{eq}$) with younger mineral assemblages Ab. chlorite (crystallization temperature on the base chlorite thermometry is 315-375°C) and Ac. muscovite (Ar/Ar ages of hydrothermal muscovite in J. Kostoľany gave 75.1 ± 1 and 75.4 ± 2 Ma); B. axinite-actinolite-calcite (FI in ferroaxinite: Th ~120-235°C, Tm -3 to -26°C, average of salinity (2 localities) ~18 wt% $NaCl_{eq}$); C. Apatite-REE phosphate (EMPA monazite dating: J. Kostoľany 83±9 Ma, Ľubietová 93±11 Ma); D. epidote-calcite; E. zeolites-calcite. Third stage have a few substages: Ni-Co-Fe-As → quartz → Cu-Fe sulphides→ Bi -sulfosalts. Ni-Co sulfoarsenides probably crystallized at the two different conditions – higher (300-550°C (?) and lower temperature (< 300°C). Two-phase fluid inclusions are very characteristic for quartz this stage (Th ~ 100-220°C, salinity 11-25 wt% $NaCl_{eq}$). On base presence of exsolutions in Bi sulphosalts (bismuthinite, pekoite, gladite etc.) these one crystallized at ~300°C. According to mineralogy, studies of fluid inclusions as well as stable isotopes is mineralization of Alpine age, minerals crystallized probably at prograde pT conditions (temperature mainly ~150-350°C) and fluids was formed various fluids at low ratio of fluid/rocks.

Mineralogical composition and mineral chemistry of supergene cobalt ores from eastern Cuba and Dominican Republic Ni-laterite deposits

Proenza, J.A.[1*], Roque, J.[2], Labrador, M.[1], Galí, S.[1], Tauler, E.[1], Gallardo, T.[1], Lewis, J.F.[3] & Longo, F.[4]
[1]Dept. de Cristal·lografia, Mineralogia i Dipòsits Minerals, Universitat de Barcelona, Barcelona, Spain
([*]japroenza@ub.edu)
[2]CEMES, Toulouse, France
[3]Dept. of Earth and Environmental Sciences, George Washington University, Washington, USA
[4]Falcondo XStrata Nickel, Santo Domingo, Dominican Republic

Cobalt is a strategic and critical metal used in many diverse industrial applications. The vast majority of identified world cobalt resources are in Ni-laterite deposits. In this contribution, new data on the mineralogical composition and mineral chemistry of cobalt ores from eastern Cuba (Moa Bay) and Dominican Republic (Falcondo) Ni-laterite deposits are reported. The samples were investigated using XRD, μXRD, μRAMAN, SEM, μXRF and EMPA.

In eastern Cuba Ni-laterites (oxide-type), the cobalt mineralization occurs in the limonite horizon, mainly in the lower part, as veins and coatings or concretions along fractures. At the hand sample scale the picture is a matrix of Fe-oxyhydroxides in which scattered bluish black aggregates corresponding to Co-Ni-Mn-oxyhydroxides are present. The cobalt ore consists mainly of lithiophorite [$(Al,Li)MnO_2(OH)_2$, with up to 13 wt.% Co], Al-rich asbolane [$(Co,Ni)_{1-y}(MnO_2)_{2-x}(OH)_{2-2y+2x}\cdot n(H_2O)$, with up to 7 wt.% Co, 14 wt.% Ni], lithiophorite-asbolane intermediate minerals (up to 10 wt.% Co), cryptomelane (< 2 wt.% Co), and minor heterogenite [CoO(OH)]. Our results suggest the existence of a continuous series between lithiophorite and asbolane.

In Dominican Republic Ni-laterites (hydrous silicate-type), the cobalt mineralization occurs at the upper part of the saprolite horizon, as veinlets, coatings along joints, and cracks developed by spheroidal weathering. At the microscopic scale, Co-bearing minerals replace pyroxene, olivine and serpentine along grain boundaries and fractures. The cobalt ore consists of heterogenite, Ni-rich asbolane (up to 5 wt. % Co, and 18 wt% Ni) and minor, lithiophorite-asbolane intermediate minerals (up to 4 wt.% Co) and cryptomelane. However, lithiophorite, a characteristic mineral in eastern Cuban Ni-laterite deposits, has not been detected. This absence of Al-rich phases is consistent with the Al-depleted composition of parent rocks in Dominican Republic deposits. In contrast, the abundant presence of lithiophorite in the Cuban deposits implies the availability of Al, consistent with the presence of plagioclase-bearing peridotites, and sills of gabbros, in the parent rocks from which the lateritic profiles were developed. In summary, the mineralogy of the Co-bearing ores depends on the composition of the parent rocks, and their depth within the laterite profile is probably related to the variation in Eh-pH.

Paleogeodynamic criteria of the presence of diamonds in the northern part of the European craton

Pystin, A.* & Pystina, Y.
Institute of Geology, Komi Science Centre, Ural Branch of RAS, Syktyvkar, Russia-Republic of Komi
(*pystin@geo.komisc.ru)

It is well known that, as a rule, diamondiferous kimberlites coexist with Early Precambrian cratones (Clifford's principle). However, these are non-uniformly distributed within the cratones. The lateral heterogeneous distribution of alkaline-ultrabasic magmatism and associated diamondiferousity over the cratones is stipulated by different causes. An assumption on connection of the heterogeneity with the location of Early Proterozoic junction zones of lithospheric plates has been made in the last few years.

According to O. G. Sorokhtin's opinion, the distance from an ancient subduction zone to the areas of productive magmatic manifestations to be expected is estimated as 390-660 km. It is taken into account that the speed of lithospheric plates movement in the Early Proterozoic was 5-6 times as large as a contemporary one, the maximum thickness of continental lithosphere reached 220 km, and the minimum depth of diamondiferous melts formation was at least 130 km.

On the ground of the above hypothesis, O. G. Sorokhtin and other researchers have explained the spatial distribution of alkaline-ultrabasic magmatism within the Archangelsk diamondiferous province.

Another Early Proterozoic paleosubduction zone has been established on the basis of investigations of the structural-material complexes in the Urals, Timan, and South-East Pritimanie. The zone is of the south-east orientation and south-west dip. The south-east fragment of the zone is exposed in the Subpolar Urals.

The territory including the Polyudov uplift in the Northern Urals (a region of diamonds present extraction from placers), the Timan, the Kanin Peninsula, and the South-western Pritimanie is prospective in respect to exploration of the diamondiferous alkaline-ultrabasic rocks connected with the zone mentioned. The territory can be treated as the Timan-Ural diamondiferous province.

Concentration technology for Devonian bauxites of Timan, Russia

Vakhrushev, A.V. & Kotova, O.B.*
Institute of Geology, Komi Scientific Center, Uralian Branch, RAS, Syktyvkar, Russia (*kotova@geo.komisc.ru)

Aluminum is the most widespread metal in the nature: its content in earth's crust reaches 8.8%. Due to its chemical activity it is not found free practically. It is widely used as constructional material, as reducer, for alloys etc.

The most important mineral of aluminum is bauxite, a mixture of basic oxide AlO(OH) and hydroxide $Al(OH)_3$. The largest bauxite deposits are located in Australia, Brazil, Guinea and Jamaica.

The probable reserves of Russian bauxites are assessed as more than 404 mln. tons (2% of the world reserves); they are related to P1 and P2 categories and distributed practically equally. The biggest part of the probable reserves (66%) is determined within Middle Timan and South Timan bauxite-bearing areas in Komi Republic.

The major reserves of Middle Timan bauxites are concentrated at the Vezhayu-Vorykva deposit. These bauxites are characterized by a high quality. About 80% of the ores suitable for Bayer processing, 20% are sintering ores.

At the deposit three types of ores are determined, which differ by their lithologic-mineralogic characteristics. The first type (77.7%) is hematite-boehmite, red bauxites. The Bayer ores make 85-90%. The second type (19%) is gematite-chamosite-boehmite, variegated bauxites. This type consists of sintering ores at 60%. The third type (3.3%) kaolinite-chamosite-boehmite, pelitomorphic bauxites (white and red). These are high-grade Bayer ores, low-developed.

The bauxites, recommended for concentration, form stony varieties. The soiled bauxites are generally high-modulus Bayer ores.

On the basis of the concentration, mineralogical and physical researches of Timan bauxites it is determined that the basic ore-forming minerals for Middle Timan bauxites are the following: boehmite, hematite, kaolinite and chamosite.

Various concentration methods are tested on the Middle Timan bauxites: dispersion, classification, annealing, magnetic separation, flotation. The results of these researches will be expressed in the report.

Ti-V oxide deposits in the Kunene anorthositic complex (SW Angola)

Villanova, C.[1*], Galí, S.[1], Torró, L.[1], Castillo, M.[1], Campeny, M.[1], Gonçalves, A.O.[2] & Melgarejo, J.C.[1]
[1]Dept. de Cristallografia, Mineralogia i Dipòsits Minerals, Universitat de Barcelona, Catalonia, Spain
([*]cvillanovadb@hotmail.com)
[2]Dpto. de Geologia, Universidade Agostinho Neto, Luanda, Angola

The Kunene Complex, outcropping between SW Angola and NW Namibia, is one of the biggest Proterozoic anorthositic complexes in the world [1]. It is cut by a set of Ti-Fe oxide dykes or lenticular bodies, which are hectometric to kilometric in length and metric to decametric in width.

The mineral associations of four oxide bodies have been studied: Dongue Sul, which presents a concentric structure with a nelsonitic core; the massive decametric ore bodies of Tchimbueio and Tchingunguanganda; and Chiange Velho, a kilometric dike, which may show millimetric foliations due to shear deformation.

The main mineral assemblage is composed by ulvöspinel, ilmenite and spinel (s.s.), in order of abundance (Fig. 1). These minerals coexist with apatite and minor graphite, phlogopite, and olivine. Most grains exhibit evidences of orthomagmatic textural equilibria in grain borders. The proportions of these minerals in the ore have been obtained by quantitative X-ray diffraction using the Rietveld fitting profile method. In average, they are: 60% Usp, 25% Ilm, 5% Spl, and 10% (Ap+Hem+Gt).

Ulvöspinel is rich in V (up to 0,15 wt%) and presents characteristic laminar or patchy micrometric double exsolutions of a Ti and Fe-richer phase and spinel (s.s.) lamellae. In ilmenite the geikielite component is 14-21 wt%, and does not contain exsolutions. Spinel is rich in the hercynite component (14-35 wt% Fe).

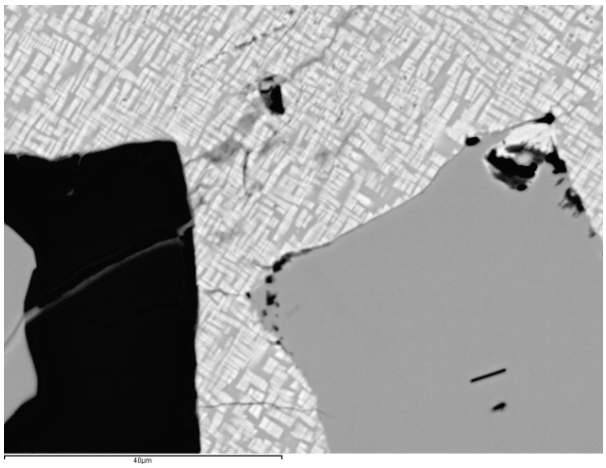

Fig. 1: Equilibrium texture between ulvöspinel (patchy texture), ilmenite (light grey), spinel (dark grey); exsolutions in ulvöspinel are clearly distinguishable. SEM-BSE Image. Field width: 100 µm.

Furthermore, when equilibrium can be assumed on the basis of textural and compositional evidences, the temperature of crystallization and the oxygen fugacity can be estimated using reported geothermobarometers [2,3]. For instance, in the case of Tchimbueio deposit, the temperatures obtained range from 973 to 1026 ºC, and the fO_2 from 10^{-12} to 10^{-10}.

Geology and geochronology of magmatic centers in the Urumieh-Dokhtar Arc, Iran

Zarasvandi, A.
Dept. of Geology, Faculty of Sciences, Shahid Chamran University, Ahvaz, Iran (zarasvandi_a@scu.ac.ir)

The relationship among of basement lineaments, volcano-plutonic suites have been studied in three parts of the Urumieh-Dokhtar magmatic arc, using by satellite images, geological and geochronological data. This magmatic arc is result of closure of the Neo-Tethys Ocean and the collision of the Iranian and Afro-Arabian plates. Almost all of the Eocene to Miocene granitoids subduction-related is located in the north western and central-south eastern parts of the Urumieh-Dokhtar belt. Volcanic and plutonic domains in several parts of the Urumieh-Dokhtar belt are separated by N-S and NW-SE trending reactivated faults and lineaments. These features are very important for distribution of granitoid magmatism. In this study, three areas selected for detailed investigation: Shahr-e-Babak, Sungun and Khezr-Abad area (Fig. 1). These areas have semi-arid type of climate with many outcrops that makes them suitable for application of remote sensing technique.

Geological, structural and location of magmatism centers were extracted from Landsat TM and IRS images and geological information. Based on these images and maps, location of volcanoes and magmatic centers can be related to structural framework of these areas, and are shown to occur near the intersections of strike-slip faults and pull apart structures. K/Ar whole rock geochronology of felsic to intermediate igneous rocks suggested that the granites are Oligocene (~28 Ma) in age, whereas the intermediate plutons are Miocene. This periods and situations are the best developed in the Urumieh-Dokhtar magmatic arc for pooling of large volumes of granitoid magmatism and several important mineralization provinces.

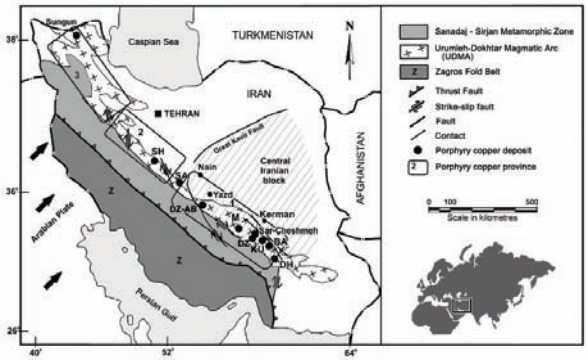

Fig. 1: Main tectonic zones of Iran and geographical position of selected studied areas.

Gold-bearing ore occurrence of Karasay, Uzbekistan: mineral-geochemical characteristics of ores

Zavarzina, M.S.[*] & Jukov, A.V.
Dept. of Mineralogy and Geochemistry, Faculty of Geology,
National University of Uzbekistan, Tashkent, Uzbekistan
([*]mzavarzina@yahoo.com)

The Karasay gold-bearing ore occurrence is located in the eastern Uzbekistan, in the north-western part of Kuraminsky mountain ridge, in Apantepa-Karatagatinsky area.

The Karasay gold-bearing occurrence is hosted by lower Devonian (D_1) quartz porphyries, which are intruded by Carboniferous to Permian sub-volcanic granodiorite-porphyries (C_3-P_1) as well as dykes of diabase porphyries. Faults in the ore occurrence have trends of differing orientation including north-eastern and north-western strike.

To study the mineral-geochemical characteristics of Karasay gold-bearing ore occurrences, samples were selected from adit and open pit.

Analysis of ore mineral composition (Jeol Superprobe 8800R) identified three main gold-bearing associations. A wall rock ore quartz-carbonate-sericite-pyrite association, was not analysed.

The first association is quartz-gold-pyrite, mainly low sulfide, with disseminations of pyrite and fine-dispersed gold.

Dark grey quartz has increased concentrations of Mo due to the presence of amorphous of molybdenite – jordisite. A $PbMoS_2$ phase is also present. Arsenopyrite was also found.

The second productive association is quartz-gold-polymetallic. It is developed as massive nests of sulfide ores or as dispersion in the first association. Main minerals are galena, sphalerite, pyrite, chalcopyrite, tetrahedrite and tennantite. Native gold has a fineness ranging from 600 to 850. The following tellurides were found: hessite, petzite and altaite.

The third hypergene association contains secondary minerals of Fe, Pb, Zn and sulfides of copper. Of note it is a secondary mineral form of molybdenum – wulfenite ($PbMoO_4$). Gold in this association has very high fineness from 900 up to almost 1000. Its variance from pure Au is due to a rare admixture of copper.

In 13 whole-rock ore samples analyzed by ICP-MS, gold content varies from 0.21 to 35.6 ppm, and silver content varies from 1.17 to 223.58 ppm.

The ratio of Au:Ag varies from 1:21.7 up to 3.2:1, though ratio of more than 1 is peculiar to high gold-bearing ores.

In the cases of sulphide-rich ores, increased concentration of Pb, Zn, Cu, As, Sb is usual. A distinctive feature of ores in the Karasay ore occurrence is a high concentration of molybdenum (0.01-0.1%). Among other noticeable admixtures Se, Te, Re, Tl, Hg, Cd, as well as Pd and Rh are noted.

Ores are distinguished by the content of non-ore oxides. Silica varies from 60 to 80%, Al_2O_3 from 6 to 19%. MgO and CaO content do not exceed 1% in average. Increased concentration of K_2O from 1.5 to 7%, Na_2O is not more than 0.5%. According to technological tests ores can be used as fluxstones

Main gold-bearing associations in the Karasay ore occurrence are hypergene and quartz-gold-polymetallic types.

After the examination of geochemical characteristics of Karasay ore occurrence, it is possible to conclude that they are complex, significantly multimetallic with high concentration of Mo, Re, As, Sb, Se, Te, Pb, Zn, Cu. Ore occurrences is an upper part of gold mineralization.

Genesis of sediment-hosted Au-As deposits: a two-stage process of early syngenetic gold followed by later epigenetic upgrading

Large, R.R.
CODES, School of Earth Sciences, University of Tasmania, Hobart, Australia (ross.large@utas.edu.au)

Currently accepted ore genesis models for orogenic and Carlin-style deposits assume that gold is sourced from deep below the deposits, in the lower crust or mantle, and transported upwards, along major crustal fractures or shear zones, during metamorphism and deformation, to become concentrated in second order structures during the peak, or post-peak, of metamorphism. Recent evidence, based on the textural and chemical association of both gold and arsenic in pyrite in certain sedimentary rock facies, supports a two-stage process of gold ore genesis for some gold provinces, with the gold sourced from organic-bearing shales in the basin.

The first gold stage involves pre-concentration of gold and arsenic in black mudstone facies of continental margin sedimentary basins. In the sediments, the gold is present as either invisible gold trapped in diagenetic arsenian pyrite or micro-nuggets (< 5 microns) of free gold associated with fine-grained clays and organic matter. These gold-bearing sediments are also enriched in a characteristic suite of elements, particularly V, As, Mo, Se (Te), Ni, Ag and Zn, giving rise to the term VAMSNAZ sediments. Gold contents of the VAMSNAZ sediments commonly range from 5 to 100 ppb, arsenic from 10 to 100 ppm, and organic carbon from 0.2 to 2 wt %.

The second stage, of the two-stage process, occurs during late diagenesis and metamorphism of the sediments, associated with deformation, basin inversion and/or granite intrusion. Gold and arsenic are released from the arsenian pyrite and from clay-organic matter intergrowths, associated with diagenetic and low grade metamorphic reactions in the VAMSNAZ sediments. Conversion of gold-bearing diagenetic arsenian pyrite to pyrrhotite at higher grades of metamorphism (lower-greenschist to upper-greenschist facies) is a particularly effective way of releasing gold to the metamorphic fluid. The H_2S-CO_2-CH_4-bearing metamorphic fluid (probably a mixture of seawater, meteoric water and diagenetic fluid trapped in the sediments), transports the gold and arsenic, through the permeable silt and sand facies sedimentary rocks, to become concentrated in zones of intense fluid flow and related pressure release, such as anticlinal fold axes, shear zones or dilatant quartz-vein reefs or stock-work zones.

This two-stage model is the first to account for the ubiquitous association of gold and arsenic in sediment-hosted orogenic and Carlin style deposits.

Geochemistry and genesis of Guqiong Ag-Au polymetallic deposit in Southern Tibet, China

Wei Huixiao[1], Sun XiaoMing[2,1,3*], Zhai Wei[2,3], Yi Jianzhou[4] & Zhou Feng[1]
[1]Dept. of Earth Sciences, Sun Yat-sen University, Guangzhou, China
[2]School of Marine Sciences, Sun Yat-sen University, Guangzhou, China ([*]eessxm@mail.sysu.edu.cn)
[3]Guangdong Provincial Key Laboratory of Marine Resources and Coastal Engineering, Guangzhou, China
[4]Geological Survey of Tibet Bureau of Geology and Mineral Exploration and Development, Lhasa, China

The Himalayan orogen is increasingly considered a remarkable orogenic gold metallogenic province [1]. The Guqiong Ag-Au polymetallic deposit (altitude ~5200 to 5500 m; total resource ~Ag 173t @ 272.2g/t, Au 4t @ 6.07 g/t, Pb 9938t @ 1.98% & Zn 8212t @ 1.39%) is a significant discovery which was found recently to the south of the east section of the Yarlung Zangbo tectonic suture zone in southern Tibet. A preliminary study on the genesis of the Guqiong deposit further indicates great prospecting potential in the southern Tibetan detachment system (STDS).

Rocks in the area are mostly made up of Triassic to Cretaceous low-grade metamorphic, intensely folded clastic sedimentary rocks. Magmatic activities in this district comprise few Jurassic andesite bodies and voluminous Cretaceous intrusive rocks. The main host rock for the mineralization at Guqiong is altered Cretaceous diabase. Ag-Au-Pb-Zn occurs principally within quartz-sulphide veins developed in the tectonic fracture zone. Ore minerals include electrum, silver-bearing tetrahedrite, pyrite, galena, sphalerite and arsenopyrite, etc. The main alterations include sulfidation, sericitization, and carbonatization.

Analysis of ore stage fluid inclusions from the Guqiong deposit indicate high content of CO_2, low to moderate temperatures (184.3~338.1°C), low salinities (4.2~6.2 wt% NaCl *eq.*) and shallow depth (0.1~1.6 km) for ore deposition. Measured $\delta^{18}O$ values for the ore-bearing quartz from Guqiong deposit range between 19.0 and 20.7 per mil; the estimated $\delta^{18}O$ fluid values range from 8.6 to 12.5 per mil, suggesting a mainly crust-derived fluid, which is similar to the typical orogenic gold deposits [2] and two proved orogenic gold deposits in southern Tibet (Mayum [1] & Bangbu [3]). A broad range of measured δD fluid values, between –172.3 and –113.9 per mil, is suggestive of a contribution from devolatilization of organic matter from the sedimentary rocks and/or minor amounts of mixing with geothermal fluids, which accord with the rock types in the area and the shallow formation depth of the Guqiong deposit.

From the above, general features of Guqiong deposit are basically consistent with orogenic gold deposits [1-3]. The ore-forming elements were deposited in the shallow part of the tectonic fracture zone, which was dominated by orogenic system. Further study on geological characteristics and genesis of Guqiong deposit would enrich the metallogenesis theory of the Himalayan orogen.

The gold-silver-tellurium mineralogy of the polymetallic Shahumyan deposit, Armenia: gold scavenged by tellurium-rich melts?

Mederer, J.* & Moritz, R.
Dept. of Mineralogy, Section of Earth and Environmental Sciences, University of Geneva, Switzerland
(*johannes.mederer@unige.ch)

The polymetallic Cu-Au-Ag-Zn±Pb Shahumyan deposit in the Lesser Caucasus of southeastern Armenia is hosted within Middle Jurassic subvolcanic quartz-dacite with a calc-alkaline signature. Pyrite, chalcopyrite, sphalerite, tennantite and galena are the main ore minerals of the more than 100 east-west striking and steeply dipping veins. Pyrite rarely contains up to 40 µm-sized inclusions of digenite, bornite, chalcocite and enargite. Quartz, carbonates (including kutnohorite) and sporadic hydrothermal apatite are the main gangue minerals.

Gold and silver distribution in Shahumyan is controlled by different Au-Ag-tellurides, including krennerite ($AuTe_2$), sylvanite ($AuAgTe_4$), petzite (Ag_3AuTe_2) and hessite (Ag_2Te). Native gold is a minor phase, altaite (PbTe) and native Tellurium are subsidiary phases. The telluride assemblages occur as droplet-shaped inclusions in pyrite, along grain boundaries between sulfide minerals, as elongated aggregates along healed microcracks in sulfides or associated with the carbonate and quartz gangue, as in Fig. 1, in which droplet-shaped tellurides are hosted by hydrothermal quartz in close proximity to an assemblage of krennerite and altaite. Most of the observed telluride occurrences consist of at least 2 different phases (e.g. petzite-hessite-altaite).

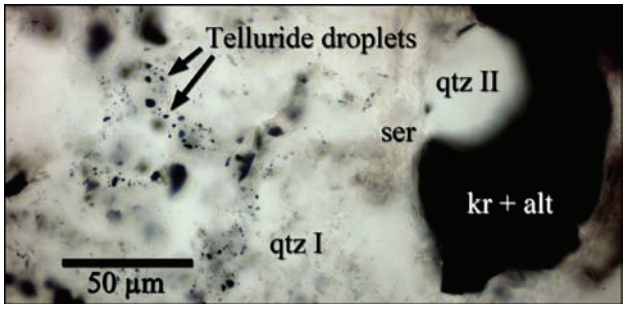

Fig. 1: Droplet-shaped tellurides within quartz (qtz) and sericite (ser) in the vicinity of a composite krennerite (kr) and altaite (alt) association.

The crystallization of tellurides from precipitates extracted from fluids as a liquid (melt) was proposed in earlier studies for the genesis of some telluride deposits, such as at Săcărîmb, Romania [1]. Thermodynamic modelling of Au-Te melt segregation from hydrothermal fluids [2] shows the potential for Au scavenging of such a melt, even from Au-undersaturated fluids. Textural relationships in the Shahumyan deposit, like droplet-shaped inclusions of tellurides in pyrite or quartz and the observation of composites commonly constituted by at least two main phases are interpreted as separation of a complex Au-Te rich melt from hydrothermal fluids at temperatures above the solvus curve/melting point of the composite, poly-component precipitate as a whole, but below the melting point of individual phases.

Geochemical characteristics and evolution of the mineralizing fluids within the Eastern Rhodopian sedimentary rock-hosted low-sulphidation epithermal gold systems, Bulgaria

Márton, I.* & Moritz, R.
Dept. of Mineralogy, Section of the Earth and Environmental Sciences, University of Geneva, Switzerland
(*Istvan.Marton@unige.ch)

A useful understanding of the origin of epithermal gold mineralization requires accurate knowledge about the source and interaction of four important components: heat, fluids, ligands and metals. The geochemical investigation and modelling is an important tool for understanding ore genesis and the interaction of these components. The ore fluids that formed fossil hydrothermal systems are difficult to study due to a number of assumptions about the ore fluid(s) that must be made, but which can be characterized by fluid inclusion analysis, by ore mineral assemblages and by alteration minerals. However, these do not necessarily define the original ore fluid but rather one, which had already interacted to an unknown extent with the host rocks.

The main purpose of this contribution is to characterize the mechanism of transport and deposition of associated gold and sulphides, which are the main ore components in sedimentary rock-hosted gold deposits from the Tertiary Eastern Rhodopes, Bulgaria. This contribution presents new major and trace element compositions, stable isotope and fluid inclusion data on these gold deposits. Emphasis is placed on comparison of ore textures, mineralogy and geochemical data from different occurrences. The likely source of the mineralizing fluids and their evolution during the gold depositional processes is discussed and modelled based on new geochemical data.

The geochemical results show, that a single ore fluid from different sources and various precipitation processes might be responsible for the range of ore types identified in the sedimentary rock-hosted gold deposits from the Eastern Rhodopes.

Abundant bladed quartz pseudomorphs replacing platy calcite suggest boiling in several prospects (Ada Tepe, Kuklitsa and Kupel), a process which is typical in case of low-sulphidation epithermal deposits. The chemical changes of the fluid during boiling included a raise in pH caused by preferential partitioning of volatiles into the steam phase, and an increase in concentration of non-volatile constituents in the liquid phase as the result of steam separation. These factors promoted super saturation, which resulted in sudden silica, adularia, sulphides and electrum precipitation.

By contrast, at other prospects, such as Rosino, Surnak, Kremenitz and Skalak, boiling textures are scarce to absent, and intense fluid-rock interaction may be responsible for gold mineralization. In such a case, gold deposition was controlled by cooling of a sulphide-rich fluid, change in oxidation state and mass transfer accompanied by sulphidation of iron present in the host rocks, as modelled for the Carlin-type gold deposits. The geochemical characteristics of the ore assemblages and the mass transfer studies show that gold might have been transported and deposited with other elements, and the thermodynamic conditions during ore precipitation can be modelled by phase relationships of the Fe-Au-As-Sb-Hg-Ag-S-O-H-Cl system. It is concluded that decline in temperature (at constant oxygen fugacity) lead to a reduction in solubility of all elements. Changes in oxidation state, accompanied by H_2S-loss during sulphidation of host rock iron, had the greatest effect on gold and arsenic solubility. As changes in arsenic mineral stability and solubility are so sensitive to the oxidation state of the system, arsenic minerals are likely an important indicator of redox conditions during the formation of sedimentary rock-hosted gold deposits in the Eastern Rhodopes.

Gold deposits along the Tethys belt: products of diverse tectonic and magmatic settings

Moritz, R.
Dept. of Mineralogy, Section of the Earth and Environmental Sciences, University of Geneva, Switzerland (robert.moritz@unige.ch)

The Tethyan orogenic belt is the result of a complex evolution, with several successive and locally overprinting subduction, collision, magmatic, and extensional events, as a consequence of convergence between the African, Arabian and Eurasian plates. Favourable conditions for gold ore deposit formation were generated in the different magmatic and tectonic settings throughout the evolution of the Tethys belt.

Tethyan gold deposits were mostly formed during three major tectonic and magmatic stages, including: (1) Jurassic-Late Cretaceous subduction extending from Romania to Iran; (2) Paleogene, calc-alkaline to shoshonitic magmatism, related to post-collisional (southeastern Europe, Armenia) and to subduction/collisional settings (northeastern Turkey-western Georgia, Iran); and (3) discontinuous Neogene magmatism, mostly related to extensional tectonics (Carpathians, Aegean Sea, Lesser Caucasus, Iran). The economically most important types of gold deposits include: epithermal, porphyry copper, and volcanogenic massive sulphide (VMS) deposits.

The metallogenic picture is still fragmentary, however several distinct patterns start to be recognized along the belt. Typically, gold deposits were formed during discrete or relatively short durations within a given tectono-magmatic zone. For instance, in the Andean-type, Late Cretaceous Timok-Srednegorie belt, major and economically important world-class high-sulphidation systems, such as Chelopech, Bulgaria, and Bor, Serbia, and associated porphyry copper deposits were emplaced within a short time span, during the early geological evolution of each tectonic zone, whereas the subsequent, younger magmatic activity produced economically less significant deposits. In the Eastern Rhodopes, characterized by Late Eocene-Oligocene post-collisional magmatism and extension, argon dating reveals that formation of the ~32 Ma old volcanic rock-hosted (e.g. Madjarovo, Sappes) and ~37.5-34.5 Ma old detachment-related sedimentary rock-hosted epithermal systems (e.g. Ada tepe) coincided with the onset of major tectonic plate reorganization in the Aegean Sea, as a consequence of African and Eurasian plate collision along the Caucasus and the Rif-Betic belts at about 35 Ma.

The Cenozoic evolution of the Tethys belt is dominated by post-collisional, orogenic collapse tectonics, in which slab detachment is interpreted as one of the key players during the geologic evolution in several gold deposit localities (e.g. Carpathians, Lesser Caucasus, Iranian Sanandaj-Sirjan zone). Slab break-off resulted in astenospheric upwelling, extension, exhumation of deep crustal rocks and a compressed geothermal gradient providing favourable settings for extensive fluid circulation, magma ascent and gold ore deposit formation.

Fluids and metals are of predominantly magmatic origin in many of the gold deposits, with variable meteoric contributions, in particular in the younger Cenozoic extensional settings. Seawater associated with gold-rich VMS deposits in the Turkish Eastern Pontides and the Bolnisi district, Georgia, is also recognized in some high-sulphidation systems, such as Chelopech, possibly recording emerging island arc-type environments during the Late Cretaceous. A magmatic-metamorphic fluid controversy exists for some gold deposits, like the ones hosted by metamorphic rock complexes in the Iranian Sanandaj-Sirjan zone interpreted by some authors as orogenic deposits, although argon dating indicates that gold ore formation coincided with Eocene extension, magmatism and basement metamorphic rock exhumation.

New Lu-Hf and U-Pb data for detrital zircon from the Eldorado Reef (upper Central Rand Group, South Africa)

Koglin, N.[1*], Zeh, A.[1,2] & Frimmel, H.E.[1]
[1]Geodynamics and Geomaterials Research Division, University of Würzburg, Germany ([*]nikola.koglin@uni-wuerzburg.de)
[2]Division of Geochemistry, Hydrogeology and Mineralogy, Freie Universität, Berlin, Germany

In order to constrain the source of the detrital components in the gold-rich conglomerates („reefs") of the Mesoarchaean Witwatersrand Supergroup, we analysed zircon grains from the approximately 2.8 Ga Eldorado Reef in the upper Central Rand Group. That reef represents alluvial fans that developed when syn-depositional folding and thrusting affected the western margin of the Central Rand foreland basin and led to intense re-working of older Witwatersrand strata.

The analysed zircon grains are of magmatic origin and mostly yielded Mesoarchaean U-Pb ages clustering at about 2940 and 3060 Ma, and minor Palaeoarchaean ages at 3285 and 3440 Ma. The initial εHf of the Mesoarchaean zircon populations is mostly super-chondritic and varies from -1.6 to +5.6, whereas the Paleoarcheaen zircons are roughly chondritic with εHf(t) ranging from -1.3 to +2.0. These data, in particular the abundant zircon grains with super-chondritic εHf(t) values, provide evidence for magmatic rocks from a depleted mantle source in the direct hinterland of the Central Rand Basin at 3060 and 2940 Ma. In agreement with geochemical and isotopic studies on calc-alkaline intrusive rocks of the same age in the immediate vicinity of the Central Rand Basin [1], a magmatic arc along the northern margin of the Witwatersrand Block is suggested as provenance at 3060 Ma. The 2940 Ma detrital zircon fraction was derived more likely from juvenile magmatic rocks in a volcanic arc setting related to subduction processes immediately prior to collision between the Witwatersrand Block and the Kimberley Block to the west. A possible source is the Kraaipan greenstone belt that occurs to the west of the Central Rand Basin. The lack of zircon grains younger than 2860 Ma in the Eldorado Reef can be explained by the development of a foreland fold-and-thrust belt that acted as a barrier between the upper Central Rand Basin and the internal zone of the Kraaipan greenstone orogenic belt, which contains abundant granite bodies with ages as young as 2.7 Ga. The Palaeoarchaean zircon grains (~3285 and ~3440 Ma) were derived from felsic intrusive rocks that formed by partial melting of even older continental crust. Sources for these zircons may be the Barberton greenstone belt and/or the Limpopo Belt.

Our data are in good agreement with the results of some previous U-Pb zircon studies across the Witwatersrand basin [2,3], which show a good correlation between detrital zircon age spectra and the grain size fraction of the sediment detritus, and thus a systematic difference between proximal and distal sources. Zircon grains from the arenitic fraction, thus reflecting a more distal source, in both the footwall and hangingwall of individual reefs show a wide range of ages. In contrast, zircon grains in the gold-bearing conglomerates, coming from more proximal sources, show a more restricted age distribution with a dominance of ages at around 3060 and 2940 Ma.

Constraining the source of the Witwatersrand gold

Frimmel, H.E.[1,2*], Depiné, M.[1], Koglin, N.[1], Emsbo, P.[3], Koenig, A.E.[3] & Minter, W.E.L.[2]
[1]Geodynamics & Geomaterials Research Division, University of Würzburg, Germany ([*]hartwig.frimmel@uni-wuerzburg.de)
[2]Dept. of Geological Sciences, University of Cape Town, Rondebosch, South Africa
[3]US Geol. Survey, Denver, CO, USA

The Witwatersrand "Basin" in the Archaean Kaapvaal Craton, South Africa, is the world's largest known gold anomaly, constituting c. 40 % of all gold that has ever been mined or is known as reserves and resources. A hydrothermally modified palaeoplacer model has been favoured by most workers over the past years to explain the high Au grades in the auriferous conglomerates most of which were deposited between 2.90 and 2.78 Ga in the Central Rand foreland basin. The source for this exceptional amount of detrital gold (in total >90,000 t) remains enigmatic. Previous studies revealed unusually high Os concentrations in the Witwatersand gold [1], which led to the suggestion that the gold was derived from a magmatic-hydrothermal source without constraining this source any further [2].

In this study we present lithogeochemical data on Witwatersrand shale units to describe the overall lithology of the source area(s) as well as data on rock fragments from Au-rich polymictic conglomerate beds, summarize important characteristics of the immediate basement rocks next to the margin of the former Central Rand Basin, and present trace element data on critical minerals of the ore assemblage, i.e. pyrite and uraninite. The results obtained, in combination with a geochronological provenance study based on detrital zircon grains, make it possible to characterize the likely setting of the primary magmatic-hydrothermal gold mineralization in the source area.

Even the fine-grained sediments now present in metapelitic units that can be correlated across the entire Witwatersrand "Basin" show distinct chemical differences depending on their position within the basin, i.e. they reflect regionally different provenances. The provenance as derived from shale geochemistry and heavy mineral populations conforms to that of a granite-greenstone terrane as presently exposed in a number of belts all over the Kaapvaal Craton. The detrital zircon age spectra in the non-mineralized arenitic fraction are complex and conform to the wide variety of Palaeo- to Neoarchaean zircon ages from the surrounding granite-greenstone belts, whereas those in mineralized conglomerates, reflecting more proximal sources, show a distinct peak at around 3060 Ma – in agreement with the available Re-Os age for the gold and associated detrital pyrite grains [1]. Basement rocks of equivalent age in the proximal hinterland are granite/granodiorite and gabbro as well as their volcanic equivalents. They have calc-alkaline composition and isotopically reflect a combination of juvenile and re-cycled older crust. The style of late- to post-magmatic alteration in these rocks is comparable to that around IOCG deposits. Equivalent rocks are found as volcanic clasts in the auriferous conglomerates. Unexpected high Au contents in detrital uraninite point to a relationship between Au-enrichment and U-mineralization in the source region for which a magmatic arc setting is suggested.

Crustal fluids formed world class gold deposits in different metallogenic provinces of Russia

Bortnikov, N.S. & Prokofyev, V.Yu.[*]
IGEM RAS, Moscow, Russian Federation
([*]vpr2004@rambler.ru)

Composition of mineral-forming fluids is a critical parameter for an identification of genesis of a mineral deposit. One may be expected that gold deposits within the same metallogenic province were formed from a similar fluid at similar physical and chemical conditions. Fluid inclusions were studied in quartz from 10 world class (productions+reserves more 100 t Au) and several ordinary gold deposits located in Lena (PR), Sayan-Yenisei (PR), Urals (Pz), Verkhoyansk (Mz), Kolyma (Mz), Okhotsk-Chukotka volcano-plutonic belt (Mz) and Eastern Transbaikalian (Mz). Deposits under consideration are Sukhoi Log, Olimpiada, Sarylakh, Sentachan, Nezhdaninskoye, Maiskoye, Natalkinskoye, Berezovskoye, Kochkarskoye, Darasun. Some of them are located in the metasedimentary sequence, while others are intrusion-hosted deposits. Four main types of fluid inclusions are recognized in quartz at room temperature in orogenic (mesothermal) deposits from Lena (PR), Sayan-Yenisei (PR), Urals (Pz), Verkhoyansk (Mz), Kolyma province: (1) two-phase aqueous inclusions, containing liquid and vapor; (2) type II, two- or three-phase, $(H_2O)L + (CO_2)V$ or $L + (CH_4)V$ or L fluid inclusions, including IIa, H_2O-CO_2-inclusions; (3) type III, vapour-rich inclusions, rarely with small liquid rims or meniscus, including IIIa, $(CO_2)V + (CO_2)L$, and IIIb $(CO_2)V + N_2 + NH_4$; and (4) type IV, multi-phase inclusions containing $(H_2O)L$-$(H_2O)V$, and solid-daughter mineral identifying as halite on the basis of habit and optical characteristics. The data obtained indicate that the commercial ore bodies in orogenic (mesothermal) deposits studied were deposited from the $H_2O+CO+NaCl\pm CH_4\pm N_2$ fluid with low- to moderate salinity. A mineral formation occurred at 100 to 450°C and 1 to 3 kbars. Dilute aqueous fluids recorded in the late gold-sulphosalts-bearing veins. Such a fluid regime is typical for orogenic gold deposits.

Compositionally contrasting fluids are responsiple for a formation of gold deposits in the the Darasun district (Transbaikalian). Brines with salinity 56.3–29.9 wt% NaCl-equiv. formed early metasomatites. Auriferous quartz -base metal-sulphosalt veins crystallized from aqueous fluids with salinity 22.2–0.4 wt% NaCl-equiv. Such fluids are characteristic for porphyry or "intrusion related" deposits.

Dilute aqueous fluids with salinity of 9.2–0.4 wt% NaCl-equiv. formed epithermal gold deposits within Okhotsk–Chukotka volcanic belt and Transbaykalia.

Acknowledgements: This work was carried out within the framework of the UNESCO-IGCP project 540 "Gold-bearing hydrothermal fluids of orogenic deposits" and the Russian RFBR (projects № 09-05-00697a and 09-05-12037ofi_m).

Gold in sedimentary basins: role of reduced basinal brines and hydrocarbons

Emsbo, P.[*] & Johnson, C.A.
U.S. Geologic Survey, Denver, CO, USA ([*]pemsbo@usgs.gov)

Epicontinental sedimentary rift basins host some of the world's largest gold deposits. It is increasingly clear that many of these basins contain synsedimentary gold enrichments that, in some cases, reach ore grade. While the metallogenic relationship between enrichments and subsequent epigenetic gold mineralization is an important question, the objective of this presentation is to explore processes resulting in primary gold enrichments. Our ongoing studies of synsedimentary gold occurrences, combined with chemical modelling and new laboratory experiments, have identified several pathways for gold transport in basinal environments.

Gold-rich sedex mineralization in Nevada, with Au as high as 70 g/t, and the occurrence of significant amounts of gold in classic sedex deposits like Rammelsberg (30 mt at 1 g/t) and Anvil (120 mt at 0.7 g/t) demonstrate that basin brines can form gold ore. Studies of ore deposits, modern brines, and chemical modelling indicates that variation in gold content is controlled by the concentration and redox state of sulfur in brine. For example, Au and Ba solubilities are highest in H_2S-rich, SO_4-poor fluids, whereas base metal solubilities are highest when H_2S is absent. The varying solubility of base metals, barite, and gold may explain a range of sedex deposits from very large Pb-Zn-Ag, intermediate size Pb-Zn-Ag-Ba±Au, to low base metal-high barite and/or Au deposits. This spectrum is believed to reflect the concentration and redox state of sulfur in the ore forming brine, which is ultimately controlled by the lithology and redox buffering capacity of basin fill sediments in the metal source regions. The lithology of basin fill is an important component of our model and has significant implications for deposit formation, metal endowment, and prospectivity of sedimentary basins.

A variety of basin hosted gold deposits are characterized by a distinct metal signature that includes V-Ni-Mo-PGE-U-Hg-Se-As. Vastly different, and sometimes contrasting, solubilities of these metals are incompatible with their transport in reducing H_2S-rich brines. Our work suggests that petroleum may transport these metals. Our analyses of bitumen in ore deposits, analyses of metals in modern petroleum, and experimental work demonstrate that petroleum uniquely explains this geochemical signature. Our experiments demonstrate that Au and other metals are significantly more soluble in petroleum then in traditional aqueous fluids and that the metals can be incorporated into oils through several pathways. As demonstrated in locally derived bitumen within the Rodeo deposit and through our hydrous pyrolysis experiments, metals are efficiently stripped from source rocks and partitioned into organometallic complexes in oils during primary catagenesis. We have also demonstrated that petroleum is remarkably efficient at scavenging metals from rocks and aqueous fluids that are encountered during secondary migration. Our interpretations are supported by analyses of petroleum by us and others, which document high concentrations of metals. In fact, mass balance estimates show that the metal content of some large petroleum systems far exceeds the metal content of conventional ore deposits. Our observations demonstrate a new environment and mechanism of metal transport with significant implications for the metallogenic evolution of sedimentary basins. Incorporation of the well-understood processes of petroleum generation and migration may enhance gold exploration efforts and provide new potential exploration targets in sedimentary basins.

The physical-chemical properties of Au-bearing hydrothermal fluids from orogenic and intrusion-related deposits based on a record of multi-technique, fluid inclusion analytical data

Garofalo, P.S.[1*], Fricker, M.[2], Günther, D.[2], Bersani, D.[3], Ridley, J.R.[4], Gibson, J.L.[4] & Prokofiev, V.Y.[5]
[1]Dept. of Earth and Environmental Sciences, University of Bologna, Italy ([*]paolo.garofalo@unibo.it)
[2]Dept. of Chemistry and Applied Biosciences, ETH Zurich, Switzerland
[3]Dept. of Physics, University of Parma, Italy
[4]Dept. of Geosciences, Colorado State Univ., Fort Collins, USA
[5]Institute of Geology of Ore deposits, Russian Academy of Sciences, Moscow, Russia

From our work towards constructing a database on the properties of Au-transporting hydrothermal fluids in the Earth's crust, we present preliminary microthermometric determinations, Raman spectra, volume fraction determinations of fluid phases via spindle stage measurements, and Laser Ablation-ICP-Mass Spectrometric analyses for a set of 25 fluid inclusion assemblages. This record has been collected for a number of well-documented orogenic (Sigma and Beaufor, Canada; Wattle Gully, Australia; Berezovskoe, Russia; and Pestarena, Italy) and intrusion-related (Fairbanks district, Alaska; Teremkin and Talatui, Transbaykalia, Russia) Au deposits from various tectonic settings and age. Where possible, data have been collected for assemblages petrographically associated with Au nuggets, in order to better constrain stages of ore fluid entrapment.

Data show that the ore fluid of orogenic deposits can be represented by a two- to three-phase (aqueous liquid, carbonic liquid, vapour) H_2O-CO_2-NaCl model fluid, with a relatively low bulk salinity (< 7.1 eq. wt% NaCl), a φ=13-50 vol% vapour fraction, and a relatively uniform vapour composition (CO_2±CH_4-N_2). A subordinate H_2O-NaCl fluid is also present. *T*h(total) range from values as low as 200°C (Wattle Gully) to 400°C (Sigma), and homogenisation occurs by bubble and liquid disappearance. LA-ICP-MS data show that the most abundant analyte in this fluid is Na (4000-28000 μg/g), with subordinate K (300-4500 μg/g) and B (200-2800 μg/g), and minor to trace amounts of (in the most commonly recognised order of decreasing abundance) As, Cu, Sr, Rb, Mg, Mn, Li, Ba, Cs, Sb, and Pb (range: 1-450 μg/g). These trace components are not systematically determined in all the studied deposits or samples. Au has been determined only in few assemblages from the Sigma deposits to be in the 0.5-5 μg/g range.

Intrusion-related deposits contain two-phase aqueous (liquid, vapour) fluid inclusions, but multi-phase aqueous inclusions containing one or more solids (halite and opaque phases), and an aqueous-carbonic fluid, are also common in some deposits, corresponding to a much broader range of bulk salinities (0.4-56 eq. wt% NaCl). The volume fraction of the vapour phase is similar to that of orogenic deposits, and its composition is dominated by CO_2 (±CH_4). The *T*h(total) documented in quartz associated with early- and main-stage Au range from about 300°C to 600°C, and homogenisation occurs by bubble and liquid disappearance. LA-ICP-MS data show that the most abundant analyte in this fluid is Na (3500-55000 μg/g), with subordinate K (850-9000 μg/g) and B (400-1500 μg/g). With the exception of Fe, Zn, Pb, and Mn, which have a high bulk concentration in the halite-saturated fluid (*e.g.* 28000 μg/g of Fe), the components As, Cu, Sr, Rb, Mn, Li, Ba, Cs, and Pb have been determined in the liquid-vapour and vapour-rich inclusions to be in the 2-300 μg/g concentration range. All these data show remarkable compositional similarities between the fluid types, which will be discussed in light of possible ore fluid source and evolution

Tourmaline Sr-O isotopes: evidence for fluid mixing in the Val-d'Or orogenic gold vein field

Beaudoin, G.[1,2]
[1]Université Laval, Québec, Canada (Beaudoin@ggl.ulaval.ca)
[2]Université de Genève, Genève, Switzerland

The Val-d'Or (Québec, Canada) vein field is a classical example of orogenic gold deposits in Archean rocks. The Val-d'Or vein field contains a large number of early quartz-carbonate and later quartz-tourmaline-carbonate (QTC) gold-bearing veins within a consistent structural setting and formed during two successive hydrothermal events.

The oxygen isotope composition of 24 coexisting quartz and tourmaline samples from 18 QTC veins representing the regional distribution in the vein field shows that quartz and tourmaline are in oxygen isotope equilibrium at temperatures ranging from 250 to 500°C (Fig. 1).

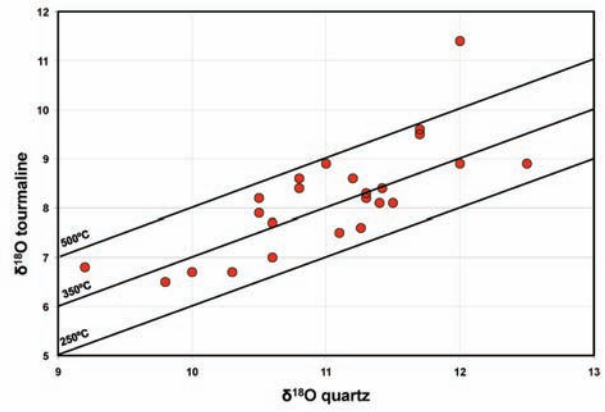

Fig. 1: Tourmaline vs quartz $\delta^{18}O$ values with 250, 350 and 500 °C isotherms. One sample with a tourmaline $\delta^{18}O$ value of 11.4 ‰ contains quartz impurities as shown by XRD analysis.

Age-corrected (2.7 Ga) initial strontium isotope composition ($^{87}Sr/^{86}Sr_{(i)}$) of 24 tourmaline samples range from 0.7007 to 0.7023. The tourmaline $^{87}Sr/^{86}Sr_{(i)}$ and $\delta^{18}O$ values show a broad inverse covariation (Fig. 2) interpreted to indicate mixing between two fluids: 1) a high $^{87}Sr/^{86}Sr_i$ (≥0.7023) and low $\delta^{18}O$ value (<3.9 ‰) fluid considered to represent evolved Archean seawater that reacted at shallow crustal levels with radiogenic felsic intrusions and, perhaps, sedimentary rocks; and 2) a low $^{87}Sr/^{86}Sr_i$ (≤0.7007) and high $\delta^{18}O$ value (>8.5 ‰) fluid, most likely derived from deep-seated metamorphism of more primitive strontium-bearing Archean volcanic-plutonic host-rocks.

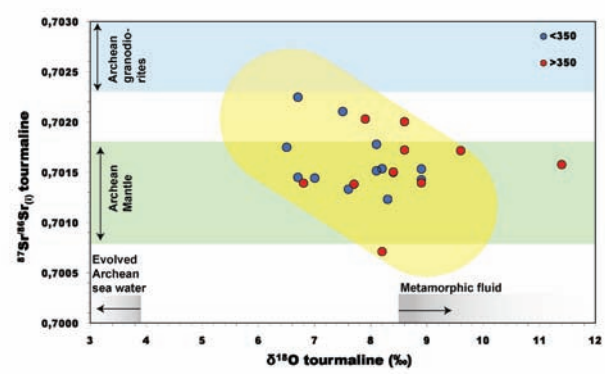

Fig. 2: Tourmaline $^{87}Sr/^{86}Sr_i$ vs $\delta^{18}O$ values with fields for Archean Mantle and granodiorite plutons, and range of values for evolved Archean sea water and metamorphic fluids. Samples with quartz-tourmaline O-isotope equilibrium temperatures below or above 350 °C shows no temperature effect on tourmaline $\delta^{18}O$ values.

Crustal scale mineralogical zonation in active orogenic gold deposits, Taiwan and New Zealand

Craw, D.[1*]**, Upton, P.**[2] **& MacKenzie, D.J.**[1]
[1]Geology Dept., University of Otago, Dunedin, New Zealand
([*]dave.craw@stonebow.otago.ac.nz)
[2]GNS Science, Dunedin, New Zealand

Gold-bearing vein systems with orogenic style form beneath active collisional mountain belts, and these are analogues for similar deposits in ancient belts. The vein systems form in a complex array of structures between the brittle-ductile transition and the near-surface. A characteristic set of mineral assemblages accompanies these veins, with mineralogy governed by the depth and temperature of formation of the veins.

Deepest formed veins (ca 10 km) have a greenschist facies mineral assemblage: quartz, albite, muscovite, chlorite, calcite, and some biotite locally. These alteration minerals formed in geochemical equilibrium with the greenschist facies host rocks. Fluid flow occurred along grain boundaries and in microfractures, and alteration is locally extensive (metres to tens of metres) adjacent to veins. This style grades up into, or is overprinted by, extensive disequilibrium alteration zones in which chlorite has altered to ankerite and pyrite. Ankeritic alteration grades up to shallow-formed vein systems with little alteration in which chlorite is a common vein mineral with quartz, calcite and, locally, adularia.

This alteration sequence is displayed in the active mountains of Taiwan. Gold-bearing vein systems in the high mountains of Taiwan are part of the youngest tectonic-hydrothermal system on Earth. Tectonic collision initiated in the Pliocene has stacked Eocene-Miocene marine sedimentary rocks to form steep mountains nearly 4 km high. Thinner portions of the sedimentary pile (ca 5 km) are currently producing hydrocarbons on the western side of the island. Orogenic gold occurs in quartz veins in thicker parts of the pile (ca 10 km) beneath the mountains in the central part of the island. Veins were formed by a mix of meteoric and metamorphic waters in localized fault/fracture zones. Deep formation of greenschist facies veins, some with gold, have caused embrittlement of the host rocks, and facilitated focusing of shallower fluid flow through the same rock packets, with auriferous ankeritic veins overprinted by late quartz-calcite veins with rare adularia.

The active Southern Alps of New Zealand also display the same sequence of mineral alteration assemblages. High mountains (4 km) and abundant rainfall cause deep circulation of meteoric water. Mesozoic basement is being reworked in this transpressive collisional orogen, releasing metamorphic fluids in the greenschist facies near the brittle-ductile transition. Localised gold deposition occurs at this level. More extensive auriferous ankeritic alteration is widespread in a fracture system that carries fluids from depth to shallow levels beneath the highest mountains. Shallow level quartz veins with calcite, chlorite, and adularia fill fractures throughout the mountains. The Southern Alps fluid flow system is more diffuse than that in Taiwan, but the mineralogical zonation is essentially identical.

Gold deposits in the central part of the Bohemian Massif: controversies and overview of genetic models

Zachariáš, J.
Inst. of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University in Prague (zachar@natur.cuni.cz)

The Bohemian Massif, a part of European Variscan Belt, hosts numerous economic and non-economic accumulations of Au, Ag-Pb-Zn and U ores. To classify gold deposits, mineral association and gold fineness represent the most practical criteria: (1) deposits with gold of high fineness (>900) where gold is accompanied by scheelite, minor molybdenite and numerous accessory Bi-Te-S phases; (2) deposits with high gold fineness (> 900) but accompanied by largely abundant Sb-mineralization (stibnite, aurostibite, Pb-Sb-sulphosalts); (3) deposits with gold of lower fineness (< 700, i.e., electrum) and lacking W-Mo-Bi-Te-S phases. A common feature of all these deposits is a variable, but generally low, sulfide content (<5 vol. % of pyrite, arsenopyrite, pyrrhotite) and quartz-dominated gangue. In the literature, these principal Au-deposit groups are referred to as high-fineness (HFAu), high-fineness Sb (HFSb) and low-fineness deposits (LFAu), respectively. They all were traditionally classified as mesothermal gold deposits (orogenic gold). Recently, for some of them a magmatic fluid phase contribution was demonstrated, and some authors used the term "intrusion-related gold deposits" [1-3]. In this paper, recent development in understanding of processes of deposit formation, based on fluid inclusion and stable isotope mineralogy studies, are summarized.

Early mineralization stages of HFAu were dated by the Re-Os method on molybdenite flakes [4]. The ages (349-339 Ma) are statistically indistinguishable from ages of individual intrusive phases of CBPC (355-336 Ma). Dominant fluid is usually represented by low-salinity aqueous-carbonic fluid. At some localities, presence of discrete pulses of CO_2-free, high-salinity aqueous fluid of likely magmatic origin was also found. Geological evidence for "continuous" transition from magmatic into hydrothermal phase is, however, missing. There is textural evidence both for early and late incorporation of gold in the ores. CH_4-rich fluids seem to be locally important and shortly precede gold precipitation. At many localities, however, gold was introduced exclusively by late aqueous fluids. Another yet unsolved observation represent spherical solid inclusions composed of Bi, Bi-Te-S, and Au and Pb-Sb-Bi-Te-S phases, sporadically also with remnants of a fluid phase. They might represent an immiscible low-temperature metallic alloy. Isotope data (S, O, C, Sr) suggest not uniform source of dissolved elements [5] and presence of fluids with both metamorphic and meteoric signatures.

The LFAu deposits are younger (ca. 300 Ma) and formed in response to a late metamorphic phase in the Moldanubian Unit. Deep seated fluids were focussed trough regional tectonic zone and mixed at subsurface levels (<2 km) with meteoric fluids [6].

Transport and deposition of gold in the Greywacke Zone, Eastern Alps

Kucha, H.[1] & Raith, J.G.[2*]
[1]University of Mining & Metallurgy, Krakow, Poland
[2]Dept. of Applied Earth Sciences and Geophysics, University of Leoben, Austria ([*]johann.raith@unileoben.ac.at)

Native gold and unusual gold-oxysulphides occur in low-grade Palaeozoic rocks of the Upper Austroalpine Greywacke Zone (GWZ). Gold is associated with tetrahedrite and can be traced in the GWZ (~250 km E-W extension) between Veitsch (Styria) and Schwaz (N Tyrol); further to the W where arseniferous tetrahedrite and tennantite are more common Au is lacking. Gold occurs as electrum, as gold of high fineness, and as refractory gold. Refractory gold shows two valence states: Au^0 in submicron native gold inclusions, and Au^{+1} where Au is bound to the host lattice of tetrahedrite or As-bearing pyrite.

In several historic stratabound to vein-type polymetallic Cu deposits (e.g., Mitterberg, Larzenbach/Hüttau, St. Veit im Pongau) gold-oxysulphides are associated with native gold in non-weathered primary ores and remobilized Cu-rich gold in weathered ores [1]. Solid inclusions of gold-oxysulphides, chalcopyrite, minor arsenopyrite and gold rich in gold-oxysulphide microinclusions occur along re-healed microfractures within tetrahedrite together with fluid inclusions.

Fluid inclusions within tetrahedrite (isolated inclusions, clusters, trails) were studied by infrared (IR) microthermometry. They are aqueous two-phase liquid (L)+vapour (V) inclusions of low to moderate salinity (Tm −3 to −14°C). Homogenisation temperatures (Th V→L) range between 85 and 200°C. The composition of these tetrahedrite-hosted fluid inclusions corresponds to one type of fluid inclusion in quartz showing a similar range in salinity (Tm −3 to −12°C) and total homogenisation temperatures (Th→V, 71.5 to 250°C). Another type of higher saline aqueous two-phase (L+V) inclusions in quartz is apparently unrelated to gold mineralization.

Tetrahedrite is replaced by arseniferous tetrahedrite/tennantite along the same microfractures hosting solid and fluid inclusions. It is therefore suggested that in addition to cooling the exchange of As for Sb on tetrahedrite surfaces was one of the factors controlling precipitation of gold.

From structural and textural considerations and the few available age data [2] we suggest that gold mineralization in the GWZ is late to post-orogenic with respect to Eoalpine metamorphism (~90 Ma). However, the association of gold with gold-oxysulphides, which are mixed S valence compounds containing sulphur and oxygen, and the T-X conditions of ore forming fluids (<250-300°C, no CO_2) are atypical for orogenic gold deposits. Hence, we suggest that S-As oxocomplexes (gold thiosulphate, possibly thioarsenite complexes) transported the gold in the hydrothermal fluid. Gold thiosulphate complexes were also involved in the supergene remobilization of gold.

Gold-bearing tetrahedrite-rich polymetallic ores in the GWZ are a neglected potential exploration target for gold in the Eastern Alps, which is distinct to the well established orogenic Au deposit type.

Submarine hydrothermal activity and gold-rich mineralization at Brothers volcano, Kermadec arc, New Zealand

de Ronde, C.E.J.[1*], Massoth, G.J.[2], Butterfield, D.A.[3], Christenson, B.W.[1], Ishibashi, J.[4], Ditchburn, R.G.[1], Hannington, M.D.[5], Brathwaite, R.L.[1], Lupton, J.E.[6], Dziak, R.P.[6], Kamenetsky, V.S.[7], Graham, I.J.[1] & Zellmer, G.F.[8]

[1]Ocean Exploration, GNS Science, Lower Hutt, New Zealand ([*]cornel.deronde@gns.cri.nz)
[2]Mass-Ex3 Consulting, Renton, USA
[3]Pacific Marine Environmental Lab, NOAA, Seattle, USA
[4]Dept. of Earth and Planetary Sciences, Kyushu University, Fukuoka, Japan
[5]Dept. of Earth Sciences, University of Ottawa, Canada
[6] Pacific Marine Environmental Lab, NOAA, Newport, USA
[7]CODES, University of Tasmania, Hobart, Australia
[8]Institute of Earth Sciences, Academia Sinica, Nankang, Taiwan

The Brothers hydrothermal system is unique among seafloor hydrothermal systems along the Kermadec arc, and elsewhere around the world, as it is host to two very different vent fields. The NW caldera field is perched on the caldera walls and is an older (up to 1,200 yrs), more mature system that has high temperature (~300°C), focused venting of metal-rich fluids. Large Cu- and Zn-rich sulfide chimneys occur at this site. The cone vent field is much younger and sits atop the summits of a main cone and a satellite cone inside the caldera, near the southern caldera walls. This field is dominated by S-rich vents with vent fluids more diffuse, lower in temperature (<120°C), very gassy and acidic (pH 1.9), and relatively metal-poor. Vent fluids of the NW caldera site show evidence for sub-seafloor phase separation. Concentrations of SiO_2 suggest these vent fluids are supersaturated and/or kinetic effects are occurring, with evidence for higher than hydrostatic fluid pressures at shallow depths. Vent fluids at the cone site have Mg and SO_4 concentrations higher than seawater, indicating these ions have been *added* to the hydrothermal fluid and are not being depleted via normal water/rock interactions.

Isotopic compositions of the NW caldera and cone vent fluids show evidence for magmatic water with negative δD and $\delta^{18}O$ values, consistent with $^3He/^4He$ values showing that the Brothers hydrothermal system has shifted towards more magmatic conditions over the past several years. Similarly, $\delta^{34}S$ values for vent fluid sulfides and for sulfide minerals from NE caldera chimneys indicate disproportionation reactions involving magmatic SO_2.

Minerals such as chalcopyrite, bornite, chalcocite, covelllite and euhedral grains of hematite occurring in high temperature chimneys from the NW caldera site are consistent with a more oxidizing, magmatic fluid, and bulk sulfide geochemical data show evidence for a higher temperature suite of elements (e,g., Mo, Co, Se) associated with Cu-rich chimneys. Gold mineralization occurs in these high temperature chimneys and is associated with the most recent deposition of high concentrations of Cu, where $\delta^{34}S$ values are most negative.

Geophysical evidence suggests that the top of a magma chamber occurs ~2.5 km below the caldera floor, beneath the cone site in the SSE quadrant of the volcano. Very low velocities of < 1 km^{-2} are seen in the seismic data and occur between the magma and the seafloor. They are interpreted to represent gas release. Harmonic tremor data provide evidence for a vertical pipe-like 'conduit' at least 500 m in length being located above the magma chamber (and beneath the cone), linking it with the overlying hydrothermal system and thus providing a mechanism for magma-derived metals to enter the hydrothermal system under the cone site.

Gold- bearing tellurides in a black smoker chimney, Brothers submarine volcano, Kermadec arc

Berkenbosch, H.A.[1*], de Ronde, C.E.J.[2], McNeill, A.W.[1] & Gemmell, J.B.[1]

[1]ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Australia ([*]heidib1@utas.edu.au)
[2]Ocean Exploration, GNS Science, Lower Hutt, New Zealand

A distinct, but relatively poorly understood magmatic component contributes to hydrothermal vent fluids and their associated mineral deposits at hydrothermal systems hosted by submarine arc volcanoes. The dacitic Brothers caldera volcano of the Kermadec intraoceanic arc is such an example, and is host to two chemically distinct hydrothermal systems. One is the cone site, a relatively recent magmatic fluid-dominated system, while the other is the NW caldera site, dominated by modified seawater but with evidence for earlier magmatic 'pulses' [1]. Here, we focus on various petrographic techniques combined with detailed geochemical analysis of the mineralogy of the Lena black smoker chimney that was recovered from the NW caldera vent field at Brothers.

In 2004 the manned submersible *Shinkai 6500* collected Lena chimney from a depth of 1,670 m. Lena is the top ~66 cm of a black smoker chimney that was venting 274°C fluids at the time of sampling. The chimney is dominated by distinct, narrow bands of Cu-rich mineralization juxtaposed against broader, more porous zones of Zn-rich mineralization towards the chimney margins. Anhydrite and barite form the initial substrate upon which later sulfides are deposited. Pyrite and marcasite are commonly deposited first, followed by chalcopyrite from hotter fluids and sphalerite from relatively cooler fluids. Finely laminated bands of chalcopyrite, separated by bands of more disseminated chalcopyrite, typically line vent orifices. Trace minerals in Lena chimney include tellurides, galena, covellite, tennantite, hematite, goethite, and Pb-As sulfosalts (Fig. 1).

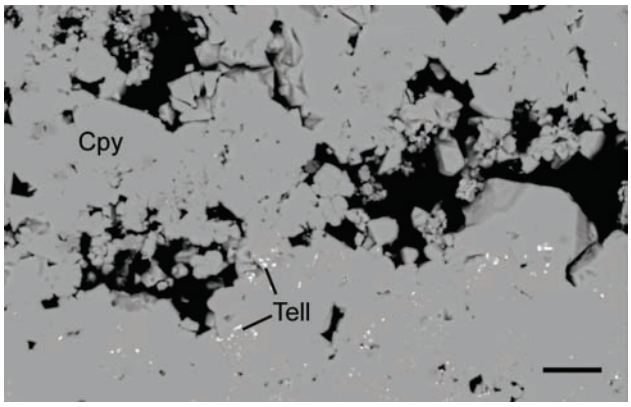

Fig. 1: Band of fine gold-rich tellurides (tell) within band of massive chalcopyrite (cpy). Black is void space, scale bar is 20 μm.

Analytical work using a SEM with EDS capability revealed both Bi- and/or Au-rich tellurides occur in some parts of the chimney. For example, they occur as inclusions throughout the major phases in anhydrite-rich areas, commonly along previous grain boundaries, and as 'trails' within some massive chalcopyrite bands. Together with the chalcocite, enargite and alunite previously described by de Ronde et al. [1] in other NW caldera chimneys, the occurrence and distribution of gold-rich tellurides are consistent with pulsed magmatic input into the Brothers hydrothermal system.

Au-Ag minerals in volcanogenic massive sulphide deposits of the Urals

Vikentev, I.V.
Inst. of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM), Russian Academy of Science, Moscow, Russia (viken@igem.ru)

Most gold in the Urals is extracted from sulfide ores from volcanogenic massive sulfide (VMS) Cu-Zn-Au-Ag deposits [1,2] but with very poor gold recoveries (20-45%). Such poor recoveries are due to the relative scarcity of Au as large, readily extractable grains in most of the Uralian VMS deposits. This study is based on mapping and sampling of the giant Gai, the large Uchaly and Uzelginsk as well as minor and medium-sized VMS deposits. In the VMS deposits of the Urals, gold occurs mainly as "invisible" gold in pyrite, chalcopyrite and sphalerite at abundances between 1 and 20 ppm. Silver occurs mainly in fahlore (0.1-6 wt % Ag) and Ag sulfosalts. Discrete Au-bearing minerals (Au-Ag alloys, tellurides and sulfides) are rare and occur as extremely fine-grained inclusions within common sulfides in the ores. They are associated mainly with pyrite, chalcopyrite, galena, bornite, fahlore.

The Au-Ag mineral assemblages are mainly argentiferous tetrahedrite, Ag sulfosalts (freibergite, kolusite, pearceite), Ag-bearing galena and bornite, various tellurides (altaite, hessite, petzite, stuetzite, krennerite, kalaverite, sylvanite), some sulfides (petrovskaite, uytenbogaardtite), native gold and native silver. Native gold and gold minerals occur in ores grading >5 ppm Au (rarely ~3 ppm). Native gold forms grains and aggregates from 2 to 50 μm (with rare larger grains up to 150 μm). The largest grains of native gold (100–1000 μm, or larger) are in deposits that have been highly metamorphosed (Gai, Degtyarsk, Karabash, San Donato, and contact metamorphosed, Tarnjer). In slightly to moderately metamorphosed deposits (Uzelginsk, Uchaly, Molodezhny, Aleksandrinsk, Valentorsk and Safjanovsk), native gold grains are rare and small (commonly <25 μm). The fineness of native gold ranges from 500 to 975 in the metamorphosed deposits, and is much lower in the non- or slightly-deformed deposits (440 to 860).

The native gold from massive sulfide deposits may be regarded as a series of continuous Au–Ag solid solutions from $Au_{0.98}Ag_{0.02}$ to $Au_{0.60}Ag_{0.40}$. Compositions of native gold of VMS deposits of the Urals cluster close to the formulae Au_3Ag, Au_2Ag and Au_3Ag_2.

Most gold contained in VMS ores (47-87%) occurs at low abundances (Au 0.2-3 g/t) and is incorporated in the sulfides as "invisible" gold; this Au is therefore unrecovered and lost to tailings, mostly along with pyrite. The proportion of visible gold minerals (chiefly native gold) as gold carriers is accordingly much higher in those massive sulfide ores which have been metamorphosed.

Variable ore mineralogy in the world-class epithermal Waihi vein system, New Zealand

Mauk, J.F.
School of Environment, University of Auckland, New Zealand (J.Mauk@auckland.ac.nz)

The world-class adularia-sericite epithermal vein system at Waihi in the North Island of New Zealand has an estimated total Au endowment that exceeds 12 Moz, including 7.5 Moz mined to December 2008. Much of the past production has come from the Martha mine, and recent production has included contributions from underground operations at the Favona and Moonlight deposits. Available geological, geophysical, and geochronology data suggest that the veins in the Waihi vein system formed as part of a single hydrothermal system at 6.1 Ma, but significant variability in the ore mineralogy of the veins indicates a more complex history.

Most veins in the Waihi vein system have some minerals in common, including pyrite, sphalerite, galena, chalcopyrite, and electrum, although the absolute and relative abundance of these minerals vary significantly. Pyrite and marcasite from altered host rocks are stoichiometric FeS_2 with no significant trace elements. In contrast, pyrite in veins commonly contains appreciable As (up to 3.2 wt%), and locally several tenths of a percent of Cu, Zn, Co, Ag and Sb. Electrum is the only source of Au in the deposits; its composition typically ranges from $Ag_{0.47}Au_{0.53}$ to $Ag_{0.39}Au_{0.61}$. Chalcopyrite is stoichiometric $CuFeS_2$. Most galena is PbS, although it commonly contains ca. 0.22% Se. Sphalerite averages 4 mol% FeS, though ranges up to 15 mol%.

Tetrahedrite $[(Cu,Ag)_{10}(Zn,Fe)_2(As,Sb)_4S_{13}]$, acanthite ($Ag_2S$), aguilarite ($Ag_4SeS$), stromeyerite (CuAgS), naumannite (Ag_2Se), and mckinstryite $[(Ag,Cu)_2S]$ have more localised distributions in the Waihi vein system. For example, the Favona deposit in the eastern portion of the Waihi vein system contains tetrahedrite, aguilarite, naumannite, rare mckinstryite and stromeyerite, but lacks significant acanthite. By contrast, at the nearby Moonlight deposit, limited petrographic and microprobe results suggest that tetrahedrite is the dominant Ag containing mineral; acanthite, aguilarite, stromeyerite, naumannite, and mckinstryite appear to be largely absent, although some samples contain either minute grains of acanthite or native Ag as <0.5 micron inclusions in pyrite.

The Martha deposit contains several veins that were mined underground over a vertical interval of 500 m, and the area is currently mined as an open pit. Ore mineralogy in the veins varies significantly. Some veins are dominated by the base metal sulphide mineral assemblage, some veins have significant acanthite, and other veins have significant concentrations of aguilarite and naumannite. The Reptile vein, which lies between the Favona and Martha deposits, contains an assemblage with base metal sulphides and electrum. The most abundant sulphide minerals are pyrite, sphalerite, galena, and chalcopyrite; the vein lacks acanthite, aguilarite, and naumannite.

Significant variability in the ore mineralogy of the veins in the Waihi vein system reflects, in part, variability with depth. At Martha and Favona, depth exerts a strong control on mineralogy as base metal sulphide minerals increase with depth at the expense of the silver sulphides and sulfosalt minerals. However, some deposits contain significant concentrations of Se-bearing minerals, some deposits lack Se-bearing minerals, and others have variable concentrations of Se-bearing minerals in different portions of their orebodies. The ultimate controls on the Se:S ratios in the Waihi vein system remain poorly understood, but these may include variations in the Se:S ratios of the fluid, different fluid sources, and/or the redox state of the fluid.

Zoning in pyrite as a source of physicochemical information

King, J.J.[*], van Hinsberg, V.J. & Williams-Jones, A.E.
Dept. of Earth & Planetary Sciences, McGill University, Montreal, Canada ([*]julia.king2@mail.mcgill.ca)

Pyrite is a common mineral in many types of metallic mineral deposits, formed over a wide range of physicochemical conditions. In a large number of these deposits, the pyrite is compositionally zoned, and thus changes in trace element concentrations between zones can be used to reconstruct the chemical evolution of the ore fluid, and potentially determine its temperature. Gold-bearing pyrite in the Bowone and Binebase high-sulphidation epithermal Au prospects on Sangihe Island, Indonesia, display evidence of both growth and sector zoning. Here we report the results of a study of pyrite from these deposits, and document the distribution of trace elements among growth and sector zones in this mineral with the goal of understanding how the deposit formed.

Compositional variations among growth zones in pyrite are controlled by changes in fluid composition, pressure and temperature. We have mapped trace element compositions for elements that show zonation (Cu, Se, Te, Ni, Zn, As, Au, Ag) in the Bowone and Binebase pyrite using EMPA and SIMS techniques as a means to quantify chemical changes parallel to the growth direction and investigate substitutions in the pyrite structure. Copper in particular shows strong zonation with an average concentration of 0.83 wt% and up to a maximum of 5.2 wt%. A similar observation was made for the Pascua high-sulphidation deposit [1].

In addition to growth zoning, the pyrite of the Bowone and Binebase deposits displays intense sector zoning. The sector zoning developed as trace elements were preferentially and systematically incorporated onto different crystallographic surfaces. The partitioning of trace elements between crystallographic faces is independent of fluid composition because the same fluid is in contact with each crystal face. However, this partitioning is very sensitive to temperature. Sector zonation can be calibrated for geothermometry, as was done for sector zoning in tourmaline [2]. Sector zoning at Bowone and Binebase is most evident for copper. For example, a late pyrite breccia vein shows, yet un-calibrated, temperature variations over time, with copper partitioning coefficients ranging from 0.32 to 0.94. Element partitioning is more pronounced at lower temperatures, thus the increased partitioning corresponds to a decrease in temperature. In the case of the above breccia vein, temperature initially increased, then decreased, increased again and finally decreased. We are currently calibrating the pyrite geothermometer using measured inter-sector partition coefficients for well-constrained natural and synthetic samples.

Although quantitative geothermometry is an eventual goal of this study, changes in the inter-sector partition coefficients provide important qualitative information on the temporal evolution of temperature and the corresponding changes in fluid chemistry. Studies of this type are useful, not only for ore depositing systems, but also for all the other environments in which pyrite forms (i.e., metamorphic, diagenetic and even sedimentary environments).

Gold deposits in the northern Fennoscandian Shield

Eilu, P.[1*], Billström, K.[2], Martinsson, O.[3], Niiranen, T.[4], Broman, C.[5], Weihed, P.[3], Wanhainen, C.[3] & Ojala, V.J.[6]
[1]Geological Survey of Finland, Espoo, Finland ([*]pasi.eilu@gtk.fi)

[4]Geological Survey of Finland, Rovaniemi, Finland
[5]Dept. of Geology and Geochemistry, Stockholm University Stockholm, Sweden
[6]Store Norske Gull AS, Rovaniemi, Finland

The Palaeoproterozoic evolution of the northern part of the Fennoscandian Shield includes a stage of repeated rifting with sedimentation and igneous activity during 2.5–1.95 Ga and the multistage Svecofennian orogeny with accretion and continent-continent collision from 1.95 to 1.77 Ga. All stages of geological evolution included hydrothermal activity some of which also produced, or were possibly indirectly related to, gold mineralisation. During the rifting stages, shallow level intrusion-related and basinal hydrothermal systems produced stratiform-stratabound (VMS-like) Cu-Zn (±Ag, Au) sulphide mineralisation throughout the region, but locally possibly also VMS(?) gold-baryte and sediment-hosted Au-Co-Cu±U occurrences. During the Svecofennian orogeny, compressional stages at 1.92–1.87 and 1.85–1.79 Ga produced structurally-controlled gold-only and gold-copper orogenic deposits. Accretional stages at ca. 1.89 Ga also produced porphyry-type copper-gold mineralisation. Iron oxide-copper-gold deposits were intermittently formed during the orogeny until ca. 1.77 Ga. The orogenic processes may also have remobilised parts of the early deposits, and even overprinted them by later alteration ± mineralisation. Much of the sulphide mineralisation is related to saline fluids potentially deriving both from originally evaporate-bearing rift sediments and from intrusions, but gold shows a good correlation with low-salinity H_2O–CO_2 fluids. There also are many potential metal sources available for the deposits: the extensive sedimentary and volcanic sequences formed during rifting, and the many types of intrusive and extrusive rocks of the Svecofennian orogeny. Also, the pre-orogenic deposits may have released metals into orogenic fluids. This 600–700 myr geological evolution, with a multitude of potentially mineralising processes, explains the large variation between gold deposits and the complexity of individual occurrences in the northern Fennoscandian shield, and also is the ultimate reason why it has been, and still is, difficult to agree on all the genetic types of the deposits in the region.

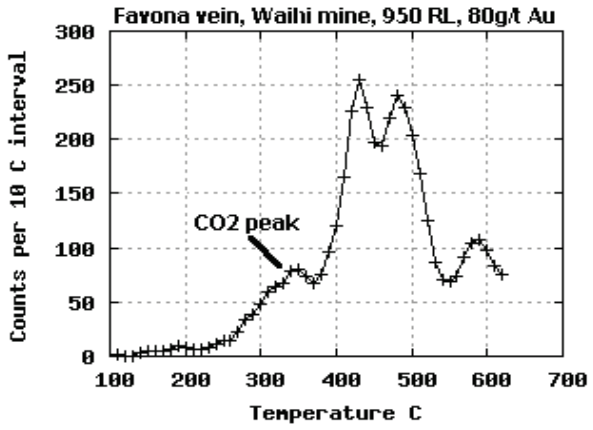
Gold exploration using baro-acoustic decrepitation

Burlinson, K.
Burlinson Geochemical Services P/L, Darwin, Australia
(kgb@synix.com.au)

Early attempts to use fluid inclusion decrepitation methods for mineral exploration were compromised by a failure to understand the importance of the presence of gas rich inclusions and their thermodynamic behaviour when heated, leading to misinterpretation and the premature demise of the technique.

We know that many gold deposits form from CO_2 rich fluids and these fluids can be readily detected using baro-acoustic decrepitation. Consequently we can use decrepitation as a mineral exploration method to locate CO_2 rich, potentially auriferous hydrothermal quartz. Using a computerised decrepitation instrument provides quick, cheap, reproducible and objective measurements of CO_2 in contrast to the slow, subjective and labour intensive microthermometric techniques. Although the method is best applied to mesothermal deposits formed at high pressures, it does also work with many epithermal deposits. Gas-rich fluid inclusions give a distinctive low temperature decrepitation peak because these inclusions have high internal pressures at room temperature and when heated, the pressure increases linearly with temperature in accordance with the gas law. In contrast, aqueous fluid inclusions have a condensed liquid phase and do not generate high internal pressures until temperatures above their homogenisation temperatures.

Samples from the Waihi epithermal gold deposit, NZ, have been analysed and they show low overall decrepitation intensities, as expected from epithermally formed fluid inclusions, but they clearly show low temperature decrepitation indicating the presence of CO_2 rich fluid inclusions. Samples from or near the active workings show low temperature decrepitation caused by CO_2 rich inclusions whereas distal samples either from the same vein or from other veins nearby lack this CO_2 caused decrepitation peak. This provides a means of evaluating potentially auriferous quartz veins based on their CO_2 fluid contents.



At the Brusson mine in northern Italy, alpine quartz veins were mined for their gold content. These mesothermal veins give intense decrepitation with large and prominent low temperature peaks caused by CO_2 rich inclusions. The decrepitation patterns can be used to distinguish between quartz samples which otherwise appear to be identical.

Baro-acoustic decrepitation can give valuable fluid inclusion data to use in mineral exploration. Many mineral deposits are “fossilized” fluid systems and we can surely benefit by using fluid inclusion information when exploring for them, not merely for forensic analysis of the deposits we have already found.

Geochemistry of Sb-Au quartz veins from Valongo, northern Portugal

Carvalho, P.C.S[*], Neiva, A.M.R. & Silva, M.M.V.G.
Dept. of Earth Sciences, Geosciences Centre, University of Coimbra, Coimbra, Portugal ([*]paulacscarvalho@gmail.com)

The Valongo area is located about 18 km from Porto, in the Dúrico-Beirão region, northern Portugal. The Valongo anticline formed during the Variscan Orogeny, comprises Cambrian to Carboniferous metasedimentary rocks and is limited to the northeast by late- to post-D3 granitic rocks and to the southwest by the Porto-Tomar-Cordoba shear zone. Several Sb-Au quartz veins crop out mainly at the western limb and rarely in the core of the anticline, filling N-S, N10-75ºE, N30-50ºW and E-W faults and are hosted by Cambrian and Carboniferous metasedimentary rocks. They were mostly exploited in the late 19th century. The Sb-Au quartz veins consist of quartz, arsenopyrite, pyrite, pyrrhotite, marcasite, sphalerite, chalcopyrite, galena, boulangerite, jamesonite, electrum, tetrahedrite, fuloppite, zinkenite, berthierite, stibnite, gold, native antimony, ankerite, siderite, calcite, dolomite and also schafarzikite, apuanite, valentinite and cervantite.

Minerals precipitated during a polyphase process due to drastic fluid cooling. Arsenopyrite and pyrite are the earliest sulfides to have formed. Arsenopyrite is rarely zoned with a Sb-rich core. The Au content is up to 0.28 wt% at Tapada and is due to minute inclusions of native gold. First and second generation of arsenopyrite formed at 390ºC and 300ºC, respectively [2]. Sphalerite and chalcopyrite are homogenous in composition and the former shows diffusion-induced segregations of the chalcopyrite. The ranges of mol % FeS in sphalerite are 0 to 5 at Medas, 9 to 11 at Alto do Sobrido and 3 to 4 at Montalto, reflecting variation in the activity of FeS in the fluid and in physico-chemical conditions during precipitation. Berthierite and stibnite are the most abundant Sb-bearing minerals and precipitated between 225ºC and 128ºC [2]. Gold occurs in different generations, in quartz, arsenopyrite, fuloppite, stibnite, carbonates and valentinite. Fineness ranges from 998 to 1000 in gold included in quartz and from 993 to 998 in gold included in stibnite.

The Sb and As mean content of granites is up to 0.43 ± 0.27 ppm and 17 ± 4 ppm, respectively. However, Cambrian metasedimentary rocks have Sb contents of as much as 56 ppm and 13 ± 5 ppm of As, whereas Sb content is 13 ppm in Carboniferous metasedimentary rocks, suggesting that ore-forming fluids were derived from Cambrian and Carboniferous metasedimentary rocks. The metamorphic fluids have low salinity with constant 2 wt % NaCl equiv. and the CO_2 content decreased during precipitation changing to aqueous fluids [1]. Variscan folding, deformation and regional metamorphism would have provided the anomalous crustal heat flow that triggered the hydrothermal activity [2]. Sb-Au deposits from Valongo would have formed during the last phases of Variscan orogeny, similarly as the Sb-Au deposits from French Massif Central and Central Iberian Zone.

Pre-Witwatersrand LREE and potassic high-T alteration of mafic hinterland to the Central Rand Basin, South Africa

Depiné, M.[1*], Frimmel H.E.[1,2], von Seckendorff, V.[1] & Harris, C.[2]
[1]Geodynamics & Geomaterial Research Division, University of Würzburg, Würzburg, Germany
([*]marco.depine@uni-wuerzburg.de)
[2]Dept. of Geological Sciences, University of Cape Town, Rondebosch, South Africa

Assuming a palaeoplacer model for the Witwatersrand gold, this study concerns the immediate hinterland to the highly auriferous Central Rand Basin (2.90-2.78 Ga), in the search for a possible source of the detrital gold. Pre-Witwatersrand granitoid bodies have been known from limited surface outcrops all around the basin. The following report is on calc-alkaline granite and hornblende metagabbro that were intersected in a drill core at the northwestern margin of the former Central Rand Basin. Both rock types are of indistinguishable age (3063 ± 5 Ma) [1], which corresponds to that of the Witwatersrand gold particles [2].

Two types of alteration can be distinguished in the intersected rock types: (i) post-Witwatersrand, low-T alteration that is comparable to that previously described from the Witwatersrand Basin fill and surrounding granitoids in the wider region; and (ii) LREE and potassic high-T alteration in the mafic rock. The contact between granite and hornblende metagabbro is marked by a distinct, meter-thick, biotite-rich zone, also containing a discrete layer rich in ferriallanite-(Ce). Breakdown of magmatic plagioclase during allanite growth is supported by a positive Eu-anomaly and high Sr-concentrations in allanite, which is in textural equilibrium with fluorapatite and microcline. The presence of hornblende and microcline (Or95) in the metagabbro are indicative of temperatures above 550 °C. The oxygen isotope ratio of hydrothermal quartz (11.3 ‰) corresponds to a δ18O of at least 9 ‰ for the precipitating fluid assuming a crystallization temperature of at least 550 °C, a value that would be in agreement with a magmatic derivation of that fluid. Thus the high-T alteration explains the formation of allanite and the high amounts of fluorapatite in the biotite-zone as well as microcline in the biotite-zone and throughout the metagabbro. The concentration of allanite in a distinct layer is interpreted as reaction front between the emplacing granite and the cooling gabbro. The infiltration zone was characterized by increasing pH with increasing distance from the granite due to progressive reaction with the hornblende metagabbro. This is reflected by decreasing and increasing amounts of biotite and microcline from the biotite-zone to the metagabbro, respectively.

The inferred magmatic character of the infiltrating fluid and Ar-Ar hornblende ages that are identical within error with the U-Pb zircon ages of the granite and the metagabbro [1], leads to the conclusion that the described high temperature alteration is due to a late-magmatic infiltration of a granite-derived fluid. In summary, this study shows that the *c*. 3060 Ma pre-Witwatersrand basement in close proximity to the Central Rand Basin experienced a late-magmatic alteration that was marked by enrichment in LREE, P, F, Th as well as U and thus compares favourably with alteration that can lead to Au-enrichment.

Fluid inclusions and gold ore genesis in the Jiaodong Peninsula, Eastern China

Fan Hong-Rui*, Hu Fang-Fang & Yang Kui-Feng
Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China
(*fanhr@mail.igcas.ac.cn)

The Jiaodong gold province in the Jiaodong Peninsula of eastern China is currently the most important gold producer in China. Seven world-class gold deposits (>100 t gold), eight large gold deposits (20 to 100 t gold) and more than one hundred medium to small gold deposits (<20 t gold) have been discovered in the Peninsula during the past three decades, accounting for about 25% of Chinese gold reserves. The gold deposits of the peninsula can be divided into two types based on vein styles: 1) quartz vein-style (Linglong style) and 2) fault-zone hosted disseminated/stockwork-style (Jiaojia style).

Fluid inclusion studies have been carried out on major gold deposits and prospects in the Tanami region to determine the compositions of the associated fluids and the processes responsible for gold mineralization. The pre-gold H_2O-CO_2 fluid inclusions occur isolated in samples of the early milk-white quartz and are assumed to have been trapped during deposition of the earliest quartz. Fluid inclusions associated with gold mineralization at both deposit types contain mostly CO_2-H_2O-NaCl±CH_4 fluids and have variable CO_2 and CH_4 contents. The molar volumes of H_2O-CO_2 and CO_2-H_2O±CH_4 inclusions calculated for the Sanshandao (stockwork) and Denggezhuang (lode/vein) deposits are 50 - 60 cm^3/mole and 55 - 70 cm^3/mol, respectively. There are similar changes of molar volumes of H_2O-CO_2 and CO_2-H_2O±CH_4 inclusions from the other deposits in the Jiaodong Peninsula. Estimated fluid trapping pressures of pre-gold and gold-stage are 1.0 - 3.5 kbar and 0.7 - 2.5 kbar, respectively. The pressure decreased during the evolution of the fluid.

Age determinations by the different techniques show that the deposits in the Jiaodong Peninsula formed at similar times within 120 ± 10 Ma. Fluid inclusion measurements and previous isotope data have determined that ore-forming fluids of Linglong style and Jiaojia style gold deposits are identical and that all deposits of the Jiaodong Peninsula have essentially formed from the same fluids under similar temperature and pressure conditions. Differences among the deposits are related to structure. As the first-order regional faults formed at an earlier time and suffered recurrent deformation, rocks in the faults show cata-clastic deformation. Mineralization by replacement and infiltration by ore-forming fluids took place in the faults and formed disseminated and stockwork-style gold deposits. In the second- or third-order faults, deformation intensities were relatively weak, and rocks in the faults have been weakly cracked. In the regional-scale faults, the degree of deformation decreased from the centre to the outside. Disseminated-style gold mineralization occurred in the fault centre. Towards the outside, fine vein or stockwork-style gold mineralization was formed, and then quartz-sulphide vein-style gold mineralization was produced. In the margin of the Jurassic basin, as deformation caused separation of the basement and volcanic rocks, interstratified shears and fractures took place. Ore-forming fluids ascended along these channels to form the special example of Jiaojia style mineralization along the interstratified shear zone.

Gold ore-forming fluids in the Denggezhuang gold deposit, Jiaodong Peninsula, Eastern China

Hu Fang-Fang*, Fan Hong-Rui & Yang Kui-Feng
Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China
(*huff@mail.igcas.ac.cn)

The Degezhuang gold deposit is currently the second largest lode gold deposit in the Muping-Rushan gold belt of Jiaodong Peninsula, eastern China. Gold occurs mainly in pyrite- and polymetallic sulfide-quartz vein/veinlet stockworks. Fluid inclusions in the altered wallrocks and gold ores show C-O-H fluids of three main types, namely H_2O-CO_2, CO_2-H_2O±CH_4 and aqueous inclusion. Early milk white quartz contains original H_2O-CO_2 inclusions and secondary CO_2-H_2O±CH_4 inclusions. In the pyrite quartz vein and polymetallic-sulphide quartz vein, CO_2-H_2O±CH_4 inclusions occur in isolation with a large range of H_2O/CO_2, whereas the aqueous inclusions occur as secondary trails in microfractures, cutting earlier quartz grains. In places CO_2-H_2O±CH_4 inclusions with variable aqueous phase proportions occur together within the same clusters, and mostly homogenize to liquid or vapor at the same temperatures, indicating immiscibility did occur at the deposit. Quartz and calcite in the late ore-forming stage developed original aqueous inclusion. Microthermometric data show homogenization temperatures (to liquid) of the CO_2-H_2O inclusions in the early ore-stage between 254 and 365°C. Homogenization temperatures, obtained mainly from inclusions with relatively small CO_2±CH_4 bubbles in the main ore-stages, range from 195 to 317°C. Homogenization temperatures (to liquid) of the aqueous inclusions in the late stage range from 156 to 219°C. The initial auriferous fluids were CO_2-dominant, and were gradually evolved into the increased amount of CH_4 in the main ore-stages and into H_2O-riched fluids with low temperature in the late stage. Fluid-wallrock interaction and fluid immiscibility possibly led to the gold precipitation.

Acknowledgements: The present study was supported by The National Natural Science Foundation of China (Project No. 40625010).

Mineralogy, mineral chemistry and isotope geochemistry of gold mineralization at San Martin de Loba, San Lucas Range, Colombia

Leal-Mejía, H.[*] & Melgarejo, J.C.
Dept. de Cristal·lografia, Mineralogia i Dipòsits Minerals, Facultat de Geologia, Universitat de Barcelona, Spain
([*]hildebrandolealm@yahoo.co.uk)

Gold mineralization in the San Martín de Loba mining district, Colombia (including the La Puja, La Chiva, La Puerta, El Cano and Juana Sanchez sectors), is hosted by the 180-190Ma San Martin-Norosi Batholith, which forms one segment of an extensive Jurassic calc-alkaline magmatic arc extending from northern-most Colombia through Ecuador and northern Peru.

At La Puja, 60-70ºSW-dipping mineralized veins are hosted within anastomosing, broadly WNW-striking left-lateral shears. Veins are composed of at least two generations of quartz, +Cc+Ser+Tourm+Py+Cpy+Aspy+Sph+Gn+Au, with related strong to pervasive Qtz-Ser+\-Py alteration extending for tens of centimentres into the intrusive wallrocks. Quartz and tourmaline grow against asperities on left-lateral shears indicating vein emplacement was synchronous with movement along the faults.

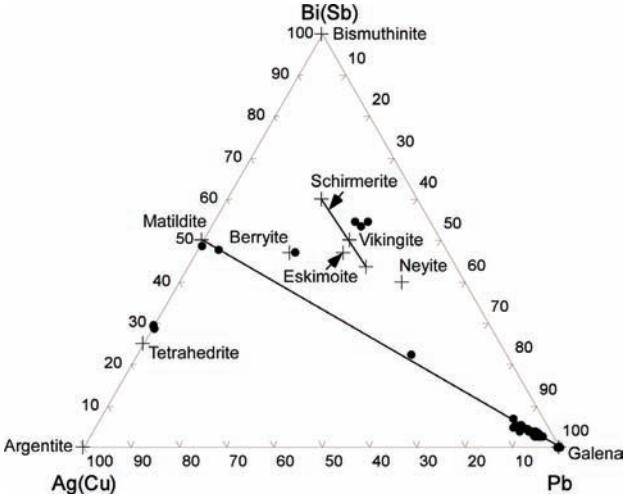

Fig. 1: Compositions of sulfides and sulfosalts analyzed in terms of the Pb-Bi(Sb)-Ag(Cu) system (dots) and of Ag-Bi-Cu sulphides and sulfosalts (crosses).

Pb isotope analyses of galena and pyrite return the following isotope ratios: $^{206}Pb/^{204}Pb$=18.097-18.147, $^{207}Pb/^{204}Pb$=15.569-15.633 and $^{208}Pb/^{204}Pb$=37.482-37.649. High Th/Pb ratios imply a lower crustal influence. The steep array in both thorogenic and uranogenic Pb-Pb diagrams indicates mixing between mantle and crustal sources [1]. Tightly constrained $\delta^{34}S$ analyses (+0.7 to +3.8‰) in pyrite and sphalerite indicate sulphur affinity with a magmatic source.

The presence of galena with intergrowths of Pb_{ss}, matildite and Bi-Ag-Cu sulfosalts, and coarse-grained alteration sericite indicates gold mineralization at La Puja is related to a multi-stage, chemically complex paragenesis at temperatures of +280 to *ca.* 400ºC [2]. Radiogenic Pb and stable S isotope geochemistry suggests mantle sourced magmatic fluids mixed with lower crustal fluids prior to the deposition of hydrothermal mineralisation/alteration in/along brittle-ductile shear zones at higher crustal levels under broadly mesothermal conditions.

Anomalous Pd values in ores of the Kalmakyr Cu-Au(Mo) porphyry type deposit, Uzbekistan

Pašava, J.[1*], Vymazalová, A.[1], Košler, J.[2], Koneev, R.I.[3], Jukov, A.V.[3] & Khalmatov, R.A.[3]
[1]Czech Geological Survey, Prague, Czech Republic
([*]jan.pasava@geology.cz)
[2]Dept. of Earth Science and Centre for Geobiology, University of Bergen, Norway
[3]National University of Uzbekistan, Tashkent, Uzbekistan

Ores and host rocks from different types of gold deposits and the Cu-Au porphyry type deposit Kalmakyr have been studied for their Platinum group elements (PGE) and Au contents. Palladium is recovered as a by-product during the processing and refining of gold ores at a number of gold and Cu-Au porphyry types deposits in Uzbekistan [1].

No anomalous PGE concentrations were detected in the studied ore samples from various types of gold deposits (Kyzylalma, Kochbulak, Charmitan, Guzhumsai, Daugystau, Amantaytau, Vysokovoltnoye, and Myutenbai) in Uzbekistan. Prosperous Pd concentrations have been found from the porphyry Cu-Au(Mo) deposit Kalmakyr in Uzbekistan. High Pd concentrations have been reported from a number of porphyry copper deposits worldwide [2,3]. However, the PGE data on porphyry systems from Uzbekistan are very limited [1,3].

The Kalmakyr deposit belongs to the Almalyk ore field and is a part of the Chatkal–Kurama ore district, in the eastern Uzbekistan, where the main host rocks are Middle Carboniferous monzonite and locally preserved remnants of Devonian volcanic and carbonate rocks [4].

The study of primary ores (disseminated and stockwork type of mineralization) at the Kalmakyr deposit showed that our average Cu-Au(Mo) ore (Cu = 2.4 wt.%, Mo = 0.18 wt.%, Au = 4.1 ppm) contains 55.2 ppb Pd, 0.95 ppb Rh, 0.49 ppb Ir and 5.5 ppb Pt. Similar Pd values were reported in flotation concentrates from the Assarel porphyry deposit, Bulgaria (54 ppb), Grasberg deposit, Indonesia (58 ppb) and Sora porphyry deposit in Russia (50 ppb) [2]. At Kalmakyr, the peak Pd content of 291 ppb was determined in a Pb-Zn-Cu-rich sample hosted in quartz veinlets in granodiorite porphyrite, characterized mainly by the presence of galena, sphalerite, chalcopyrite, tetrahedrite and gold.

Geochemical study showed an important relationship between Pd and a group of metals (Cu, Ag, Se, S). Subsequent mineralogical and laser ablation ICP-MS study of base metal sulfides confirmed that anomalous Pd concentrations are likely bound to the crystal lattice of chalcopyrite and tetrahedrite or, alternatively, homogeneously distributed as sub-micron inclusions of PGE minerals. Chalcopyrite contains up to 110 ppm Pd and tetrahedrite up to 20 ppm Pd.

In-situ trace element and ID-TIMS Sm-Nd analysis of scheelite and Re-Os dating of molybdenite at Schellgaden, a Au-(W) deposit in the Eastern Alps, Austria

Raith, J.G.[1*], Wieser, B.[1], Thöni, M.[2], Cornell, D.[3], Stein, H.[4] & Paar, W.H.[5]
[1]Dept. of Applied Earth Sciences and Geophysics, University of Leoben, Austria ([*]johann.raith@unileoben.ac.at)
[2]Dept. of Lithospheric Research, University of Vienna, Austria
[3]Dept. of Earth Sciences, University of Gothenburg, Sweden
[4]AIRIE Program, Colorado State University, Fort Collins, USA
[5]Dept. Materials Engineering and Physics, University of Salzburg, Austria

Scheelite-bearing gold occurrences ("Schellgaden type") are located along the eastern margin of the Penninic Tauern Window in the upper parts of the pre-Alpine sequences of the Storz-Kareck complex. The volcano-sedimentary and calc-alkaline plutonic rocks of this complex, interpreted as an island arc sequence, were intruded by Variscan granitoids (Central Gneiss). Subeconomic molybdenite mineralization, which is spatially distal and presumably unrelated to the Au-(W) occurrences, is associated with an aplitic granite gneiss. Both host rocks and the ore deposits were affected by polyphase deformation and metamorphism during the Alpine orogeny. Three types of sulfide-bearing Au-quartz veins are known: concordant mylonitic (Type 1), remobilized sub-concordant (Type 2), and discordant (Type 3)[1]. Scheelite is restricted to Type 1 veins. It shows bluish fluorescence under UV light and is associated with galena, pyrite, minor other sulfides and native gold. Large scheelite crystals (Scheelite 1) are deformed and show metamorphic re-crystallization (Scheelite 2).

Molybdenite from the aplitic granite gneiss was dated with the Re-Os chronometer. Two runs of one molybdenite sample yielded ages of 362 +/-3 and 366 +/- 1 Ma, the first run less than optimally spiked. Trace element concentrations in scheelite were obtained using EMS and LA-ICPMS techniques [2]. Both scheelite generations are Mo-poor, do not show pronounced zonation in cathodoluminescence images and have similar trace element concentrations. Total REE concentrations in scheelite are high (454-2378 ppm). Chondrite normalized REE patterns of both scheelite generations show enrichment in MREE and a relative depletion of LREE and HREE, resulting in convex (bell-shaped) patterns. Similar REE patterns are known from orogenic (mesozonal) gold deposits.

Sm-Nd isotope systematics of scheelite 1 obtained by micro-drilling from polished sections was analyzed by ID-TIMS [2]. Concentrations of Sm (65-171 ppm) and Nd (111-365 ppm) are remarkably high. However, $^{147}Sm/^{144}Nd$ ratios vary only within a very narrow range from 0.1836 to 0.2623. Thus, the calculated regression ages have very large uncertainties. An age of 322+/-140 Ma can be calculated from all (n=12) analyzed samples. Initial ε_{Nd} values for all scheelites are slightly positive (+1.9 to +2.9). Hence, an old crustal source, strongly enriched in LILE, can be ruled out and an Alpine age for Type 1 mineralization is excluded. An epigenetic hydrothermal formation for the Au-(W) deposits during the Variscan orogenic cycle is favored, although the large age uncertainty does not preclude a pre-Variscan, syngenetic origin.

Multistage gold mineralization at Lapa mine, Abitibi greenstone belt (Canada)

Simard, M.[*], Daigneault, R. & Gaboury, D.
Centres d'Études sur les Ressources Minérales, Université du Québec à Chicoutimi, Chicoutimi, Quebec, Canada
([*]marjorie.simard@uqac.ca)

The Lapa gold deposit (1.1 Moz of Au @ 8.8 g/t Au) is one of the few deposits located directly within the Cadillac Larder-Lake Fault Zone (CLLFZ), a first order crustal fault that separates two Archean terranes, the Abitibi Greenstone Belt to the north and the Pontiac Subprovince to the south. This deposit is characterized by a number of features that are compatible with orogenic gold deposits including: (1) deformed and metamorphosed host rocks, (2) low sulfide content, (3) abundant quartz veinlets, and (4) spatial association with transpressional or compressional structures (e.g. CLLFZ). However, this deposit differs by being hosted directly within the CLLFZ and by showing well-developed mineralogical and metallic vertical zoning.

Mineralization defines vertically continuous ore zone from 400 to 1400 m depth hosted in strongly altered and foliated mafic to ultramafic units, metamorphosed at upper greenschists to lower amphibolite facies. Metamorphic grade transition defines a subhorizontal isograd, at depth of about 1 km, coincident with a well-developed wallrock alteration assemblage of biotite-dominated above 1 km depth and amphibole-dominated below. The metallic zoning is defined by an Au-Sb association developed mostly in the upper half of the deposit (depth≤ 1 km) whereas an Au -As association is relatively evenly distributed along main ore zones. Gold mineralization occurs mostly as disseminated sulfides (arsenopyrite-pyrrhotite ± pyrite) and as native gold in deformed quartz ± carbonates veins and veinlets and their alteration selvages.

Textural and mineralogical relationships show evidence of peak prograde metamorphism followed by a retrograde metamorphic event in the ore zones, including: (1) hornblende porphyroblasts partially replaced by actinolite; (2) biotite plages replaced by chlorite, and (3) occurrence of actinolite-albite assemblage whereas hornblende-orthoclase assemblage occurs in distal zone. Furthermore, backscattered electron images and electron microprobe analysis on disseminated arsenopyrite reveal primary crystallographic zoning with rims that are enriched in As over S. LA-ICP-MS analysis show that gold are homogeneously distributed in arsenopyrite crystals as solid solution. Theses results reflect that arsenopyrite are affected by an overall increase in temperature at the deposit-scale, caused by the prograde metamorphic event. This event has permitted liberation of invisible gold promoted by recristallisation and As enrichment of arsenopyrite.

Conversely, native gold is common in transposed quartz veinlets, and as free grains in altered wallrocks. This style is clearly associated with Sb-bearing phases at shallower depth in the deposit, is interpreted as indicative of a later decrease in temperature. Precipitation of native gold and Sb-minerals may results from the vertical cooling path of hydrothermal fluid, during retrograde metamorphic event.

These complex relationships between ore, alteration and metamorphic mineralogical and chemical assemblages indicate that gold mineralization has a protracted history of precipitation and remobilization, a feature not typical of most orogenic gold deposits. However, this can be explained by the complex deformation and metamorphism recorded by the CLLFZ induced by the successive variations of tectonic regime and strain, crustal level, heat flow and fluid flow.

Fluid inclusion investigation and Re-Os dating of the Pataz-Parcoy intrusion-hosted gold deposits, Eastern Cordillera, Peru

Szappanosné-Vágó E.[1*], Moritz, R.[1] & Barra, F.[2]
[1]Dept. of Mineralogy, Section of the Earth and Environmental Sciences, University of Geneva, Switzerland
([*]edina.vago@unige.ch)
[2]Dept. of Geosciences, University of Arizona, Tucson, USA

The major Carboniferous continental arc, intrusive belt of the Eastern Peruvian Cordillera is hosting auriferous quartz-sulphide veins. Subvertical to subhorizontal veins striking approximately to north-northwest, with a typical width of one to two meters, were emplaced along several km in two main districts located about 40 km from each other, within granodioritic to monzogranitic bodies. The genetic classification of gold deposits of the Pataz and Parcoy districts has been the subject of controversy in the last twenty years. On the one hand, they are considered as hydrothermal ore deposits related to deeper intrusive bodies associated to the Carboniferous magmatic activity. On the other hand, they are classified as orogenic, shear zone-hosted gold deposits emplaced along the western margin of the South-American continent. The present study addresses the issue of the controversial genetic classification of the Pataz-Parcoy gold belt, and presents new geochronological data on the magmatic and mineralising system and fluid chemical characteristics of the vein forming hydrothermal systems.

New Re-Os geochronological data on molybdenite from an early quartz-arsenopyrite-molybdenite vein from the Parcoy deposit constrains the early stage of the mineralisation to 331.9±1.7Ma. The host Pataz Batholith was dated by previous authors with ages ranging between 336 and 329 Ma (zircon TIMS U-Pb and Ar-Ar plateau biotite and hornblende ages) and between 314 and 301 Ma (zircon LA-ICP-MS U-Pb dating). In previous studies, hydrothermal muscovite associated with the gold veins yielded Ar-Ar plateau ages of 312-314 Ma at Pataz.

Our new results from fluid inclusion microthermometry allow us to define three different fluid stages responsible for the hydrothermal vein formation. Euhedral early stage-quartz contains primary low salinity (1-5wt% NaCl equiv.) aqueous-carbonic fluid inclusions with moderate to high homogenisation temperatures (170-300°C). Pseudosecondary fluid inclusions in quartz of the intermediate sphalerite-galena-chalcopyrite-bismuthinite-gold stage show entrapment of a medium to high salinity (5-25 wt% NaCl equiv.) $CaCl_2$-NaCl-H_2O($\pm CO_2$) fluid with low homogenisation temperatures (100-160°C). Low temperature and low salinity NaCl-H_2O fluids (100-120°C; ~5 wt% NaCl equiv.) have been trapped in secondary fluid inclusion trails, and represent the late stage of the mineralising system. This study is the first report of bismuthinite in the Pataz-Parcoy belt.

The strongly banded texture of the whole vein system reflects recurrent, incremental vein opening during hydrothermal fluid circulation. The new Re-Os age reveals a close temporal and spatial association of early vein formation with respect to its host intrusion. The approximately 15 m.y. difference between the Re-Os molybdenite age at Parcoy and the Ar-Ar plateau age of gold mineralisation at Pataz raises the questions whether there were distinct pulsating magmatic hydrothermal systems continuously over a duration of 15 m.y. or discrete overlapping mineralizing fluid events from different sources (magmatic vs metamorphic?), at time interval of several m.y.

Chemical variations in tetrahedrite-tennantite minerals from the Berezovsk mesothermal Au deposit, Ural, Russia: mineralogical zoning and ore fluid evolution

Vikenteva, O.V.[*] & Bortnikov, N.S.
Inst. of Geology of Ore Deposits, Petrography, Mineralogy, and Geochemistry (IGEM), Russian Acad. Sci., Moscow, Russia
([*]ovikenteva@rambler.ru)

The large Berezovsk gold deposit is located in metamorphosed volcanosedimentary rocks (S_1ln-v) with subconformable bodies of serpentinized ultrabasic rocks. The rocks are crosscut by numerous granitoid dykes and are located above the gently dipping roof of the Shartash granite massif. Mineralization is represented by sulfide-quartz veins in the granitoid dykes and host rock and by disseminated gold-sulfide mineralization in the wall-rock metasomatites. Ore minerals in the gangue mass account for no more than 10 vol%. Quartz, calcite, ankerite, pyrite, galena, fahlore, chalcopyrite, aikinite, sphalerite, and native gold are the most abundant minerals.

Fahlore may be a sensitive indicator of physicochemical conditions during ore deposition and therefore can be used as a tool for fluid evolution with respect to time and space. Fahlore is enriched in the tennantite component with As/(As+Sb) ratio ranges from 0.50 to 0.98. Zink predominates over iron (Fe/(Fe+Zn) = 0.15 - 0.67). Contents of silver is very low (0-0.9 wt %) and there is a correlation between the Sb and Ag contents in fahlore (r = 0.8) (Fig. 1).

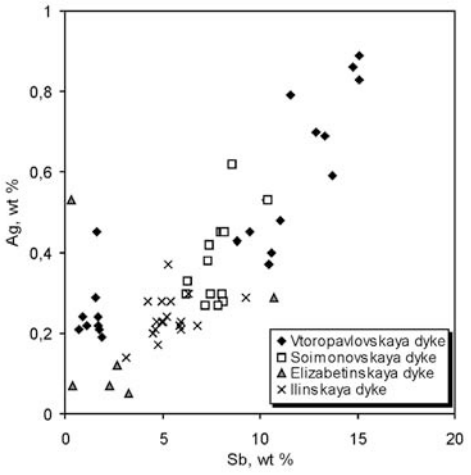

Fig. 1: Relationship between Ag and Sb in tennantite-tetrahedrite from Berezovsk deposit.

The model of fractional crystallization of fahlore from hydrothermal solution [1] is discussed for explanation of the variations of the Sb/As and Cu/Ag ratios in minerals of tennantite-tetrahedrite series.

Ag content in native gold decreases (and accordingly fineness of gold becomes higher) along with increase of Ag and Sb contents in coexisting fahlore. There is the direct correlation between Fe in coexisting fahlore and sphalerite related with the temperature of mineral formation. The chemical composition of tennantite-tetrahedrite can record some of the chemical variables of the hydrothermal fluids at the time of mineralization.

The formation mechanism of shear zone-related gold deposits as exemplified by the Tianger gold deposit (Xinjiang, NW China)

Zhu Yongfeng
School of Earth and Space Sciences, Peking University, Beijing, China (yfzhu@pku.edu.cn)

Orogenic gold deposits typically formed in the later part of the deformational - metamorphic - magmatic history of the evolving orogen. The nature of gold-bearing fluids and the mechanism of gold deposition in shear zones in orogenic gold deposits are still largely unknown. Some studies have demonstrated that gold has been introduced syn-deformationally during a period of brittle-ductile shear development of the shear zone, with the gold-bearing sulfides subsequently deformed in the brittle field [1-3]. Others have shown that gold introduction is post-deformational and related to a brittle fracture event [4].

In this contribution, we attempt to address these problems in our study of the Tianger gold deposit in the west Tianshan mountains (NW China), a typical shear zone hosted gold lode deposit. We provide a detailed petrographic description of Au-bearing rocks and report, in detail, on the trace element, S, H, O, Ar, and Rb-Sr isotope geochemistry of the deposit.

The Tianger (also called Bingdaban in China) shear zone strikes roughly E-W, varies between 500 and 2,000 m in width and extends >100 km. This shear zone cuts a Silurian gneissic granite, dated at 442 Ma by zircon SHRIMP [5]. The shear zone is comprised of mylonitized granite with a strong mylonitic fabric and yellowish alteration. Disseminated sulfides are abundant in sheared rocks and rare in weakly deformed rocks.

Three gold deposits have been found in the Tianger shear zone: Wangfeng, Tianger, and Saridala. The orebodies and their wall rocks in these deposits are heterogeneously mylonitized. The degree of mylonitization of the wall rocks increases gradually towards the orebodies. Sub-horizontal fractures are filled with syntaxial quartz-fibres and antitaxial fibrous muscovite, which was dated to be 220Ma by Ar-Ar technique [4]. Pyrite is mainly disseminated in mylonite consisting of quartz subgrains, albite, muscovite and calcite. The pyrite-bearing mylonite is cut by a late-stage sulfide-quartz vein, which generally is 1-2 mm wide and consists of pyrite and quartz showing undulose distinction. Such pyrite-quartz veins formed after the major ductile deformation stage of the Tianger shear zone. They are, in turn, crosscut by micro-scale veins carrying pyrite, mica and quartz.

Based on stable isotope characteristics and high initial 87Sr/86Sr ratio, ore-forming materials are interpreted to have been sourced in gold-bearing rocks of the continental crust.

The Ag-Pd-Se system – experimental study and mineralogy

Vymazalová, A.[1*], Drábek, M.[1], Laufek, F.[1], Chareev, D.A.[2], Kristavchuk, A.V.[2], Voronin, M.V.[2] & Osadchi, E.G.[2]
[1]Czech Geological Survey, Prague, Czech Republic
([*]anna.vymazalova@geology.cz)
[2]Institute of Experimental Mineralogy RAS, Chernogolovka, Russia

The Ag-Pd-Se system comprises Platinum-group minerals like chrisstanleyite $Ag_2Pd_3Se_4$, verbeekite $PdSe_2$ and palladseite $Pd_{17}Se_{15}$ and silver selenide naumannite Ag_2Se. Furthermore nine binary phases are known from the system Pd-Se [2,3] and these phases could be found as new minerals in nature. Nevertheless only phase relations within the binary sub-systems are known. Therefore we carried out experiments in the Ag-Pd-Se system.

The isothermal sections 350, 427 and 527°C were studied using the evacuated silica glass tube technique [1]. Our first results are presented herein.

The experimental study revealed the existence of two new ternary phases in the system: Ag_2Pd_2Se and $AgPd_3Se$. The crystal structure of the phases was solved and refined from the powder X-ray diffraction data. The $AgPd_3Se$ phase is cubic ("cubic approximant of quasicrystals") with space group *Pa*3 and *a*=8.6288(1) Å. The first results of the X-ray data evaluation of the Ag_2Pd_2Se phase have shown that the phase is most likely tetragonal. The new Ag_2Pd_2Se and $AgPd_3Se$ phases are stable at temperature interval 350 – 527°C. The Ag_2Pd_2Se forms an extensive solid solution, chemical composition at 350°C varies between 38.3-46.3 at.% of Ag, 31.9-41.2 at.% of Pd, and 20.5-22.0 at.% of Se.

Our experiments confirmed the following binary phases to be stable in the temperature interval 350-527°C: Pd_4Se, Pd_7Se_2, $Pd_{34}Se_{11}$ (stable up to 430°C), Pd_7Se_4 (stable up to 415°C), Pd_5Se_4, $Pd_{17}Se_{15}$, PdSe, $PdSe_2$, and Ag_2Se. PdSe forms a narrow solid solution and dissolves up to 5 at.% of Ag at 350°C. At 427°C the ternary melt appears in the Ag_2Pd_2Se – Pd_4Se – Pd_7Se_4 field.

At 350°C the ternary $Ag_2Pd_3Se_4$ phase, an analogue to mineral chrisstanleyite, forms stable associations with naumannite (Ag_2Se) and verbeekite ($PdSe_2$) and coexists with PdSe and the new ternary phase Ag_2Pd_2Se. At 527°C the phase $Ag_2Pd_3Se_4$ is not stable.

The new recognised ternary phases Ag_2Pd_2Se and $AgPd_3Se$ and binary phases Pd_9Se_4, Pd_4Se, Pd_7Se_2, $Pd_{34}Se_{11}$, Pd_7Se_4, Pd_5Se_4, and PdSe, so far unknown as minerals could be found in nature in close association with other PGM, particularly with known minerals of the Ag-Pd-Se system.

X-ray absorption spectroscopic study of oxygen-bearing platinum-iron grains from New Caledonia

Hattori, K.H.[1*], Takahashi, T.[2] & Auge, T.[3]
[1]Dept. of Earth Sciences, University of Ottawa, Ontario, Canada
([*]khattori@uOttawa.ca)
[2]Dept. of Earth and Planetary Systems Science, Hiroshima University, Higashi-Hiroshima, Japan
[3]BRGM, Orléans, France

Oxygen-bearing platinum group minerals have been reported in weathered rocks and placers from many locations, but their mineralogy has been debated. We obtained X-ray absorption spectra of Pt and Fe from oxygen-bearing Pt-Fe grains collected from a stream in southern New Caledonia. The use of a micro X-ray beam allowed us to obtain spectra from target grains in polished sections. The absorption spectra of Pt-L_{III} edge show that Pt is mostly in the metallic state, not combined with oxygen or OH^-. The calculated bond length between Pt and the neighbouring atoms is much longer than that of Pt-O bond, indicating that Pt is not bonded with oxygen or OH^-. A quantitative simulation of the atomic structure around Pt in the oxygen-bearing Pt-Fe indicates that Pt has lower coordination numbers than that of isoferroplatinum. The results suggest that the oxygen-bearing Pt-Fe has a similar, but disturbed crystal structure around Pt compared to isoferroplatinum.

The absorption spectra of Fe *K*-edge show prominent two peaks at 7122 eV and 7128 eV. Isoferroplatinum has also two peaks at these positions with a larger peak at 7122 eV. On the other hand, oxygen-bearing Pt-Fe has a larger peak at 7128 eV and a smaller peak at 7122 eV, suggesting the presence of a different phase in the sample. Considering the electron probe data of these Pt-Fe grains, possible phases are Fe^{3+}-bearing phases. A 10:90 mixture of ferrihydrite (Fe^{III}-O-OH) and isoferroplatinum yields the observed absorption spectra. The data suggest that the oxygen-bearing Pt-Fe is a physical mixture of relict isoferroplatinum and newly precipitated Fe^{III}-O-OH. We suggest that oxygen-bearing Pt-Fe grains formed from isoferroplatinum by the dissolution of metallic Fe from isoferroplatinum in reduced alkaline waters within weathering ultramafic rocks, followed by the dissolution of Pt and precipitation of Fe^{3+} after the host ultramafic rocks are exposed to the atmosphere.

Application of laser micro-Raman spectroscopy: an efficient tool to identify platinum group minerals

Zaccarini, F.[*], Bakker, R.J., Garuti, G. & Thalhammer, O.A.R.
Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria ([*]federica.zaccarini@unileoben.ac.at)

The identification of nanometer-scale minerals, such as most of Platinum group minerals (PGM) is a challenging target. The main reason for that resides in their size and mode of occurrence (i.e. polyphasic aggregates) that prevent any XRD structural study. Although with some limitations, optical and electron microscopy and determination of micro-hardness are the most used techniques for mineralogical identification of PGM. Even the most precise technique, the electron microprobe, requires accurate calibration of the instrument in order to reduce analytical uncertainties. In this contribution we present the results obtained using laser-Raman microprobe on different PGM, such as sulphides, arsenides, sulpharsenides and alloys. All the analyzed PGM, with the exception of alloys, show a very well-defined and characteristic spectrum, suggesting the presence of covalent bonding. On the contrary, the Raman spectra of alloys are flat suggesting that the possible bonds present in these PGM are metallic or ionic. Our data indicate that Raman is also sensitive on the compositional variation, particularly in the PGM characterized by a solid solution substitution such as laurite-erlichmanite series. These results, although preliminary, demonstrate that Raman spectroscopy is a fast and cost-efficient technique that can be considered innovative and complementary method with a huge potential to identify and to better characterize the nanometer-scale PGM. However, this technique does not provide a chemical composition of the investigated minerals. Therefore, it is intended to apply the Raman spectroscopy to a great number of different PGM, already characterized by electron microprobe, with the aim of assembling a future data base of Raman spectra of PGM.

Mineral chemistry of Pt-Fe-Cu-(Ni) nuggets from the Yubdo placer deposit (Ethiopia)

Mogessie, A.[1*], Zaccarini, F.[2], Garuti, G.[2], Belete, K.H.[3] & Mali, H.[2]
[1]Dept. of Earth Sciences, Karl Franzes University, Graz, Austria ([*]aberra.mogessie@uni-graz.at)
[2]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria
[3]Golden Prospect Mining, Addis Ababa, Ethiopia

The system Pt-Fe-Cu-Ni consists of the following phases accepted by IMA: platinum (Pt), isoferroplatinum (Pt_3Fe), iron (Fe) all of which are cubic in symmetry have a cubic structure, and tetraferroplatinum (PtFe), tulameenite Pt_2CuFe and ferronickelplatinum, which are tetragonal. On the basis of chemical composition, a phase with ideal formula Pt_2Fe has been recognized in Russian samples, and in particular in nuggets from Nizhny Tagil and Guli massifs and in the chromitites of Kytlim and Uktus complexes. Tetraferroplatinum and tulameenite crystallized in the same system and have a similar cell size. Therefore, a possible solid solution between these two phases is postulated. In this contribution we report on the chemical composition of about 100 Pt-Fe-Cu-(Ni) nuggets collected in the Yubdo placer deposit (Ethiopia). The nuggets have a size variable from 100 µm up to 3 mm. According to their mineral chemistry (about 800 analyses), the following alloys in the Pt-Fe-Cu-Ni system have been identified: 1) Pt_3Fe, possibly isoferroplatinum, 2) tetraferroplatinum that always contains appreciable amounts of Cu and minor Ni, 3) tulameenite and 4) an unknown phase that approaches the Pt_2Fe composition. Based on the chemical composition of the investigated Pt-Fe-Cu-Ni nuggets, we can conclude that: 1) the continuous substitution Cu-Fe at constant Pt found in the Yubdo alloys clearly indicates a complete solid solution between tetraferroplatinum and tulameenite, as previously postulated on the basis of their structural parameters and 2) a Pt_2Fe phase, previously described in Russian localities, has been also found in the Yubdo nuggets. Data available suggest that this alloy possibly represents a new mineral in the Pt-Fe-Cu-Ni system. However, it is not possible to support this conclusion because of the absence of X-ray data (work in progress).

Mineral chemistry of apatite and its relationship to enrichment of platinum-group elements in the South Kawishiwi Intrusion (Duluth Complex)

Gál, B.[1*], Molnár, F.[1], Mogessie, A.[2] & Peterson, D.[3]
[1]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]galbenedek@yahoo.com)
[2]Institute of Mineralogy and Petrology, Karl-Franzens University, Graz, Austria
[3]Duluth Metals Ltd., Minnesota, Duluth, USA

The South Kawishiwi Intrusion is one of the intrusions that constitute the 1.1 Ga old Duluth Complex, one of the largest unexploited reserves of magmatic Cu-Ni-PGE of the Earth. Involvement of hydrothermal fluids in the partial remobilization and enrichment of platinum-group elements has been reported by several authors in the Duluth Complex [1-3], which is further supported by the results of our current research.

The connection of the late-stage sulfide segregation and fractionation processes with hydrothermal fluid segregation is traced by the halogen chemistry of various minerals phases, primarily apatite. Halogen content of apatite is variable as a function of type and texture of the host troctolitic rocks and stratigraphic height above the footwall contact (Table 1). The Cl-content of apatite is generally the lowest in medium-grained, homogeneous and unmineralized troctolitic units. The presence of a fluid phase enriched in Cl is indicated by the elevated Cl-content of apatite in pegmatitic patches from the same depths. Segregation of a magmatic fluid during crystallization is moreover implied by the increase of F-content (and coeval Cl-depletion) in apatite within single grains and also in late-stage differentiates.

Table 1: Proportions of F, Cl and OH (%) in apatite from selected samples

Drillhole & height above footwall (feet)	Description	X^F	X^{OH}	X^{Cl}
Dh-1 – 178 ft	homogeneous troctolite	73.0	5.5	21.5
Dh-1 – 178 ft	pegmatite	55.4	4.2	40.4
Dh-1 – 73 ft	apatite core[1]	48.9	34.1	17.0
Dh-1 – 73 ft	apatite rim[1]	52.1	36.5	11.4
Dh-2 – 207 ft	average value of sample	51.5	39.3	9.3
Dh-2 – 270 ft	average value of sample	37.8	48.8	13.4

[1] apatite is from a late-stage, differentiated felsic dyke

Platinum-group minerals (e.g. Platinum-Arsenides, Platinum-Palladium-Bismuth-Tellurides, and Rhodium-Arsenides) have been found in association with magmatic sulfides, fractionated sulfide stringers as products of late-stage sulfide melt differentiation, felsic differentiates and hydrothermal alteration (serpentine, Ca-enriched plagioclase). It is clear that distribution of PGEs is not only a function of simple intrusion and crystallization of a silicate melt but interaction with the felsic footwall and later segregation of a volatile-rich phase had its role in later redistribution of these metals.

Pt- and Pd- sulfides in ores from Noril'sk region (Russia)

Sluzhenikin, S.F. & Evstigneeva, T.L.[*]
IGEM RAS, Moscow, Russia ([*]evst@igem.ru)

Pt- and Pd- sulfides occur in ores of Noril'sk deposits as cooperate, braggite and vysotskite. As in other deposits these minerals contain Ni less pyrite-chalcopyrite exocontact ores where there is no Ni (Fig. 1).The field of Noril'sk cooperite is quite narrow ranging from $(Pt_{0.96}Pd_{0.02}Ni_{0.02})_{1.00}S_{1.00}$ to $(Ptt_{0.84}Pd_{0.09}Ni_{0.07})_{1.00}S_{01.00}$. Grains of cooperite are always homogeneous in composition. In contrast to those of the braggite – vysotskite series, these are heterogeneous and often zoned.

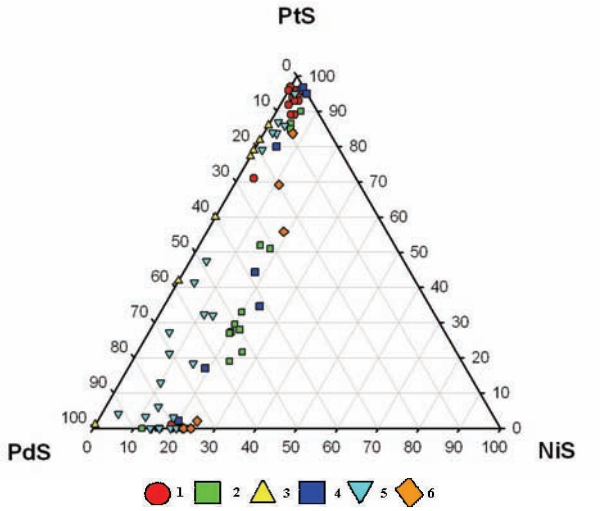

Fig. 1: Composition of Pt-Pd sulfides from Noril'sk region (1 and 6 – Noril'sk 1, 2-5 – Talnakh): 1. Disseminated ores (Noril'sk 1); 2. Dissem.-veinlet exocontact Mil-Bor-Cp and Mil-Pyr-Cp ores; 3. Veinlet-dissem. exocontact Pyr-Cp ores; 4. Breccia ores; 5. Low-sulfide platinum ores; 6. Vertical Cp veins, Morozov mine.

The cores of these zoned aggregates are enriched in Pt, and the rims in Pd e.g., cores with compositions $(Pt_{0.83}Pd_{0.14}Ni_{0.03})_{1.00}S_{1.00}$, middle zones with compositions $(Pd_{0.56}Pt_{0.31}Ni_{0.13})_{1.00}S_{1.00}$, and rims with compositions $(Pd_{0.89}Ni_{0.11})_{1.00}S_{1.00}$. The clearly defined boundary is observed between zones of Pd- and Pt braggites. Grains of Pt- and Pd- braggites are often heterogeneous too. Zoned overgrowths are also typical for Ni-poor Pt- and Pd monosulfides: cores are characterized by "Σ_{metals}:S" varying up to $(Pd,Pt)_{16}S$; intermediate zones are braggite; and the rims are vysotskite. By contrast, monomineral vysotskite grains are homogeneous with compositions that lie within narrow limits, $(Pd_{0.76}\ Ni_{0.24})_{1.00}S_{1.00}$ - $(Pd_{0.86}Ni_{0.14})_{1.00}S_{1.00}$.

The compositions of (Pt,Pd,Ni)S minerals can often be represented using integral numbers of atoms in their formulae, i.e. $Pt_1Pd_1S_2$, $Pd_4Pt_3Ni_1S_8$, $Pt_3Pd_1S_4$ etc. This is in good agreement with composition of phases synthesized in the system Pt-Pd-Ni-S, and characterized by ordered metal atom distribution among 2d, 2e and 4j positions in the tetragonal structure derivative from PdS structure type [1]. Based on this data the minerals relationships in the series PdS-PtS-NiS are discussed.

Acknowledgements: This study was carried out thanks to the financial support of Fundamental Research Programme n.5, Dept.Dci.Earth RAS.

Jamestownite: a new PGE-rich rock type from the Barberton greenstone belt, South Africa

Tredoux, M.[1*], Chabangu, N.[1], Wildau, A.[1], Miller, D.E.[2], Zaccarini, F.[3], Garuti, G.[3] & Madala, F.[1]
[1]Geology Dept, University of the Free State, Bloemfontein, South Africa ([*]mtredoux@ufs.ac.za)
[2]Centre for Materials Engineering, University of Cape Town, Rondebosch, South Africa
[3]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria

It has been demonstrated [1] that the mafic and ultramafic rocks of the Barberton greenstone belt can be interpreted as the remnant of an Archean ophiolite, which was named the Jamestown complex [1]. Part of the lowermost stratigraphic unit of this ophiolite is exposed in the northwestern flank of the belt on the farm Bon Accord (BA); it is an ultramafic rock which has been intensely altered to talc and serpentine. All the contacts are sheared, indicating that it is allochthonous. The geochemistry shows a severe depletion in the LILEs, and dating (Sm-Nd and Pb-Pb) [1,2] points to ~3.5 Ga as the most likely time for the depletion. This rock is therefore interpreted [1,2] as the depleted upper mantle restite from which the overlying volcanic rocks were extracted at an Archean ridge system.

In 1920, a very Ni-rich body was discovered embedded in the BA ultramafite [3] — see Table 1 for its major element chemistry, and Table 2 for some of the unusual Ni minerals it contains. Initially the body was described as an oxidized meteorite [3], but this was rejected on geological and geochemical grounds by Tredoux et al. [2], who postulated a deep mantle origin of a metal-rich silicate, potentially from the D" layer, which got progressively oxidized as it moved through the various redox boundaries in the mantle in a plume.

Table 1: Major element chemistry of the BA body; all values in wt %; analyses obtained by WDXRF

SiO_2	Fe_2O_3	NiO	MgO	Al_2O_3	CoO	Cr_2O_3	Total
15.51	32.57	47.27	2.39	0.88	0.68	0.23	99.52

Table 2: Some of the major minerals in the BA body

Mineral	Composition	Group
Liebenbergite	Ni_2SiO_4	Olivine
Nepouite	$Ni_3Si_2O_5(OH)_4$	Serpentine
Trevorite	$NiFe_2O_4$	Spinel

Investigation of sub-mm sized phases and mineral inclusions in the trevorite has indicated the presence of Fe-Ni alloy, and metallic Si and Ag. Although the body is highly enriched in the PGE (PGE_{tot} > 5000 ppb), only occasional small (<1μm) grains of Ru have been identified as yet.

A metal-rich (FeNi alloy) rock type, found in rivers which drain the Josephine ophiolite in Oregon, USA, was first described and named 'josephinite' in 1892 [4]. In 1975, Bird and Weathers [5] suggested that josephinite may have a deep mantle origin, a suggestion that received support from a study of its $^{186}Os/^{187}Os$ in the 1990s [6].

In light of the fact that BA and josephinite may have a similar origin, we suggest, in line with the naming convention created by Melville [4], that BA be recognised as a new rock type, called jamestownite.

[6]Mineralogy Dept., Natural History Museum, London, United Kingdom

Garutiite (Ni,Fe,Ir) is a new hexagonal polymorph of native Ni discovered in chromitite from Loma Peguera, Dominican Republic. The mineral was identified in heavy mineral concentrates obtained through the use of electric pulse disaggregation (EPD) and hydroseparation (HS) techniques. It forms as anhedral, botryoidal grains typically 10 to 60 μm in size (maximum of 110 μm). Grains are single or composite, frequently porous and zoned, and occasionally display an unusual lamellar internal texture. Associated minerals include hexaferrum, ferrian chromite, chlorite-group minerals, serpentine-group minerals, awaruite, irarsite, laurite, native Ru and unidentified species including Ru-Os-Ir-Fe and Pt-Ni-Fe-Ir compounds, $Pt(Ni,Fe)_3$, $(Fe,Ru,Ni,Os,Ir,Co)_2S$ and RhNiAs. The mineral is megascopically grey to grey-black with a metallic luster. In plane-polarized light, garutiite is white in color, exhibits a very weak anisotropy and no pleochroism, bireflectance or internal reflections were observed. No cleavage was noted and the hardness could not be determined owing to the porous nature of the mineral. The calculated density is 11.33 (1) g/cm^3. Reflectance values (%) in air are: 63.8 at 470, 65.9 at 546, 67.0 at 589 and 68.0 at 650 nm. The average result of electron microprobe analyses (n = 42 from 27 grains) is: Ni 27.91, Fe 19.94, Ir 43.78, Pt 6.98, Co 0.55, Cu 0.43, Ru, 0.50, Rh 0.74, Os 0.67, total 101.51 wt. %, corresponding to $(Ni_{0.421}Fe_{0.316}Ir_{0.202}Pt_{0.032}Co_{0.008}Cu_{0.006}Rh_{0.006}Ru_{0.004}Os_{0.003})_{\Sigma 1}$ or the simplified formula, (Ni,Fe,Ir). Garutiite is the Ni analogue of hexaferrum, osmium and ruthenium and is classified as belonging to the osmium group. As such, the mineral is considered to be hexagonal, crystallizing in space group $P6_3/mmc$ with a 2.6941(4) and c 4.2731(6) Å, V = 26.86(1) Å^3, Z = 2. The strongest lines of the X-ray powder diffraction pattern [d(in Å)(I)(hkl)] are: 2.330(50)(100), 2.136(30)(002), 2.046(100)(101), 1.576(30)(102), 1.3470(40)(110), 1.2155(40)(103). Based on its morphology, internal texture, and the associated minerals, garutiite is interpreted to be secondary in origin, *i.e.*, having formed at low temperatures during post magmatic processes, such as serpentinization and/or lateritization. The mineral may have developed as a highly strained *hcp* polymorph of Ni that was stabilized through heteroepitaxial growth on a precursor phase (native Ru?).

Clay minerals as PGE precursor

Evstigneeva, T.L.* & Trubkin, N.V.
IGEM RASS, Moscow, Russia (*evst@igen.ru)

Some PGM assemblages are closely associated with secondary minerals or their alteration products. Such observations lead to the conclusion that PGM formation could be happened under large temperature scale, possibly up to low-temperatures. There is no question that there are minerals making possible PGM crystallization under different conditions. In such processes clay minerals play a role as natural buffers and PGE precursor.

The formation of PGE-phases under low-temperature conditions with the clay mineral participation was studied experimentally earlier [1]. Results of these experiments showed that the phenomenon of clay saturation in PGE by metal adsorption by clay minerals remains not clear, as well as the position of "adsorbed" metal atoms in clay minerals. These atoms could: a) occupy the structural positions of clay minerals; b) be distributed within the interlayer space; c) form "germs" of proper phases etc. For study the mechanism of PGE-concentration in clay minerals, and check if there is any dependence between PGE content and clay mineral crystal structure the "clay minerals – PGE precursors" a reinvestigation of clay mineral pre-saturated in PGE-bearing solutions at T~60°C was carried out using SEM+EDD and XRDA.

The following results are obtained:

1. Despite the low temperature of "saturation", ~60°C, this process may result in PGE phase formation;
2. After treatment in PGE-bearing solutions near all clay minerals contain different Pt- and Pd- phases with grain dimension ~ 0.0n-0.n microns;
3. In spite of different adsorption capacity of clay minerals used as precursors, kaolinite/halloisite and montmorillonite/smectite there is no remarkable difference in PGE content in clay minerals after saturation;
4. PGE phase composition depends on the solution used for saturation. High acidity favours the formation of Pt/Pd-phases. When the starting solution is Cl-bearing the crystallization of Pt/Pd phases is "blocked" because of Cl-bearing Pt and Pd complex stability.

The presence of tiny PGE particles shows that there is any PGE adsorption by clay minerals. According to XRDA Pt and Pd are not included in clay mineral structures. Based on data obtained the reason PGE concentration in clay minerals is not the surface charge, as was proposed [2], but the precipitation of PGE nanoparticles or their aggregates on the clay mineral surface. The similar fine-grained PGM (i.e. Pt, PtS and Pd-sulphides) were found in coals and black shales (i.e. [3,4]).

Acknowledgements: The reinvestigation of PGE-precursors was carried out thanks to the financial support of RFBR, Grant n. 08-05-01016a, and Fundamental Research Programme n.5, Dept.Dci.Earth RAS.

Gold-platinum mineralization in the laminated pluton, the Polar Urals

Pystin, A.M.*, Pystina, Yu.I. & Potapov, I.L.
Institute of Geology, Komi Science Centre Ural Branch of RAS, Syktyvkar, Russia, Republic of Komi (*pystin@geo.komisc.ru)

Endogenic platinoid manifestations in chromite-bearing ultrabasites of the Paleozoic ophiolite association have been well known in the Polar Urals for a long time. The platinum group minerals are represented by relatively infusible Ru-Os-Ir–content varieties with secondary Pt, Pd, and Rh. During the additional geological study (scale 1:200000) of the territory, in 2002, a low-sulphide copper appearance has been discovered in the Kharamatalou river drainage system. Au and Ag minerals in association with Pd, Bi, and Te ones were established for the first time in the above mentioned region's copper ores; Pt minerals were revealed later.

According to a modern point of view, the Ozernoe manifestation is confined to the Kershor intrusive complex being a gabbroid part of the Voikar ophiolite complex chiefly. As a result of our investigations, the Dzelyatysher ore-bearing wherlite-clinopyroxene massif (1.0 x 4.0 km in area) was established to be sharply different from surrounding it basic-ultrabasic formations in rhythmic sheeting, orientation of primary structures (transversal in relation to the Uralian ones), and peculiar chemical composition of rocks and rock-forming minerals. On the basis of these characteristic features, the massif is considered as similar to laminated plutons and is construed as a fragment of the ancient (Precambrian) sheeted pluton combined with the Paleozoic ophiolite association rocks tectonically [1].

The precious metal mineralization in the Dzelyatysher massif is confined to the olivine pyroxenites taking middle to upper positions in the observed section.

Precious metal minerals are represented by Au, Ag, and Pt native formations; Au, Ag, Pt, and Pd intermetallids; arsenides, tellurides, antimonides, and Pt-Pd bismuthides. The natural formations and intermetallids of precious metals, as well as Pt and Pd sulphides, compose little inclusions in initial silicates and ore minerals. The arsenides, tellurides, antimonides, and bismuthides constitute two genetic groups. One of them consists of the substitutional products after native platinoids, intermetallids, and sulphides. The other is characterized by the independent neogeneses in association with secondary silicates and ore minerals.

The following model of ore elements formation and accumulation is proposed:

- Precious metals and copper were stored in magnesial rocks (high-olivine content clinopyroxenites) during the massif formation.

- Hydrothermal-metasomatic processes, which were connected with intruding and cooling of gabbro intrusions, led to the formation and accumulation of Au-Cu sulphide mineralization along the borders on the gabbro intrusions and in zones parallel to them. The same processes resulted in transformation of platinoids into the sulphide type.

- Low-temperature alterations of rocks, majorly appearing in their serpentinization, brought to Au and Cu sulphides redistribution. The processes contributed to crystallization of platinoids as arsenides, antimonides, and bismuthides.

Primary and secondary platinum group minerals (PGM): an example from the chromitites of Bursa ophiolite (NW Turkey)

Uysal, I.[1*], Zaccarini, F.[2], Garuti, G.[2], Koprubasi, N.[3], Demir, Y.[4] & Thalhammer, O.A.R.[2]
[1]Dept. of Geological Engineering, Karadeniz Technical University, Trabzon, Turkey ([*]iuysal@ktu.edu.tr)
[2]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria
[3]Dept. of Geological Engineering, University of Kocaeli, Turkey
[4]Dept. of Geological Engineering, University of Gumushane, Turkey

Based on their textural position, shape and morphology, the PGM associated with ophiolitic chromitites have been grouped in: (1) primary magmatic and (2) secondary hydrothermal or weathering-related. Primary PGM form polygonal grains and generally occur enclosed in fresh chromite. They crystallized at magmatic T, above 1000°C, under the appropriate condition of $f(S_2)$. Secondary PGM have an irregular shape and zoning and are associated with altered minerals. Their origin is still not totally understood. They may have formed in situ, after a pre-existing unstable PGM or precipitate from a solution at low T. We report on the presence of primary and secondary PGM discovered in the Bursa ophiolitic chromitites, (NW Turkey). The PGM have a size between 1 and 10 μm and according to their chemical composition, PGE sulphides (laurite, erlichmanite, cuproiridsite and unknown Ir-Ni-Fe-S), sulpharsenides (irarsite and hollingworthite) and alloys (iridium) have been found. Considering their morphology and textural position, the PGE sulphides are primary. Irarsite, hollingworthite and iridium are secondary. The absence of magmatic Os-Ir-Ru alloys and the presence of abundant Os-rich laurite, erlichmanite and other Ir sulphides as primary PGM indicate that they crystallized at T of about 1000°C, under relatively high $f(S_2)$. Few PGM (iridum, irarsite and hollingworthite) were altered and it was possible to establish that iridium represents a low-temperature exsolution product, whereas the presence of secondary sulpharsenides suggest an increase in the As activity, probably related with hydrothermal solutions, capable to remobilize PGE at small scale.

Platinum group minerals in Brazilian chromitites from Serro, Alvorada de Minas and Pedra Branca: evidence for a stratiform origin

Angeli, N.[1*], Zaccarini, F.[2], Garuti, G.[2], Thalhammer, O.[2], Proenza, J.A.[3] & Walsh, L.[1]
[1]Sao Paulo State University, Rio Claro, Brazil ([*]nangeli@rc.unesp.br)
[2]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria
[3]Dept. of Crystallography, Mineralogy and Ore Deposits, University of Barcelona, Spain

Chromitites from Serro and Alvorada de Minas (Minas Gerais) and Pedra Branca (Ceara) have been studied for Platinum-Group Minerals (PGM), using the traditional *in situ* investigation. Therefore, the PGM were previously located on polished section using reflected-light and electron microscopy, and subsequently they have been identified by electron microprobe analyses. PGM are less than 10 μm in sizye and they have been found in the altered silicate matrix, mainly composed of chlorite, or in contact with ferrian chromite. They occur either as single-phase grains or associated with secondary Co-Ni sulfarsenides. The mineralogy includes laurite (RuS_2), irarsite (IrAsS), hollingworthite (RhAsS), native osmium, sperrylite ($PtAs_2$), cooperite (PtS), and unnamed Pd-Te-Bi-(Sb) compounds, possibly referable to one of the following species: merenskyite ($PdTe_2$), kotulskyite $Pd(Te,Bi)_2$, michenerite (PdBiTe). Besides the Co-Ni sulfarsenides, the assemblage comprises pentlandite, millerite, pyrite, pyrrhotite, chalcopyrite, galena and a number of secondary sulfides formed at low temperature (siegenite, heazlewoodite, polydimite). Texture and paragenesis of the PGM indicate that the minerals were reworked or re-deposited under hydrothermal conditions, possibly by alteration-dissolution of primary PGM originally occurring in the rim of chromite grains or in the interstitial silicates. The most abundant PGM contains PPGE, whereas IPGE phases are rare. Although the PGE mineralogy has been modified by hydrothermal alteration, it strongly suggests a stratiform origin of the chromitite layers and their ultramafic host. This assumption is also supported by the composition and texture of the host chromite (well preserved cumulate texture).

PGE concentrations in spinel-group minerals from Guli massif, Polar Siberia

Zaitsev, V.A.
V.I. Vernadsky Institute for Geochemistry and Analytical Chemistry (GEOKHI), RAS, Moscow, Russia (va_zaitsev@inbox.ru)

Guli massif (Polar Siberia, Russia) is the word-largest alkaline-ultramafic massif. Among the alkaline-ultramafic massifs with native-metal mineralization, Guli massif is unique by the Os-specific. If was shown that ultramafic rocks of Guli massif strongly vary in concentrations of PGE [1].

Our studies, as well as studies ones, show that ultramafites of Guli massif vary in spinel-group minerals composition from ferrichromite to titanomagnetite and magnetite [2-4].

We studied samples of dunite with chromite and magnetite idiomorphic crystals, dunite with xenomorphic chrommagnetite and olivenite with titanomagnetite. We have obtained the native-metal concentrations in monomineral concentrates of spinel-group minerals using neutron-activation analyses.

Wall-rock concentrations of PGE do not correlate with spinel composition. But Os, Ir and Ru content in monomineral fractions decrease from chromite (161 ppb Os+Ir+Ru) to chrome-magnetite (78 ppb Os+Ir+Ru), titano-magnetite (47 ppb Os+Ir+Ru) and magnetite (0.5 ppb Os+Ir+Ru). In the same time, all spinel concentrates are close in Pt-content (115-250 ppb).

We believe that difference in PGE behaviour can be explained if spinel minerals concentrate the Os-group metals during magmatic stage, while Pt – in postmagmatic process.

Platinum-group elements (PGE) – mineralization from ophiolitic complex of Albania

Çina, A.
Institute of Geosciences, Polytechnic University of Tirana, Albania (al_cina@yahoo.com)

The Jurassic ophiolitic complex of Albania, situated between the Dinarides and Helenides, is constituted by two well distinguished belts: the Eastern belt is of IAT-type, composed of low-Ti basaltic pillow-lavas, and is considered to be formed in a SSZ. The Western belt is of MORB-type, composed of high-Ti basaltic volcanites. The Eastern belt is characterised by high partial melting of upper mantle and is remarkable for its metallageny, particularly important are Cr-deposits of metallurgical type. Four types of PGE mineralizations were identified, on the basis of the geological setting, the mineral assemblages, the chemical composition, and the PGE contents [1,4].

The first PGE-mineralization is related to the deepest mantle chromitites. It is composed of Ru-Os-Ir alloys and their sulphides, occurring as minute inclusions within host chromite grains. The (Pt + Pd)/(Ru + Os + Ir) ratios are very low, less than 0,1, but Pt/ (Pt + Pd) ratios are very high, from 0,65 to 0,75. The PGE concentration is very limited, ranging from 200 to 350 ppb.

The second type is related to upper mantle chromitites. It is represented by PGE-BM sulphides and arsenides, forming interstitial grains between the chromite. The Pt/(Pt + Pd) ratios are high (i.e. 0,65 to 0,75). The PGE concentrations are relatively higher, ranging from 580 to 2050 ppb [1,2].

The third type of PGE mineralization is represented by PGE-hosting pentlandite disseminations related to super MOHO dunites. The Pt+Pd concentrations dominate compared to Ru+Os+Ir expressed by Pt+Pd/(Ru+Os+Ir) ratios from 50 to 80. Pd predominates over Pt, the Pt/(Pt +Pd) ratios are 0,26 - 0,32. This PGE mineralization-type is similar to those in stratiform complexes; the total PGE concentrations range from 2200 to 8820 ppb.

The fourth type is related to cumulate Fe–rich chromitites, of a brecciated dunite-pyroxenite sequence. The mineral composition comprises of dominant PGE + BM alloys and PGE-BM sulphides and arsenides. The abundant minerals are Pt+Fe alloys, tetraferroplatinum and isoferroplatinum. Pt+Pd concentrations predominate over Ru+Os+Ir, the Pt+Pd/(Ru+Os+Ir) ratios range from 14 to 16. The Pt/(Pt + Pd) ratios are 0,8 to 0,9, mirroing the predominance of Pt. The total PGE concentrations lie between 1950 and 9750 ppb. The PGM usually form euhedral inclusions within chromite grains, but some of them are situated as interstitial grains [3,4].

The mineralogical and geochemical characteristics of these PGE mineralizations, are strongly related to the geological settings and the evolution of mineral-forming processes, starting from the lower mantle upwards to cumulate sequences. A primary magmatic genesis is suggested for PGM, followed by latter hydrothermal-serpentinization processes, which had partly transformed early minerals, into new PGM and BMS [1,4].

Platinum group minerals in podiform chromitites from Khoy and Neyriz ophiolites (Iran): genetic implications

Azim Zadeh, A.M.[1*], Zaccarini, F.[1], Garuti, G.[1], Moayyed, M.[2], Uysal, I.[3] & Mirmohammadi, M.[4]
[1]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria ([*]amir.azimzadeh@unileoben.ac.at)
[2]Faculty of Natural Sciences, University of Tabriz, Tabriz, Iran
[3]Dept. of Geological Engineering, Karadeniz Technical University, Trabzon, Turkey
[4]School of Geology, University College of Science, University of Tehran, Tehran, Iran

We report on the presence of platinum group minerals (PGM) in podiform chromitites from the Khoy and Neyriz ophiolites (Iran), with the aim of better understanding the mechanism of PGM precipitation in ophiolitic chromitites. The Khoy massif is Upper Cretaceous in age, originated in a slow-spreading oceanic ridge. The Neyriz complex is considered a supra subduction zone (SSZ) ophiolite of Cretaceous age. The investigated chromitites are hosted in serpentinized mantle tectonites. The Khoy chromitites are Al-rich, whereas those of Neyriz are Cr-rich. Both the chromitites proved to contain PGM less than 10 microns in size. The PGM generally occur included in fresh chromite, suggesting their magmatic origin. With the exception of one unnamed Ir-Cu sulfide, possibly cuproiridsite, laurite is the only magmatic PGM found in the Khoy chromitites. Most of the laurite occur as single phase grains. The Neyriz chromitites contain laurite, erlichmanite, osmium and iridium. Most of these PGM occur associated with amphibole and chlorite. The Khoy PGM crystallized in a narrow range of T around 1000°C, at relatively low $f(S_2)$ and in absence of fluids. PGM in the Neyriz precipitated at higher T, up to 1200°C, at very low $f(S_2)$, as testified by the prsence of PGE alloys, and continued up to reach the erlichmanite stability field at lower T and higher $f(S_2)$. The common paragenesis of PGM + hydrous silicates found in the Neyriz chromitite suggests that they precipitated in the presence of fluids, in a similar way proposed for PGM associated with other SSZ chromitites. The PGM of Iranian chromitites, coupled with chromite composition, can be successfully used to model the mechanism of their precipitation as well as to provide information on the geodynamic setting in which their host chromitites formed.

PGM types and trends from Novoseltsi placers, Bourgas district, Bulgaria

Bogdanov, K.B.[1*] & Tsintsov, Z.L.[2]
[1]Dept. of Mineralogy, Petrology and Economic Geology, Sofia Universiy "St. Kl. Ohridski", Sofia, Bulgaria ([*]kamen@gea.uni-sofia.bg)
[2]Central Laboratory of Mineralogy and Crystallography, Bulgarian Academy of Sciences, Sofia, Bulgaria

Wide variety of PGM [1,2,6] including the type locality of vasilite $(Pd,Cu)_{16}(S,Se)_7$ [1] occur amongst the Middle Eocene gravels, sands and clays around the Novosetsi (Konstantinovo) village in the Eastern Srednogorie of Bulgaria. The PGM obtained from the heavy mineral concentrates include: 1) Fe-bearing platinum and isoferoplatinum Pt_3Fe; 2) Os-rich (Os-Ir-Pt) alloys and Cu-Sn-Zn alloys; 3) Sulphides: PtS, (Pt,Pd)S, (Pd,Ni)S, RhAsS, RuS_2, OsS_2, $(Cu,Pt.Ir)S_2$, $(Rh,Ir,Pt)_{1.77}S_3$ and $(Pd,Cu)_{16}(S,Se)_7$[1,2,6]; 4) Tellurides: Pd_9Te_4. Other minerals found in the polished sections are Cu-Sn-Zn alloys ($Cu_{0.83-0.88}Sn_{0.03-0.12}Zn_{0.05-0.10}$) and gold displaying zoned pattern of electrum rich core ($Au_{0.61}Ag_{0.39}$) and rim almost devoid of Ag ($Au_{0.99}Ag_{0.01}$) as a result of leaching during the transport.

The individual grains of the studied PGM are subhedral to anhedral and from about 10μm to 2-3mm in size. Os-dominant minerals are most abundant varieties associated with Fe-bearing platinum which also occur as homogeneous and separate grains. Some grains have euhedral shapes and others have round shapes, suggestive of melt droplets. Most of these grains consist mainly of Pt (62.33-81.85 at%) and Fe (11.96-24.73 at%) accompanied by varying amounts of other PGE such as Pd (0.30-19.49 at%), Rh (1.44-4.38 at%), Ir (0.27-6.18 at%) and Os (0.10-2.19at%). Os-rich (Os-Ir-Pt) alloys (56.65-87.18 at% Os) are intergrown with Fe-bearing platinum and contain Ir (13.37-27.69 at%), Pt (2.36-20.04 at%), Ru (1.64-2.84 at%) and Rh (0.39-1.12at%). Os:Ir ratios are most commonly approximately between 5:1 and 2:1 with two compositions with empirical formulas $Os_{0.57}Ir_{0.16}Pt_{0.20}Fe_{0.03}Ru_{0.02}Rh_{0.01}$ and $Os_{0.62}Ir_{0.17}Pt_{0.15}Fe_{0.03}Ru_{0.02}Rh_{0.01}$ plotted in the field of the given immiscibility gap [3,5].

Os and Pt dominant alloys represent the main magmatic trend. The close association of the Pt-Fe alloys and Os-dominant alloys suggests a common origin. Next, abundant and characteristic for Novosetsi placers is the sulphide trend with exsolution of laurite, erlichmanite, braggite, vysotskite, hollingworthite, vasilite, indicating for rise of fS_2 with increasing role of Pd, Ni, Cu and As in addition to Se and Te with decreasing temperature. The Pt x 100/(Pt+Ir+Os) ratio [4] seems to be extremely high (>98) supporting the conclusion that possible source for the PGM are relics of non-ophiolitic pyroxene bearing hidden, or eroded mafic intrusions affected by post magmatic alterations.

First report of Platinum Group Minerals in garnet peridotites from the Central Vosges, France

Delangle, C.[1], Ohnenstetter, M.[1,2*], Ohnenstetter, D.[1,2] & Grémillet, J.P.[1]
[1]Centre de Géologie Terrae Genesis, Saint Amé, France
[2]C.R.P.G.-C.N.R.S. Nancy-Université, Vandoeuvre-lès-Nancy, France ([*]mohnen@crpg.cnrs-nancy.fr)

Platinum Group Minerals (PGM) are described for the first time in garnet peridotites from the Moldanubian zone of the Central Vosges. Garnet peridotites occur as lenses of variable size (length up to 1 km) in the uppermost leptynitic granulite unit [1,2]. During their rapid ascent towards the upper crust, garnet peridotites evolved from high pressure >4.9 GPa and T >1100°C, towards lower pressure conditions 1.6-2 GPa and 700-800°C [3], bedore final emplacement against crustal granulites [4]. PGM have been found in garnet dunite and garnet pyroxene-poor lherzolite samples from the Blanchefontaine and Malpoirier bodies, respectively. PGM are of very small size, less than µm. Some of them were analyzed using an EDS coupled with a Hitachi SEM.

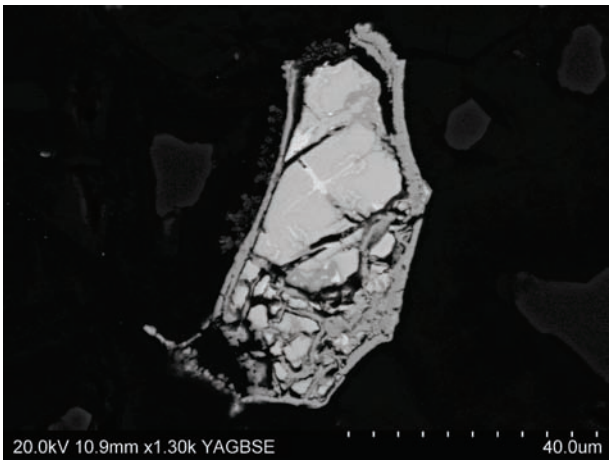

Fig. 1: Sperrylite (inside the circle) within a Co-rich pentlandite partly transformed into hematite (scale bar 40 µm).

Sperrylite ($PtAs_2$), genkinite $(Pt,Pd)_4Sb_3$, kotulskite $Pd(Te,Bi)_2$, zvyagintsevite Pd_3Pb, and pasavaite $Pd_3Pb_2Te_2$ have been found as well as a Pt-bearing aurostibite $AuSb_2$. PGM are often associated with Co-bearing pentlandite (see Fig. 1) and less commonly with pyrrhotite and millerite.

The presence of tellurides, antimonides and intermetallic compounds reflects hydrothermal low temperature formation conditions [5] possibly related to late-stage serpentinization. It is suggested that high temperature sulphide solid solutions and some PGM such as sperrylite, would have been deposited during melt percolation in an ascending garnet peridotite sub-continental mantle slice. This process is comparable to what is recorded in some oceanic and ophiolitic mantle diapirs [6] and documents a new case of platinum-group element resetting.

A self-aggregation of platinum group minerals from clusters

Distler, V.V.[*] & Yudovskaya, M.A.
IGEM RAS, Moscow, Russia ([*]distler@igem.ru)

The surfaces of crystals of isoferroplatinum, Os-Ir-Ru alloy and other noble-metal bearing minerals recovered from active volcanic fumaroles have been analyzed and found to contain distinctive, nano-sized features. The nano-block “parquet”-type structure was first observed using atomic force microscopy (AFM) on the facet surface of crystals of isoferroplatinum (Fig.1). The surface is characterised by a structure that is based on the regular combination of square-shaped (for isoferroplatinum) or rhomb-shaped blocks (for Os-Ir-Ru alloy) The different scales and self-similar character of the nano-block integration were estimated using conventional Fourier- and wavelet transforms. This specific type of scalable structure, comprising a regular combination of nano-blocks (or parquets) of different sizes, can be considered as a quasi-crystalline structure. The smallest elements of the structure were estimated to be a few tens of nm.

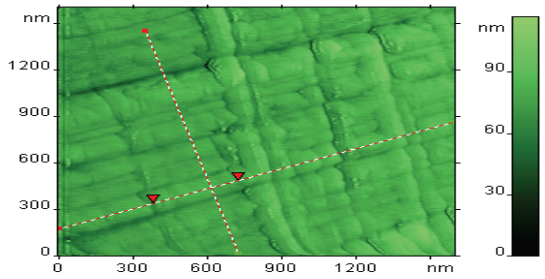

Fig. 1: AFM-image of the surface of isoferroplatinum which reveals parquet-type pattern.

A possibility of the nano-phase self-aggregation was also observed in the sublimates of gaseous fluids in the fumarole fields of the Kudryavy volcano, the Iturup Island, Kuril islands. Nano-sized particles of native Pt, $Pt(OH)_2$ and platinum-chloro-phosphoro-hydrocarbon compound $PtCl_2[P(C_4H_9)_3]_2$ in an assemblage of various rare- and noble-metal phases were identified using an XPS.

New additional evidence of a naturally occurring periodic structure was recently obtained for natural alloy Khatyrskite $(Cu,Zn)Al_2$ that confirm that quasicrystals can form and remain stable under geologic conditions [1]. It was also experimentally shown using in situ transmission electron microscopy that a growth of platinum nanocrystals can occur not only by monomer attachment but also by particle coalescence or self-aggregation [2].

The given data confirm the existence of such periodic structures as quasicrystals in nature. Their structure is characterised by rotational symmetry and fractal ordering although the absence of a translation mechanism. The formation of similar fractal structures in nature appears to relate to specific disequilibrium conditions involving steep temperature or chemical gradients that lead to formation of great number of compounds with various structures. Such processes can be a result of heterogeneous gas-transport reactions of gas - solid and gas - liquid - solid under disequilibrium conditions. One of the most important features of the gas-transport reactions is that they provide formation of zero-valent metal state without achieving high-reduced conditions of mineralisation.

[1] Bindi, L. et al. (2009) *Science*, **324**, 1306-1309. [2] Zheng, H. et al. (2009) *Science*, **324**, 1309-1312.

Platinum Group Minerals of Ranomena chromitite, Tamatave district, Madagascar

Grieco, G., Merlini, A.*, Cazzaniga, A. & Moroni, M.
Dept. of Earth Science, University of Milan, Milan, Italy
(*anna.merlini@unimi.it)

Madagascar is rich in chromite deposits scattered through the Archean terranes. The main ore districts are, from North to South, Befandriana, Andriamena and Tamatave. Platinum Group Minerals (PGMs) were detected as inclusions in chromite grains as well as in the chromitite matrix in the Ranomena deposit, belonging to the Tamatave chromite district. The Ranomena deposit is characterised by a series of highly deformed and metamorphosed, subparallel metric chromitite lenses, hosted within basic-ultrabasic rocks. Chromitite is characterized by variable textures from disseminated to massive.

The chromitite mineral assemblage is mainly composed of low Cr_2O_3 chromite (with compositional variation up to ferritchromite and magnetite), orthopyroxene, olivine and secondary phases like chlorite, amphibole, talc and serpentine. Rutile and ilmenite as well as minor sulphides, like chalcopyrite, pentlandite and hazlewoodite, occur in the matrix.

Several small (10-30 µm) PGM grains were observed in almost all samples, regardless of the chromitite texture.

The most abundant phase is euhedral laurite (RuS_2) included in chromite grains. X-ray atomic maps confirmed the polyphase nature of very fine-grained PGM aggregates, in which at least the occurrence of irarsite ((Ir, Ru, Rh, Pt,)AsS) and stillwaterite (Pd_8As_3) was ascertained by micro-analysis. Some alloys containing Pt, Ru, Fe and traces of As were also detected within the matrix.

Platinum Group Elements (PGEs) were analysed on whole rock samples by Nickel Suphide Fire Assay- Instrumental Neutron Activation Analysis (INAA). All analysed samples show similar trends characterized by a general depletion in Pt, Pd and a high Os/Ir ratio. The general PGE trends are in accordance with the occurrence and the composition of PGMs detected, therefore suggesting that they are representative of the chromitite PGM assemblage.

According to the model proposed by Maier and Barnes [1] for the UG1-UG2 Bushveld chromitites, the PGE geochemical signatures (except for Pd) suggest a Bushveld-type genesis for the Ranomena Cr-PGE ores. The low abundance of Pd in Ranomena ores might be related to post-ore metasomatic processes.

The relationships between the Ranomena chromitite and the other main chromitite ores of Madagascar are still unclear. Chromitite ores display significant compositional differences, in spite of their similar geological settings. These differences might be related either to different depositional processes that influenced also the distribution of PGMs (less abundant in the Andriamena and Befandriana chromitites than in Ranomena), or to different post-ore processes (e.g., metamorphic imprints).

In-situ, MLA-based mineralogical assessment of Platinum Group Minerals associated with chromitite stringers in the Merensky Reef of the Eastern Bushveld Complex, South Africa

Rose, D.H.*, Knoper, M.K, Rajesh, H.M. & Viljoen, K.S.
Dept. of Geology, University of Johannesburg, South Africa
(*derekr@postgrad.uj.ac.za)

Although primarily optimised for the examination of mineral concentrates (e.g. platinum group minerals, PGM), modern, automated electron microscope-based image analysers such as FEI's Mineral Liberation Analyser (MLA) has proven to be useful in mineralogical studies at the thin section scale [1]. In view of this, a study to assess the nature and abundances of PGM's occurring within the Merensky Reef was undertaken at the Two Rivers Platinum Mine on the Eastern Limb of the Bushveld Complex in South Africa. The application of the Field Emission MLA at the University of Johannesburg allows for rapid data acquisition, while the examination of thin sections ensures that mineral association information is preserved. A primary aim of the study is to identify the PGM phases present in chromitite stringers within the Merensky Reef at Two Rivers, and also to determine the nature of associated phases, in a statistically representative manner. As is typical for the Merensky [2], three primary mineral associations are observed, being (i) PGM-base metal sulphide (BMS), (ii) PGM-silicate, and (iii) PGM-chromite.

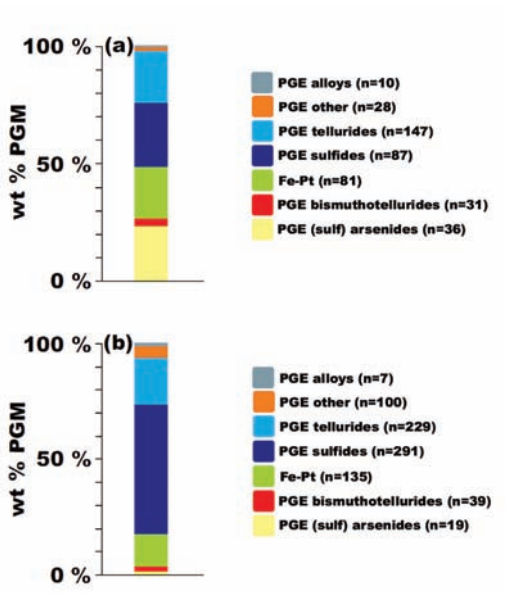

Fig. 1: Histograms illustrating the variation in PGM abundance (wt%) for samples from (a) Upper and (b) Lower chromitite stringers in the Merensky Reef at Two Rivers. n = grain counts of the PGM.

Zonation of the PGM assemblages associated with the chromitite stringers is observed (Fig. 1). Chromitite stringers that occur in the uppermost reaches of the Merensky Reef are associated predominantly with ferroplatinum, PGE sulfarsenides, sulfides and tellurides, all of which occur in similar proportions. These PGM assemblages are also observed in samples of basal chromitites The PGE sulfarsenides however now form a negligible group relative to that of the same group in the chromitites of the uppermost reaches. PGE sulfides are also dominant in the basal chromitite stringers

Associations and genesis of Pd, Pt, Au, Ag, Co, Cu, Ni, Fe in magmatic sulphide ores in Pay-Khoy (Russia, Nenets Autonomous District)

Shaybekov, R.
Institute of Geology, Komi Scientific Center, Uralian Branch, Russian Academy of Sciences, Syktyvkar, Russia, Republic of Komi (shaybekov@geo.komisc.ru)

The work presents new data on the composition, associations and genesis of sulphide minerals and minerals of platinum group (MPG) in copper-nickel shows in the Central Pay-Khoy (370±2.0 – 381.4±2.0 Ma). By now a wide areal distribution of differentiated intrusions of basic composition is determined in the Central Pay-Khoy, where sulphide copper-nickel ores are found. The sulphide mineralization is spatially and genetically related to subintrusive bodies of dolerites, having a distinct stratigraphic distribution and being confined to the horizons of the most differentiated coarse-crystalline dolerites. In ore occurrences the primary Co, Cu, Ni, Fe associations and later are determined, which are formed by substitution of earlier ore associations. Fe – Ni – Co – Cu – sulphides are developed in intergranular space of plagioclase and pyroxene; less frequently they form accretions with late- and postmagmatic minerals.

As a rule, the sulphides are dominated by pyrrhotine, chalcopyrite, pentlandite, cobaltite. *Pyrrhotine*, predominating mineral of the given object, forms small buildups in rock forming minerals and shliers of different sizes. *Chalcopyrite*, the second sulphide by the level of distribution is found as separate xenomorphic grains of irregular form in distal parts of pyrrhotine shliers and inclusions or forming independent inclusions. One of the most important ore minerals and rather widely developed, *pentlandite* is observed as xenomorphic grains in distal parts of pyrrhotine shliers and inclusions, often at the boundaries of pyrrhotine and chalcopyrite. *Nickel cobaltite* is mineralogically the most interesting mineral, and found as independent angular and irregular white or grey grains. Often cobaltite formed along distal pyrrhotine, chalcopyrite, pentlandite grains.

The sulphide minerals are associated with native gold, silver, lead, cobalt, melonite, nagyagite, altaite-clausthalite minerals, tellurides, selenides. *Isomorphic altaite(PbTe)-clausthalite (PbSe)* is rather common, formed generally in edges and as small inclusions in pyrrhotine and nickel cobaltite, and represented by foliated scaly plates, rarer isometric grains. Among inclusions there is gold, silver, iron and sulphur. *Melonite* appears as impregnations and inclusions in interstitials and fractures of cobaltite. Among admixtures only iron is found. *Nagyagite* is formed in distal parts and fractures in pyrrhotine and represented by nano-size elongated and irregular white-grey grains. Light irregular nano-size grains of *native gold* are observed as impregnations and inclusions in the main bulk of nickel cobaltite. Admixtures are represented by silver (11,4–13,6%). *Native cobalt* is concentrated in fractures and main bulk of julukulite, as nano-size white filling forms. As cobald, *native lead* is concentrated in fractures and between crystals of nickel cobaltite as stannic white nano-size irregular grains, but it is relatively abundantly and product of later generation.

Pt-Pd minerals are found in association with magmatic sulphides and represented by kotulskite, sperrylite and vavrinite. Apart from intrinsic minerals, Pd and Pt are found as admixture in nickel cobaltite, pentlandite, chalcopyrite and arsenopyrite. The substitution of primary sulhide minerals and formation of complex submicron and nano-size accretions and substitutions of the sulphides by platinoids, silver and gold are resulted from several mineral-forming processes and definitely connected to fluid-hydrothermal processes and redistribution of minerals from primary sulphide to later associations. This resulted in a complex character of platinum element distribution and consequently their mineral associations.

An in-situ, MLA-based mineralogical investigation of the Akanani Platinum Group Metal Project, Bushveld Complex, South Africa

Van der Merwe, F.*, Viljoen, K.S. & Knoper, M.W.
Dept. of Geology, University of Johannesburg, South Africa (*fritsvdm@postgrad.uj.ac.za)

Modern mineral processing operations require detailed characterization of the ore for beneficiation purposes. In the past, mineralogical aspects of ore characterization (e.g. mineral liberation, particle size distributions, and mineral associations), critical to recovery grade, were typically performed utilising optical microscopy. With the more recent introduction of automated electron microscope-based instruments such as the Mineral Liberation Analyser, the speed and accuracy of these measurements have advanced to such a degree, that fully quantitative and statistically relevant data can now be acquired with ease [1]. The metallurgical extraction of platinum group elements (PGE) from the Platreef on the Northern Limb of the Bushveld Complex is complicated by the mineralogical variability of the ore. In spite of this, and, in comparison to the more established PGE sources of the Bushveld Complex (Merensky and UG2), the Platreef has recently experienced a phase of increased expansion of exploration and mining activity e.g. the establishment of a mining operation by Anglo Platinum [2]. To date, very little data on platinum group mineral (PGM) assemblages, size frequency distributions and associated mineral phases are available for the Platreef [2,3]. Two drill cores through the main mineralized zone of the Platreef at Lonmin's Akanani project (adjacent to, and down-dip from, Anglo Platinum's Sandsloot and Zwartfontein mines) were selected for detailed mineralogical study of PGM's, utilising a FEI 600F Mineral Liberation Analyser at the University of Johannesburg. A variety of PGM's were encountered (Table 1).

Table 1: List of Major PGM's and associated phases present

Mineral Name	General Formula	Area%
Maslovite	PtBiTe	27.63
Michenerite,	PdBiTe,	14.17
Kotulskite	Pd(Te,Bi)	
Isoferroplatinum	Pt_3Fe	10.84
Hessite, Empressite	Ag_2Te, AgTe	8.23
Sperrylite	$PtAs_2$	7.99
Altaite	PbTe	6.27
Cooperite	PtS	5.28
Plumbopalladinite	Pd_3Pb_2	4.60
Electrum	AuAg	4.26
Platarsite	(Pt,Rh,Ru)AsS	2.71
Maslovite	(Pt,Pd)(Bi,Te)	1.49
Hollingworthite	(Rh,Pt)AsS	1.11
Other PGM's (<1%)	-	5.38

Mineral phases co-existing with these PGM's comprise predominantly of pentlandite, chalcopyrite, pyrrhotite, magnetite, and pyroxene. Mineral association data obtained prove the existence of both primary and secondary PGE mineralization within the Platreef. Hydrous silicate phases and their association with PGM's correspond to the degree of alteration present, being variable.

The samples that the information was derived from are at this stage not considered representative of the entire Akanani Mineral Resource. However, the data may be used to derive some preliminary qualitative conclusions. The ultimate aim of the project is to better understand the mineralogy, mineralogical associations, and genesis of the various PGM's at Akanani. This will eventually assist in optimising recovery of PGE's from the Platreef.

Synthetic analogue of naturally occurring 'Pt_2HgSe_3'

Vymazalová, A.[1], Cabral, A.R.[2,3*], Drábek, M.[1] & Lehmann, B.[3]

[1]Czech Geological Survey, Prague, Czech Republic

[2]Exploration Geology, Rhodes University, Grahamstown, South Africa ([*]a.cabral@ru.ac.za)

[3]Lagerstätten und Rohstoffe, Technische Universität Clausthal, Germany

A naturally occurring selenide of platinum and mercury was recently described from auriferous, specular haematite-rich veins that truncate the host itabirite rock at Itabira, Minas Gerais, Brazil [1]. The selenide is about 50 μm across and coexists with haematite, auriferous potarite and atheneite. Its empirical composition, determined by electron-microprobe analysis, corresponds to Pt_2HgSe_3. A selenide mineral with such a stoichiometry is unknown in both natural and synthetic systems.

In an attempt to properly characterise the selenide phase, experimental work was carried out at the Experimental Laboratory of the Czech Geological Survey. The synthetic Pt_2HgSe_3 phase was prepared following the Kullerud's evacuated silica-glass tube method [2]. The phase was synthesised using pure elements (Pt, Hg and Se) as starting material. The silica tube with the charge was heated at 800°C for 840 hours and at 400°C for 1704 hours. The experimental result of the quench at both temperatures, 800 and 400°C, is identical. The strongest lines in the X-ray powder diffraction pattern of synthetic Pt_2HgSe_3 are [*d* in Å (I)]: 6.1416(57), 5.2885(100), 5.0779(13), 4.0625(14), 2.7241(67), 2.6452(15), 2.4416(37), 2.0326(73), 1.8357(29), 1.7631(90), 1.6993(23), 1.5901(19), 1.5424(35), 1.5224(16), 1.3632(19), 1.3235(51), 1.2964(16.7), 1.2729(26). This diffraction pattern is unique, suggesting that the natural phase is a potential new mineral species.

Further investigation to resolve the crystal structure, as well as other physical and chemical characteristics of the synthetic phase is currently underway. The experimental study has hitherto confirmed the existence of the phase Pt_2HgSe_3 at 400 and 800°C.

A tale of two elements - the Gamsberg Zn study illustrating the importance of a geometallurgical approach

Schouwstra, R.P.[1*] & De Vaux, D.[2]
[1]Mineralogical Research, Anglo Research, Johannesburg, South Africa ([*]rschouwstra@angloresearch.com)
[2]Metallurgical Services, Anglo Research, Johannesburg, South Africa

The study of exploration samples and process feeds and products using metallurgical test work is practised by many mining companies. This happens either in-house, or is outsourced to service providers. Although, historically, mineralogical information has been used to supplement metallurgical test work on an infrequent basis, the growth in automated mineralogical techniques over the last 10 to 15 years has contributed to increased utilisation of mineralogical data in this important area of research.

The combination and interaction of the disciplines of geology and metallurgy (geometallurgy) leans heavily on mineralogy, but few mining houses have access to in-house mineralogical facilities. Therefore, with the work being outsourced, the necessary integration of metallurgical and mineralogical data can become quite problematic.

Without a thorough understanding of the metallurgical processes and final product requirements, it will be difficult for the mineralogist to establish data needs. For this reason the mineralogist might provide irrelevant or inappropriate information, or worse, withhold relevant information without realising its importance. Similarly, if the project metallurgist is not aware of the type of information that mineralogy can provide, the interpretation of test work could be flawed. Information such as the variation in mineral compositions (including penalty element deportment), the impact of grind size on liberation, and the reason for the deportment of minerals to certain streams can be decisive. In the worst case scenario incorrect interpretation could lead to incorrect decisions being made.

It is only by utilising a variety of techniques and integrating the knowledge of the various disciplines that geometallurgy becomes a powerful instrument. To demonstrate this, the presentation will focus on a study of a Zn-ore. A team consisting of mineralogists and metallurgists made use of in-house mineralogical as well as metallurgical techniques to study the relationship between the mineralogy and the floatability of the ore from various reef intersections.

Quantitative mineralogy of the nonsulphide zinc ores at Jabali (Yemen) using the Rietveld method

Mondillo, N.[1*], Boni, M.[1], Balassone, G.[1], Grist, B.[2] & Woollett, A.[2]
[1]Dipto. di Scienze della Terra, Università di Napoli, Naples, Italy ([*]aktort@tin.it)
[2]ZincOx Resources plc, Surrey, UK

The Jabali deposit (ZincOx Resources - Jabal Salab Ltd), which is located 110 km northeast of Sana'a, the capital city of Yemen (http://www.zincox.com/projects/jabali.asp), contains a resource of 12.6 million tonnes of oxide ore grading 8.9% zinc, 1.2% lead and 68g/t silver, with potential to further increases.

The zinc-lead ores are hosted in dolomitized limestones of Jurassic age, which were later partly de-dolomitized [1]. They occur as massive and disseminated orebodies, characterized by vuggy to highly porous, brown to orange and white Zn-"oxide" minerals with variable reddish-black Fe-Mn staining. The ore will be treated by means of a proprietary hydrometallurgical process (LTC), test work on which has indicated an 80 % zinc recovery so far. A complete mineralogical study of a number of mineralized core samples, selected as representative of the Jabali ore, coupled with a quantitative evaluation of the different mineralogical phases, has been carried out recently.

Through petrographic characterization, X-ray diffractometry and SEM-EDS analysis, it was possible to identify at Jabali the most important nonsulphide ore and gangue minerals. Quantitative phase analysis (QPA) was performed using the Rietveld method [2]; X-ray powder diffraction data were analyzed using the GSAS package (General Structure Analysis System) [3] and its graphical interface EXPGUI [4].

The most abundant Zn-mineral in the Jabali cores is the Zn carbonate smithsonite ($ZnCO_3$), which is generally ranging from few units to 20 wt. % in average, with a maximum abundance of about 80 wt. %. No hydrozincite was detected in the core samples; Zn-smectite is rare. Cerussite, anglesite and pyromorphite have been recorded locally. A resource evaluation based on the overall mineralogical composition of the drill cores, inferred by quantitative X-ray diffraction of the key economic minerals in the Jabali deposit, shows that the results are only partly consistent with the metal grades derived from the chemical assays. In respect to the latter, both lower and higher Zn wt.% have been calculated. This difference between the assayed and calculated zinc amounts in the drill cores can be related to the presence of several dolomite phases with variable Zn content (up to 20% Zn in the lattice), as well as to the local occurrence of Mg-smithsonite (up to 12% Mg in the lattice), as detected from the SEM-EDS analyses.

It is still extremely difficult to define with quantitative diffractometric methods, the zinc contained in several dolomite phases with variable contents of this metal; nevertheless, the occurrence of this "concealed", hardly recoverable zinc should be taken into account when evaluating the assay data. The work carried out has successfully confirmed why the projected recovery for the Jabali deposit, based on earlier metallurgical testwork, is constrained to around 80%.

Novel mineralogical quantitative phase analysis methodology applied to Canadian oil sands for ore characterization, processability prediction, and optimization of froth treatment technologies

Mercier, P.H.J.[1*], Patarachao, B.[1], Kung, J.[1], Dongbao, F.[1], Kingston, D.M.[1], Le Page, Y.[1], Sparks, B.D.[2], Kotlyar, L.S.[1], Woods, J.R.[1], Toll, F.[1], McCracken, T.[1], Ng, S.[3] & Kresta,J.[3]
[1]National Research Council of Canada, Ottawa, Ontario, Canada ([*]patrick.mercier@nrc-cnrc.gc.ca)
[2]V. Bede Technical Associates, Ottawa, Ontario, Canada
[3]Syncrude Canada Ltd., Edmonton, Alberta, Canada

Recent papers [1,2] underscore the key role played by relatively minor amounts of clay minerals and clay-organic complexes in the hydrocarbon recovery and environmental problems associated with the exploitation of the Alberta oil sands of Canada [3,4]. This bitumen deposit is the largest in the world and is second only to Saudi Arabia in proven oil reserves. In a talk abundantly illustrated with examples, we detail here a novel methodology merging weighted experimental results from X-ray fluorescence (XRF) spectrometry, carbon and sulphur analyses, and X-ray diffraction (XRD) powder profiles in a single least-squares refinement, leading to a complete phase analysis of solid fractions in the soils, including crystalline, amorphous and organic phases. Particular attention is given to standard uncertainties (*s.u.*) through use of singular-value decomposition (SVD) of the normal matrix. This allows objective identification of the source of singularities and quasi singularities [5] that cause large *s.u.* values unless properly accounted for in the statement of the solution.

To determine precisely the mineralogical composition of oil sands ore and input/output streams from bitumen extraction processes, a novel quantitative phase analysis methodology parameterized with SVD-based least-squares refinement was developed. An over-determined linear system of weighted observations $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ is first built by combining experimental results from (i) metal concentrations by XRF, (ii) carbon and sulphur contents by standard elemental analysis techniques, and (iii) mineral mass ratios determined by Rietveld analysis of XRD powder patterns. The mineralogical composition of the analyzed sample is then obtained directly as the least-squares solution $\mathbf{x} = \mathbf{C}^{-1} \cdot \mathbf{A}^{\mathbf{T}} \cdot \mathbf{b}$, where $\mathbf{C} = \mathbf{A}^{\mathbf{T}} \cdot \mathbf{A}$ is the matrix of normal equations and the elements of $\mathbf{x}$ (x_i) are the mass fractions of each individual mineral phase comprised in the sample. Non-uniqueness problems associated with linear combinations of variables x_i giving rise to identical overall sample composition are unambiguously identified as described elsewhere [5] by performing the SVD of matrix **C**.

The practical examples detailed in the presentation involve the application of this novel methodology to characterize two different sets of oil sands materials. First, key correlations are identified between bitumen recovery and mineralogical compositions for a set of ten oil sands in which currently used processability markers such as bitumen and fines (<44μm solids) contents show no correspondence with recovery rates. Second, it is shown how the evolution of mineralogical compositions, precisely determined with our novel methodology, can be useful in process design and optimization of bituminous froth treatment technologies to analyze the effect that different processing conditions can have on bitumen product quality.

A comparative study of quantitative methods in ore microscopy: digital image analysis *vs.* point counter device

Pérez-Barnuevo, L.[*], Castroviejo, R. & Espí, J.A.
School of Mines, Universidad Politécnica de Madrid, Spain ([*]laura.perez.barnuevo@upm.es)

Quantitative mineralogical analyses of metallic concentrates from an ore-processing plant with reflected light microscopy have been carried out independently, on the same samples, by an expert mineralogist using a point counter device (**PCD**), and by digital image analysis (**DIA**) operated by a post-graduate student in order to compare the performance and results obtained with both methods [1].

The results obtained by both methods (Table 1) are broadly similar [2] and differences do not exceed the expected margin of error inherent to the statistical significance of the samples studied [3]. But there are major differences when comparing the performance of both methods. While at best some 3000 particles per hour can be registered with PCD, it is possible with DIA to process 100000 particles per hour, extracting data not only about volumetric fractions, but also about morphological parameters of every mineral grain. This difference is enhanced if the work conditions are considered. While a human operator may work with PCD some 6 h a day, if risk factors as fatigue are to be avoided, DIA systems can work 24 h a day. Moreover, PCD should be handled by an expert ore microscopist, but there is at present a trend to reduce this training at universities, thus leading to a gradual disappearance of this type of experts. DIA does not need such a high grade of expertise, even if some sort of supervision is needed [4].

Table 1: Modal analysis by PCD vs. DIA

	Mo	SFsCu	Py	Ccp
PCD (%)	69	13	8	10
DIA (%)	62	14	11	13

Pay-back for both methods has been calculated based on data shown on Table 2 and considering the number of samples that it is possible to analyze by means of each method. Although initial investment for DIA is more than twice the investment for PCD, pay-back is just one year for DIA, while the return of investment increases to three years for PCD.

Table 2: Pay-back comparison for PCD vs. DIA

	Equipment Cost	Labour (annual)	Income/ sample	Pay-back
PCD	30 000 $	50 000 $	150 $	**3 years**
DIA	70 000 $	30 000 $	150 $	**1 year**

To conclude, DIA coupled to reflected light microscopy is a powerful and cost-efficient tool to support ore-processing with varied quantitative mineralogical data, as modal analysis, morphological characterization of mineral particles, and mineral liberation analysis. DIA can provide more complete, reliable and efficient mineral characterizations than the traditional methods as PCD, which are less performing and do not preclude human error, e.g. by fatigue. It is also by far more economical than the methods based on SEM images, while providing comparable results. DIA can satisfy the demands of geometallurgy with low investment and maintenance costs.

Minor element distribution and partitioning in bornite and associated Cu-sulphides

Cook, N.J.[1,2*], Ciobanu, C.L.[1,2], Danyushevsky, L.V.[3] & Gilbert, S.[3]
[1]University of Adelaide, Australia
([*]nigel.cook@adelaide.edu.au)
[2]South Australian Museum, Adelaide, Australia
[3]CODES, University of Tasmania, Australia

Bornite (Cu_5FeS_4) is a major Cu-mineral in high-sulphidation epithermal deposits, sedimentary-hosted Cu-deposits, Cu- and polymetallic skarns, parts of porphyry-Cu and VMS deposits, and in iron oxide-copper-gold (IOCG) systems. The Cu-rich corner of the system Cu-Fe-S is complex, featuring many low-T phases. This complexity is reflected by the presence of fine intergrowths and varying textures.

We provide a baseline dataset on minor element contents in bornite and accompanying Cu-sulphides using *in situ* LA-ICP-MS methods; 22 samples from 12 deposits were analysed. 122 spot analyses of bornite, and 42 of chalcocite/digenite (40-80 μm diameter) were made using an Agilent 7700 Quadripole ICPMS instrument; 28 elements were monitored. Samples are (i) from 5 vein-type deposits in the Late Proterozoic Sveconorwegian province of Scandinavia and (ii) bornite-bearing samples from skarns, porphyry and epithermal deposits from the Late Cretaceous Banatitic Magmatic and Metallogenetic Belt, SE Europe. One bornite sample from the Olympic Dam IOCG deposit, Australia, was analysed for comparison.

Although the samples are from different deposit types and provinces, the resulting dataset shows common trends:

(1) Silver and Bi have the highest measured values among analysed elements; all bornites contain hundreds or thousands ppm Bi (up to 1 wt.%) and mean Ag concentrations from 71 to ~8000 ppm. Both elements mimic the behaviour of Cu in the time-resolved downhole profiles, regardless of whether Ag- or Bi-minerals are present in the sample, suggesting both elements reside in solid solution. Data for samples where both bornite and Cu-sulphides coexist shows partitioning between bornite and Cu-sulphides: Ag is preferentially partitioned into Cu-sulphides whereas Bi is partitioned into bornite. Highest Ag concentrations in bornite are from a sample in which chalcocite is conspicuously absent.

(2) Bornite from deposits characterized by an abundance of selenides and tellurides show enrichment in Se (up to >2,000 ppm) and Te (up to >400 ppm). These elements also mimic Cu in the profiles, suggesting residence in a solid solution.

(3) Concentrations of Co, Ni, Ga, Ge and Cd in bornite are low; Zn, Mo, Sb and U are at or below minimum detection limits (<1 ppm). Considering large signal variations in the time-resolved LA-ICPMS downhole profiles, a few anomalous concentrations of Co, Ni, Pb, Sn and As relate to μm- and sub-μm-scale inclusions rather than solid solution.

(4) Measured Au values in bornite are low (rarely >0.1 ppm). Although individual spots from some samples gave values up to 6 ppm, large signal variations in the time-resolved profiles suggest these concentrations relate to sub-μm inclusions. The aforementioned partitioning trend extends to Au: values in digenite may be an order of magnitude higher than coexisting bornite and when the proportion of digenite to bornite is low, values can go up to 24 ppm. We believe that Au is partitioned preferentially into the Cu-sulphide(s) during cooling.

The Elura Pb – Zn – Ag deposit, central NSW, Australia: ore characterisation and geo-metallurgy, preliminary results

Loidl, G.C[1*], Plimer, I.R.[1] & Thalhammer, O.A.R[1,2]
[1]School of Earth and Environmental Sciences, Dept. of Geology and Geophysics, University of Adelaide, Australia
([*]gernot.loidl@adelaide.edu.au)
[2]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria

The Elura lead-zinc-silver deposit, with an estimated total pre-mined resource of 45Mt at 8.5% Zn, 5.3% Pb and 69g/t Ag, is located in central NSW, approximately 800km west of Sydney, Australia. The orebody is of epigenetic nature, sediment-hosted and strongly structural controlled. Sulphides comprise sphalerite, galena, pyrrhotite, pyrite, chalcopyrite, arsenopyrite and argentian tetrahedrite, quartz, siderite, subordinate calcite and ankerite, with varying quantities of sericite and chlorite as the major gangue minerals. The host rock is a turbiditic sequence, characterised by interbedded sand-, mud- and siltstone layers. The first mining activities commenced in 1983. The deposit, now known as Endeavor, is currently exploited by CBH Resources Ltd. Despite (a) the long and continues mining history, (b) the frequent and significant fluctuations of Zn and Pb ore to concentrate metal recovery rates, and (c) elevated Bi concentration in the lead concentrate, no comprehensive ore characterisation study has been undertaken in the past. In order to increase the knowledge and the understanding about geo-metallurgical characteristics, a detailed multi-disciplinary study covering mineralogy, mineral chemistry, ore textures and trace element distributions, in particular those of smelter penalty elements e.g. Bi, has been undertaken as part of a PhD project.

Trace elements were analysed by ALS (Australia), electron microprobe analyses (EMP) were conducted on a JEOL Superprobe JXA 8200 at the University of Leoben, particle mineral analyses (PMA) and field scans were conducted on a QEMSCAN® E430 by AMDEL (Adelaide).

Trace elements on whole rock samples revealed several significant concentration trends as a function of depth within the orebody. Bi and Se have rather low concentrations in the uppermost parts and significantly increasing with depth and reaching a maximum of 714ppm and 45ppm, respectively. A converse trend has been observed for Hg and Sb, which reach maxima in the uppermost zones of the ore body. The observed maximum values are over 2000ppm for Sb and 66ppm for Hg. As concentrations are highly variable, ranging between 10ppm and 1.5wt%. EMP analyses of galena showed elevated Bi concentrations with maximum values between 0.1 and 0.7wt%. Element mapping suggests that Bi is occurring in solid-solution rather than as discrete Bi mineral phases intergrown with galena. Elevated Hg concentrations are observed in pyrite, pyrrhotite, sphalerite and chalcopyrite. The increase of Sb corresponds with the occurrence of argentian tetrahedrite in the uppermost zones of the orebody.

QEMSCAN® analyses are being processed by the author; preliminary results will be presented at the conference. Particle mineral analysis on particle separates mounted on polished blocks were undertaken in order to investigate mineral liberation, mineral associations and mineral specific surface exposure for all major sulphide phases. Field scans on polished thin-sections were used to study textural ore characteristics such as grain size distributions, intergrowths, inclusions and exsolutions. Both data sets will help to identify host mineral phases for smelter penalty elements not identified in the course of microscopic and EMP investigations.

The geometallurgical characterization of different Merensky Reef facies in the western limb of the Bushveld Complex, South Africa

Smith, A.J.B.[1*], Viljoen, K.S.[1], Schouwstra, R.[2], Roberts, J.[2], Schalkwyk, C.[2] & Gutzmer, J.[1,3]
[1]Dept. of Geology, University of Johannesburg, South Africa ([*]bertuss@uj.ac.za)
[2]Mineralogical Services, AngloResearch, Johannesburg, South Africa
[3]Dept. of Mineralogy, Technische Universität Bergakademie Freiberg, Germany

The Merensky Reef is a major platinum group element (PGE) bearing unit in the Bushveld Complex of South Africa [1] and is laterally continuous throughout most of the western and eastern limbs [2]. Variations in platinum group mineral (PGM) content [2] and lithostratigraphy [3] of the reef do however occur across the complex. Lithostratigraphic variations include the width of the pegmatoidal feldspathic pyroxenite (PFP) which constitutes the reef, development of chromitite stringers and incidence of potholing which results in reef development at several different stratigraphic positions. These lithostratigraphic variations have been used by mining houses to classify the Merensky Reef into many different geological reef facies types [3].

The genetic impact of the lithostratigraphic controls on the mineralogical characteristics of the PGM is poorly understood and can have an important bearing on the milling, liberation and flotation response of the reef. Geometallurgical characterization of the different Merensky Reef facies in a mining area provides valuable insight into these potential problems. This approach aims to 1) quantify the lateral and vertical distribution of PGMs in each facies type; 2) establish the flotation behaviour of each facies type in relation to the mineralogical characteristics of the milled flotation feed and 3) perform detailed petrographic and geochemical studies on each reef facies type to establish trends and correlations with the mineralogical and metallurgical data. Apart from some traditional optical microscopy, this approach makes liberal and extensive use of recent advances in automated scanning electron microscope technologies [4] to quantify the mineralogy of coarsely crushed as well as milled fractions.

Preliminary results from a study of potholed Merensky Reef from the western limb of the Bushveld Complex show that the top of the mineralised envelope is rich in PGE-sulphide whereas the bottom portion has a high PGE-telluride, iron-platinum-alloy and olivine content. The PGMs show a strong association with base metal sulphides. Most of the olivine is altered to serpentine.

Geometallurgy of the northern Kalahari manganese deposit, with respect to smelting operations

Chetty, D.[1,2*] & Gutzmer, J.[2,3]
[1]Mineralogy Division, Mintek, Randburg, South Africa ([*]deshc@mintek.co.za)
[2]Paleoproterozoic Mineralisation Research Group, Dept. of Geology, University of Johannesburg, South Africa
[3]Dept. of Mineralogy, TU Bergakademie Freiberg, Germany

The Kalahari Manganese Field is situated in the northern Cape Province of South Africa, and accounts for 80% of the world's Mn reserves. South Africa is the second largest producer of manganese alloys, with virtually all the feedstock derived from the KMF.

A study into mineral distribution in the northern part of the main deposit (Fig. 1) has revealed not only that mineralogy varies as a function of distance from faults that abound in the area [1], but that overall, mineralogical changes are evident from W to E across the deposit.

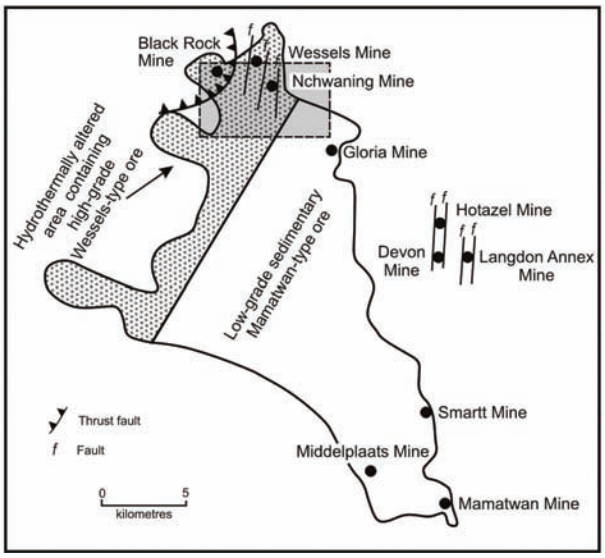

Fig. 1: Map of the KMF, showing the faults in the study area (rectangular block).

Changes in mineralogy as function of distance from the faults may be ascribed to non-redox reactions and the degree of fluid-rock interaction, such that high-grade alteration represents the highest influx of fluid, whereas lower degrees of fluid-rock interaction result in less pronounced alteration.

Modelling physico-chemical and structural controls allows prediction of mineral assemblage distribution. This is useful for selective mining, ore blending or changes to the smelting plant parameters, since mineral distribution is predicted to affect 1. energy input, 2. reductant input and 3. boron content in the smelter feed.

High alteration hausmannite-rich assemblages dominate the eastern part of the deposit, and should require increased energy input, result in lower reductant consumption and have low B levels. Lower alteration braunite-group-rich assemblages dominate the western part of the deposit, and should require lower energy input, result in higher reductant consumption, and contribute more B to the system, a concern in silicomanganese production.

Evaluation of nonsulphide zinc ores of Accha (Peru) using QEMSCAN automated mineralogy and Rietveld analysis

Stickland, R.J.[1], Rollinson, G.K.[1], Andersen, J.C.[1*], Balassone, G.[2] & Boni, M.[2]
[1]Camborne School of Mines, University of Exeter, Cornwall Campus, Penryn, UK ([*]J.C.Andersen@exeter.ac.uk)
[2]Dipto Scienze della Terra Università di Napoli, Naples, Italy

The mineralogy of supergene nonsulphide zinc ores from the Accha deposit (Peru) [1] was investigated using QEMSCAN analysis and quantitative X-ray diffraction (XRD) by the Rietveld method. The methodology was developed to gain a detailed insight into the mineralogical relationships of different lithotypes in the deposit. The QEMSCAN instrument is a Scanning Electron Microscope with automated energy dispersive X-ray spectrum collection, recognition and classification that allows for the rapid determination and quantification of mineral species and their spatial relationships.

The QEMSCAN study included the development of a Species Identification Protocol (SIP) to facilitate the automatic recognition of mineral species. The resulting SIP facilitates the detailed mapping of mineral distributions in the individual lithotypes within the Accha deposit. The method provides detailed mineralogical information, visualization and quantitative information on mineral abundances and associations. This information is essential to evaluate how the ore would respond to different mineral processing techniques. The mineralogical data obtained by QEMSCAN are in agreement with previous mineralogical studies, but provide increased knowledge of mineral quantities, associations, and accessory phases. The main limitation of the method is that minerals with closely matching X-ray spectra cannot be discriminated (for nonsulphide zinc ores this includes the mineral pairs hydrozincite/smithsonite and hemimorphite/willemite). These minerals need to be verified independently by XRD and/or optical microscopy.

The Rietveld methodology allows for calculated XRD profiles of individual minerals to be fitted to the measured profiles of multi-mineral mixtures by least-squares analysis. This allows for quantification of the mineral percentages in rock samples based on their crystal structure. XRD was used at Accha as a tool to evaluate the proportions of ore and gangue minerals. The quantitative evaluation was carried out with the Rietveld-based processing system (GSAS-EXPGUI) on the same samples analyzed by QEMSCAN. The Rietveld analysis confirmed smithsonite and hemimorphite at Accha rather than hydrozincite and willemite.

The spatial information collected by the QEMSCAN method provides valuable insight into the nature of the Accha ore. Although the bulk quantification of minerals is largely in agreement between the QEMSCAN and the quantitative XRD, there are variations between the results. These can be explained by short-range sampling variations. Where the QEMSCAN in this case measured a thin slice through the sample, the XRD collected information from a larger homogenized bulk. Disaggregation and homogenization of the sample for QEMSCAN would give a better compositional match but at the expense of the valuable mineral association information.

Characteristics, recovery and provenance of rutile from the Namakwa Sands heavy mineral deposit, South Africa

Rozendaal, A.[*], Philander, C. & Carelse, C.
Dept. of Earth Sciences, Stellenbosch University, Stellenbosch, South Africa ([*]ar@sun.ac.za)

The Namakwa Sands heavy mineral deposit is located along the West Coast of South Africa and the mine is a world class producer of high quality zircon ($ZrSiO_4$), ilmenite ($FeTiO_3$) and rutile (TiO_2) concentrates from essentially unconsolidated marine and aeolian sands of Cenozoic age. Resources are in excess of 650 million tons at a grade of approximately 10 per cent total heavy minerals with a life-of-mine of 30 years.

The objective of this study was to characterize rutile with respect to distribution, grain size, textures, colour and mineral chemistry within the Namakwa Sands Orebody with the aim to explain its overall poor recovery. A representative suite of heavy mineral concentrates from various sections of the ore body and stages in the recovery circuit has been investigated microscopically and by means of SEM-EDS and LA-ICP-MS. This allowed the study to establish the relationship between grain size distribution, mineral chemistry, density and sediment maturity for the Namakwa Sands placer deposit. The rutile grain size distribution displays a wide range and is directly related to its variable chemistry and consequently density. In placer deposits such as Namakwa Sands, mineral sorting is a function of hydraulic equivalence and high density grains are smaller than the lighter grains when deposited under similar conditions. Grain size is also a function of sediment maturity and the highly mature red aeolian sand (RAS) component of the deposit has a finer grain size than the less mature orange feldspathic marine sands (OFMS). The above primary characteristics of rutile are responsible for the loss of the fine-grained fraction during screening and given the empirically determined relationship that increased substitution elements reduce conductivity, also during electrostatic separation.

Provenans studies using geothermometry have shown that the heavy mineral suite has been mainly sourced by the proximal medium-to high-grade Namaqualand Metamorphic Complex. The positive relationship between substitution elements and temperature of formation explains their high concentration in rutile of this deposit.

The heterogeneity of rutile, produced by the combination of a high temperature primary source and the typical marine-aeolian placer genesis is deposit-specific and unfortunately not conducive to high recovery levels in the Namakwa Sands beneficiation circuit.

Mineralogical variability in a New Zealand ironsand deposit and its impact on ironmaking

Cocker, H.A.[1*], Mauk, J.L.[1], Rogers, H.[2] & Padya, A.B.[3]
[1]University of Auckland, Australia ([*]h.cocker@auckland.ac.nz)
[2]BlueScope Steel Ltd, Australia
[3]Waikato North Head Mine Site, New Zealand Steel Ltd, New Zealand

The Waikato North Head ironsand mine on the west coast of the North Island of New Zealand contains sub-horizontal stratigraphic layers of ironsand with an inferred resource of 620 Mt at 21 percent magnetic minerals. The ironsand was sourced from Neogene to Quaternary volcanoes, and transported by longshore drift, and then aeolian processes to form titanomagnetite-rich Quaternary sands. Ironsand is dry mined by bucket wheel excavators and wet processed by the mine-site concentrator using magnetic and gravity methods. The ironsand is not crushed at any stage. Ironsand concentrate is conveyed 18 km by slurry pipe–line to New Zealand Steel's integrated steel mill at Glenbrook

Titanomagnetite is the most abundant oxide in the ironsands. It predominantly occurs as homogeneous grains, but some grains contain exsolution lamellae of titanium bearing hematite-ilmenite and spinel. Inclusions of pyrite, apatite and other gangue minerals, occur locally. Gangue minerals consist of pyroxenes (diopside and hypersthenes), feldspars, hornblendes, quartz, and minor biotite. Gangue grains commonly occur with inclusions of titanomagnetite through to, composite titanomagnetite / gangue grains. The average concentration of gangue in the magnetic fraction of samples from the ironsand mine varies among the stratigraphic units (Table 1). The base of the most ore-rich unit, the Waiuku Black Sands, is the lower limit of open pit mining. Samples from mine faces show that there is significant vertical and lateral variability in the abundance of gangue in the magnetic fraction within individual stratigraphic units.

Table 1: Stratigraphy at the Waikato North Head deposit showing the average % gangue in the magnetic fraction; %Fe (mags) is the % Fe in the magnetic fraction, % Mags is the % magnetic minerals in a sample

Formation		Description	% Fe (mags)	% Mags	% Clay minerals	Average % gangue in the magnetic fraction samples	
10 ka to recent	Mitiwai Sands	Alder Sand	50.6	8.0	2.6	26.2	↑
		Entrican Sand	54.8	13.4	2.7	8.7	mined
200 ka to 10 ka	Hood Sands	Ash	58.4	16.6	16.2		
		Bothwell Sand Upper Hood Sand	58.8	19.7	8.7	4.0	
		Waiuku Black Sand	60.4	47.1	6.7	1.8	
		Lower Hood	56.6	12.7	9.2	8.4	
1.2 Ma to 200 ka	Awhitu Sands	River Sand					
		Awhitu Clay	57.9	7.7	18.4	16.6	not mined
		Awhitu Sand	58.2	4.6	11.5	29.0	
		Sandstone					↓

The New Zealand Steel ironmaking process involves the sequential processing of the ironsand concentrate through multi-hearth furnaces (mixing with sub-bituminous coal, drying and partial coal devolatilisation), SL/RN rotary reduction kilns (solid state ironsand reduction) and submerged arc melters (final reduction and melting). Formation of accretions in the multi-hearth furnaces and kilns occurs from time-to-time. Understanding the mineralogical and geochemical variability in the mined resource, the incorporation of gangue into the ironsand concentrate, and the transformations in the concentrate on high temperature processing are key elements in developing an understanding of accretion formation.

Green liquids - acid leaching of Ni-laterites

Hunter, H.M.A.[1*], Herrington, R.J.[1] & Oxley, A.[2]
[1]Mineralogy Dept., Natural History Museum, London, UK
([*]h.hunter@nhm.ac.uk)
[2]European Nickel, London, UK

European Nickel, a mid-tier mining company, has pioneered a low temperature acid leach extraction method for Ni-laterites which is being heralded as a breakthrough in environmentally conscious mining.

Our Industry-Academia collaborative research, based at the NHM in London, has been using EPMA and XRD techniques, coupled with mass balance calculations, to examine the leaching characteristics of various Ni-laterite ores, with a view to predicting their process efficiency using this extraction method. XRD confirms that the ore is dominated by nickeliferous goethite with quartz, relic serpentinite and minor calcite also present.

Small-scale experiments on the Turkish Çaldağ ore were carried out with material examined over various lengths of time. Typically 45ml of a 75gpl sulphuric acid solution was used to leach 1.0g of ore fragments, for between 2-72 days. These tubes were capped and placed on a rotating/shaking table at room temperature before being removed periodically and tested. The supernatant liquor was analysed by ICPAES, whilst the residual ore material was prepared as polished blocks for SEM and a powdered sample was examined by XRD and analysed by whole rock chemical methods.

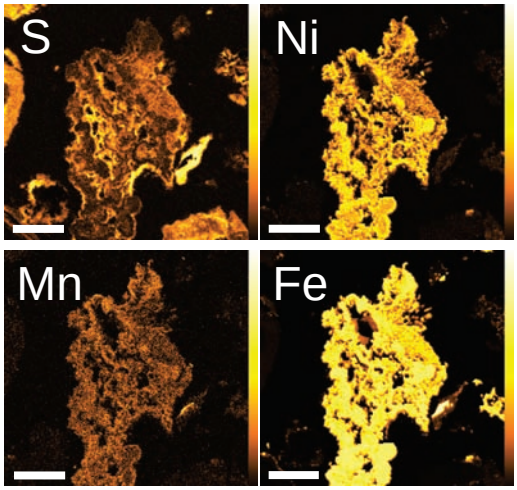

Fig. 1: X-ray element maps for a nickeliferous goethite grain exposed to 35 days of acid leaching (scale bar = 100μm).

The data have been analysed to investigate the chemical and mineralogical changes that occur during leaching. Figure 1 shows a sample of Çaldağ goethitic ore that was subjected to 35 days of acid leaching. Of note is the developed porosity and clear indication of sulphur penetration (Fig. 1, top left) into the ore fragment. Further experiments indicate that there is a staged dissolution of relic silicate and goethitic phases. These results have implications for the design of larger scale leach testing. The full results will be discussed in the presentation.

A fully automated system for multispectral ore microscopy

Castroviejo, R.[1*], Catalina, J.C.[2], Bernhardt, H.J.[3], Pirard, E.[4], Segundo, F.[2], Brea, C.[1] & Pérez-Barnuevo, L.[1]
[1]School of Mines, Universidad Politécnica de Madrid, Spain
([*]ricardo.castroviejo@upm.es)
[2]AITEMÍN, Madrid, Spain
[3]Ruhr-Universitaet Bochum, Germany
[4]Université de Liège, Belgium

A joint research to develop an efficient method for automated identification and quantification of ores [1], based on Reflected Light Microscopy (**RLM**) in the *VNIR* realm (Fig. 1), provides an alternative to modern SEM based equipments used by geometallurgists, but for ~ $1/10^{th}$ of the price.

Fig 1: Equipment used on automated Leica DM6000M scope.

Quantitative measurements as reflectance and hardness, mainly *VHN*, are traditionally used to support RLM ore identification. Still, this relies mostly on qualitative observations, which can not be applied directly for automated reconnaissance. Today, accurate colour measurements [2] and systematic spectral reflectance data from QDF3 [3] provide a sound base for automation [4] and for multispectral imaging [5,6]. Once automated identification is achieved [7,8], processing the digital images can provide results similar or superior in discrimination compared to the SEM methods. The method is also more performant than the classical point-counter [9].

The automated ore identification procedure now presented is based on direct classification of individual pixels. Training of the identification system has been carried out by using actual pixel multispectral reflectance values of a subset of the mineral regions selected for the database. Tests of the system have provided very good recognition rates, well in excess of 99% of the pixels for mineral regions selected for the database. To further enhance the efficiency of the process, additional mineralogical criteria [10] may be applied.

New data on the specular reflectance of ores (VNIR: 400 - 1000nm) and their significance for ore microscopy

Brea, C., Castroviejo, R.[*] & Samper, J.
ETSI de Minas, Universidad Politécnica de Madrid, Spain
([*]ricardo.castroviejo@upm.es)

This work is part of the project *CAMEVA* for the development of an expert system aimed at the automatic identification of ores [1,2]. It relies on the measure of their reflectance values, **R**, on digital images. Software for calibration, acquisition and analysis of the multispectral data was designed by *AITEMIN* [3]; the research was also assessed by H.J. Bernhardt and E. Pirard [1].

The work deals with the first stage in the development of the system: the creation of a reference data base, **DB**, including multispectral reflectance values of the most important ore minerals in the *VNIR* realm [4,5]. A most delicate step is the selection of the ores and fields to be measured, implying a previous and very careful study of the samples. A poor quality of the polished surface or an ill-defined mineralogy would invalidate the results. The samples studied belong essentially to the collections of the Madrid School of Mines, and to the well-known Rehwald / Ramdohr collection of ores.

The DB, still to be completed, allows some insights [6] into the behaviour of the common ore minerals beyond the visible spectrum (Fig.1). The change in the slope of some spectral curves entering the IR realm is very remarkable, as is the case with pentlandite and niccolite, whose R exceeds that of pyrite, marcasite and arsenopyrite in IR. The same contrast is seen in the *VNIR* behaviour of couples like pyrrhotite – chalcopyrite, pyrrhotite – galena and cubanite – galena. On the other hand, the spectral curves of pyrrhotite and cubanite, very close in the visible realm, are diverging in IR.

Furthermore, it is important to note that on entering the IR realm some minerals, as tetrahedrite, hematite, and magnetite, show a sensible decrease in their reflectance values, while others like covellite and bornite undergo a dramatic increase.

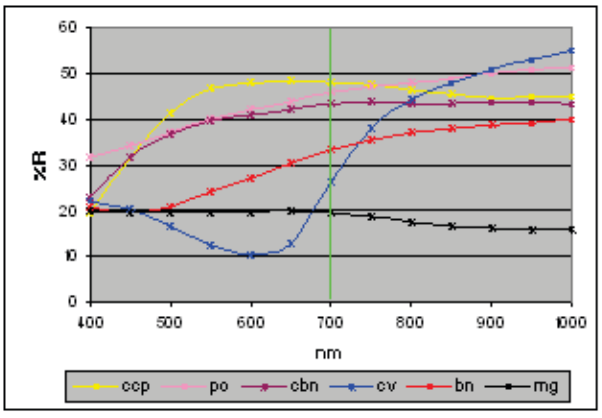

Fig. 1: Reflectance curves of chalcopyrite (ccp), pyrrhotite (po), cubanite (cbn), covellite (cv), bornite (bn) and magnetite (mg).

The DB is consistent with published values in the visible realm [7: values 400 – 700 nm], and shows that the new information in the near IR (700-1000 nm) may be of high diagnostic value.

Pulsed power methods for hydrocarbon raw

Kotova, O. & Tropnikov, E.*
Institute of Geology, Komi Scientific Center, Uralian Branch,
Russian Academy of Sciences, Syktyvkar, Russia
(*tropnikov.83@mail.ru)

Surface of minerals represents a nice field for studying natural processes. The knowledge of dependencies of surface kinetics and organic matter transformation on physical parameters with the use of achievements un the field of mineral surface physics allows generating the organics-mineral surface model for revealing mechanisms of formation of hydrocarbon raw, synthesis of new carbon-containing materials and to create new technologies.

Within the framework of our studies on the convergence of hydrocarbon raw, experiments on modeling of controlled growth of diamond from Yarega oil raw under influence of pulse laser radiation (impulse duration 0.5 ms) have been conducted.

The structure of the initial and irradiated crystal were studied by means of four-circle X-ray diffractometer P4.The study of parameters of lattice, distribution of electron density, and also tension and sizes of blocks, coherently disseminating X-rays, specify that the pulse laser irradiation renders essential influence on monocrystals, namely, it creates a high pressure in oil disperse systems resulting in change of size of complex structural units even beyond the area of irradiation. The received results can be treated as buildup of layers and individual formations on the surface of monocrystals with lattice parameters slightly exceeding the parameters of initial crystal.

Parameters were determined by angular position of reflection from 30 atomic planes alternately taken in vertical position. The distribution of electronic density was made on the basis of Fourier transformation. Tensions and sizes of the blocks were determined by the width of reflexes.

Thus, as a result of the experiments, build up of monocrystal layers of diamond on the surface is observed. The experiments specify the opportunity of crystallization of molecules of diamond and (or) classes of compounds known as diamondoids in Yarega oils.

Fluid evolution in Cordilleran polymetallic veins – insights from microthermometry and LA-ICP-MS of fluid inclusions

Catchpole, H.[1*], Kouzmanov, K.[1], Fontboté, L.[1], Guillong, M.[2] & Heinrich, C.A.[2]
[1]Ore Deposits Group, Dept. of Mineralogy, University of Geneva, Switzerland ([*]Honza.Catchpole@unige.ch)
[2]Isotope Geochemistry and Mineral Resources, Dept. of Earth Sciences, ETH Zurich, Switzerland

Cordilleran polymetallic veins, massive manto- and chimney-type carbonate replacement bodies are important Zn-Pb-Ag-Cu resources. Although post-dating mineralised porphyry systems, the meso- to epithermal polymetallic ore bodies are considered to be genetically related to porphyry intrusions. However, it is not yet well understood where the mineralising fluids that produce polymetallic mineralisation originate from, nor how they evolve in time and space.

In this contribution we present microthermometric and LA-ICP-MS data of fluid inclusions throughout the paragenesis of polymetallic veins cutting barren and mineralised Cu-Mo porphyries in the Morococha district, Central Peru. Fluids related to early precipitation in the veins are moderately-low saline (~ 4-5 wt% NaCl eq), have homogenisation temperatures (T_h) of up to 380°C, up to 5 mol% CO_2 and high metal contents of over 1000 ppm Cu and Fe, 100 ppm Pb, 10 ppm Ag, and several 100 ppm Zn. Several thousand ppm S are recorded in inclusion fluids, mostly precipitating as pyrite in early vein formation stages, but enough S is present in the fluid to later precipitate all of the economically interesting minerals such as sphalerite, galena and fahlore. Metal contents decrease with T_h, showing different precipitation trends corresponding to the paragenetic position of the ore minerals. Copper content decreases several orders of magnitude. Coinciding with abundant carbonate precipitation in late stages of vein formation, the latest fluids have T_h ranging from 260 to 240°C, low metal values, no measurable CO_2 and salinities of about 2 wt% NaCl eq.

Secondary fluid inclusions in porphyry-related quartz stockwork veins predate polymetallic vein formation and show typical characteristics of a single-phase magmatic fluid with vapour-liquid ratios of 50 - 60%, ~8 mol% CO_2, very high Cu values of around 1 wt%, T_h of 420 - 440°C and salinities of 3 – 4 wt% NaCl eq. These results, together with preliminary O and H isotope data, support the hypothesis that the fluids producing the Cordilleran polymetallic veins developed from similar low to moderately saline and metal rich fluids, rather than evolving from strong dilution of porphyry brines with meteoric water, as previously assumed.

Au-Ag deposits along the Cauca River canyon, northwestern margin of the Central Cordillera, Colombia

Gallego, A.N.[*], Akasaka, M. & Roser, B.P.
Dept. of Geosciences, Shimane University, Matsue, Japan
([*]albanurygh@yahoo.com)

The Buritica, Titiribi and Marmato gold mines are major deposits located at the northwestern margin of the Central Cordillera in Colombia. The occurrence and chemical compositions of ore minerals in each were investigated to determine the genetic processes of the ore minerals and the genesis of the deposits overall.

These three deposits are related to small but prominent Neogene hypabyssal porphyry geoforms of andesitic to dacitic composition. The Neogene age of the porphyry body in the Burica area is still controversial. However, its form and chemistry are similar to the porphyry bodies in the other two mining areas. Sulfides in the Buritca veins comprise sphalerite, pyrite, chalcopyrite, Ag-rich tetrahedrite, hessite, electrum, and bornite. Gangue minerals are K-feldspar, sericite, apatite, quartz, and carbonates. Argillic alteration is predominant. Crystallization temperatures have been measured in fluid inclusions from both quartz and calcite grains, revealing a minimum crystallization temperature between 220°C and 300°C. Tellurium and sulfur fugacities are estimated to be between $10^{-12.96}$ to $10^{-9.55}$ and $10^{-6.3}$ to 10^{-10} atm, respectively.

The Titiribi mining district contains two different styles of mineralization. The first is represented by the El Zancudo deposit, which has a long history of production. The ore veins are emplaced in schist, and contain differing Ag-Cu-Pb-Sb-bearing sulfosalts along with sphalerite, pyrite, arsenopyrite, galena, chalcopyrite, and electrum. At least two main crystallization stages have been defined; the second stage is accounted for the crystallization of most of the ores, and is divided into two sub-stages with minimum crystallization temperature ranging from 264 to 350°C and 134 to 262°C, respectively. Sulfur fugacity varies from 10^{-3} to 10^{-7} atm. for temperatures higher than 300°C. Gangue minerals accompanying the ore veins are quartz, carbonates, sericite and K-feldspar. Argillic and advanced argillic alteration is observed in the host rocks. The second style of mineralization comprises magnetite-hematite rich veins hosted in a porphyry body. These veins also contain sphalerite, chalcopyrite, and bornite. Hydrothermal titanite, chlorite, K-feldspar and sericite occur as gangue minerals. Propylitic and argillic alteration are predominant, and homogenization temperatures measured in quartz fluid inclusions range from 306 to 420°C.

The Marmato mine is one of the historically most significant mining districts in this area. The constituent sulfide minerals are sphalerite, pyrite, chalcopyrite, galena, argentite and electrum. Gangue minerals are carbonates, sericite, K-feldspar, and quartz. Homogenization temperatures in both quartz and carbonates reveal temperatures between 259 to 292°C. Argillic and propylitic alteration is commonly observed.

The chemistry of the hydrothermally altered host rocks of these deposits was compared with that of unaltered porphyries from the Titiribi district. The common geomorphologic features among these prominent porphyry bodies are also well correlated with Nb/Y and Zr/Ti immobile element ratios, which indicate andesite to rhyodacite magmatism. Although the time gap between each crystallization stage in these deposits remains unclear, some evidence suggests the main mineralizing stages are linked to late Miocene magmatic activity. Extensive Middle-Miocene to Early-Pliocene magmatism is well documented along the north Andes. These three hydrothermal-related deposits are classified as intermediate sulfidation mesothermal to epithermal type (Cordilleran polymetallic vein deposits).

Hydrothermal gold mineralization in island arc environment: case study in Western Java, Indonesia

Rosana, M.F.
Faculty of Geology, Padjadjaran University, Bandung, Indonesia (mega_fr@unpad.ac.id)

Western Java area occupies a part of Sunda Banda magmatic belt, and is well known for the prevailed hydrothermal gold mineralizations where active gold mines of the Gunung Pongkor, and Cibaliung and formerly produced mines of the Cikidang the Cirotan and the Cikotok are located. And several other areas are under exploration such as Arinem, Cineam, Cipunagara, Ciemas and Gunung Subang.

Hydrothermal gold ore deposits of western Java are mainly distributed along the NNE-SSW strike-slip faults cutting Miocene to Pliocene volcanic and plutonic formations. The ore veins are hosted mainly in calc-alkaline andesitic and dacitic volcanic breccia and tuff, less commonly in limestone, sandstone, claystone and microdiorite intrusive. Pervasive hydrothermal wall rock alterations are well developed in the mineralized area. An intensive silicic, propylitic and argillic alterations are generally observed in the most of deposits, indicated by chlorite/smectite and/or illite/smectite, epidote, sericite, kaolinite and locally montmorillonite.

The mineralization ages are ranging from 1.7 to 11 Ma based on the K-Ar dating among the deposits. The deposits are extensively in the form of gold bearing quartz veins of epithermal low sulfidation type characterized by the occurrence of sericite, adularia and manganese oxide, and also in the quartz-carbonate-polymetallic gold bearing veins of epithermal to shallow mesothermal and/or transition to porphyry tin type environment.

In the former low sulfidation type deposits, the ore is composed mainly of gold and silver minerals. This type deposits are estimated to be formed under the shallow (180-350m in depth) epithermal conditions from low salinity (<4 wt% NaCl eq.) fluids in the temperature from 170 to 250°. Gold might be transported as $Au(HS)^{2-}$ under nearly neutral pH and relatively high fS_2 (10^{-14} to 10^{-11}) and fO_2 (10^{-30} to 10^{-45}) in conditions. On the other hands, the latter mesothermal and/or transition to porphyry type ore is characterized by the occurrence of not only gold and silver minerals, but also the presence of tin minerals such as canfieldite and cassiterite, wolframite, and bismuth and tellurium minerals. This type deposits are estimated to be formed at the depth below 400m from slightly higher salinity (1.5 to 7.5 wt% NaCl eq.) fluids in the temperature at 260 to 350°. Gold might be transported under neutral to slightly acidic and relatively high fS_2 (10^{-20} to 10^{-10}) and fO_2 (10^{-30} to 10^{-40}) in conditions.

The Pb, S, and C isotope ratios indicate the magmatic source for associated metals, while the association of tin-minerals, wolframite and bismuth minerals suggest the recycling of older continental crust underlying the Malaysia-Sumatra porphyry tin belt as the source of the metals. The oxygen stable isotope ratio suggests a mixing of hydrothermal fluids with meteoric water in the ore depositions.

The mineralization ages (Pongkor: 2.7 to 8.6Ma, Cikidang: 2.4Ma, Cipanglengseran: 2.1Ma, Cirotan: 1.7Ma, Cibaliung: 11 Ma, and Arinem 8.8 Ma) indicate a lateral shift of volcanic front, where they are getting young toward south of Java island. The time-spatial change of hydrothermal activity with gold mineralizations corresponds to magmatic activity in the Sunda-Banda magmatic arc, which was caused by subduction of the oceanic plate under the continental crust. The crust is relatively thin and young with mostly intermediate composition accompanying a few ignimbrite deposits, such as in the Bayah dome where most of gold mineralizations are localized in western Java.

Magmatic control of volcanic hosted mineralization in the Carpatho-Pannonian region

Lexa, J.[1*], Molnár, F.[2] & Szakács, A.[3]
[1]Geological Institute, Slovak Academy of Sciences, Bratislava, Slovakia ([*]geoljalx@savba.sk)
[2]Dept. of Mineralogy, Eötvös University, Budapest, Hungary
[3]Dept. of Environmental Sciences, Sapientia University, Cluj-Napoca, Romania

Paleogene and Neogene volcanic-hosted mineralizations of the Carpathian-Pannonian region show a great variety of styles and geological settings. Simple andesite stratovolcanoes either show no mineralization or they host unmineralized advanced argillic alteration. Mature andesite stratovolcanoes involving differentiated rocks and shallow subvolcanic intrusions host either this kind of alteration and/or productive HS (high sulphidation) and IS/LS (intermediate/low-sulphidation) epithermal systems. Multiple-stage complex andesite stratovolcanoes with some felsic rocks host early intrusion-related porphyry-style mineralization and usually late-stage IS/LS hydrothermal systems. Areas of the bimodal andesite/rhyolite volcanism host intrusion-related advanced argillic alteration and/or IS/LS as well as hot-spring/LS hydrothermal systems related to rhyolite dome/flow complexes and regional extension. In volcanic centers eroded down to the level of subvolcanic intrusions, we distinguish counterparts of the above-mentioned mineralization styles - unmineralized andesite/diorite porphyry intrusions, intrusion-related IS/LS base metal stockworks ± IS/LS epithermal veins, skarn type magnetite and base metal mineralizations, skarn/porphyry or porphyry Cu ± Mo, Au mineralizations, and porphyry Au mineralizations, with a related suite of HS and/or LS epithermal veins.

The observed variability of mineralization styles reflects differences in magmatic evolution and structural control. Ore-productive systems associates only with those intrusive-volcanic systems that have reached the maturity stage including evolution of magmas in the high level crustal magma chambers. Favourable systems show long-lasting volcanic activity associated with evolution of volcano-tectonic grabens in back-arc tectonic settings. High-level magmatic chambers/ systems are principally of two types: those associated with andesite stratovolcanoes and those associated with rhyolitic magmatism.

Intrusive systems of andesite stratovolcanoes are of diorite composition and evolve towards granodiorite composition due to AFC processes. If they give rise to a shallower subvolcanic stock magmatic fluid partitioning into vapour and brine creates conditions for the development of advanced argillic alteration in the volcanic edifice which may evolve into a HS type ore, as well as for the complementary Cu-porphyry and intrusion-related IS/LS systems. Due to gradual crystallisation of the stock and decrease in temperature, the early stage marked by the vapour-brine partitioning and related advanced argillic alteration in the shallow volcanic zones is followed by the stage of deeper fluid separation giving rise to mineralization only if a larger magma chamber is involved. A deeper subvolcanic stock will not experience processes related to magmatic fluid partitioning and thus the diluted magmatic fluids will generate LS hydrothermal systems without contemporaneous HS and Cu-porphyry systems. Longer-living shallow crustal magma chambers evolve via AFC processes towards more felsic compositions with or without a prior stage of andesitic volcanism at surface. This type of shallow magma chambers supply fluids to the deeply-rooted IS/LS systems associated with rhyolite magmatism and horst/graben tectonic structures. Structural control by normal faults played an important role in their localization.

Mineral zoning, cross-cutting relationships, and radiometric dating: keys to trace fluid evolution during polymetallic stages of porphyry intrusion-related systems

Fontboté, L.
Ore Deposits Group, Earth and Environmental Sciences, University of Geneva, Switzerland (lluis.fontbote@unige.ch)

Epithermal and sub-epithermal polymetallic Cordilleran ores occur frequently in porphyry intrusion-related systems [1]. High Zn, Pb, Ag and Mn contents are traced in hypersaline fluid inclusions formed during potassic alteration [2], and it it could be perhaps followed that the polymetallic mineralization just represents distal low temperature precipitation of these metal rich fluids. However, detail study of several Cordilleran polymetallic deposits, suggests that the history is more complex. Cross-cutting relationships and radiometric dating indicate that Cordilleran or Butte Type polymetallic veins and replacements bodies cut early potassic and, in places, phyllic alteration assemblages and that they postpone by several hundred of thousands of years the early stages of deposit life span [3] a temporal evolution that is comparable to that of many porphyry deposits [4].

The sulfidation state and fluid acidity in Cordilleran ore deposits depends on several factors, including the involvement or not of acidic gas phases [5], the formation depth, and in general the temperature and spatial path followed by the ore forming fluids. Thus, the zoned character is a frequent, but not compulsory characteristic of the class. Strongly zoned deposits are characterized by the presence of cores with high sulfidation and/or advanced argillic mineral assemblages. In such cases, cores dominated by enargite or famatinite, pyrite, quartz±(tennantite, wolframite, chalcopyrite, covellite, chalcocite, alunite, dickite, kaolinite) grade to external parts with Fe-poor sphalerite, galena±(sericite, kaolinite, dickite, hematite, Fe-Mn carboantes). In contrast, weakly zoned deposits may display internal parts bearing pyrrhotite, pyrite, quartz±(chalcopyrite, arsenopyrite, tetrahedrite, carbonates, sericite, chlorite, quartz) and external parts of Fe-rich sphalerite, galena, pyrrhotite±(rhodocrosite, siderite, and other carbonates, sericite, chlorite, quartz). In extreme cases, both end-member styles may be present in the same deposit.

Available information [6,7] suggests that Cordilleran polymetallic deposits may be formed by low to moderately saline fluids of magmatic isotopic signature. Therefore, it is more likely that these fluids represent single-phase magmatic fluids than diluted magmatic brines.

Formation of advanced argillic lithocaps over porphyry systems by increasingly acidic fluid

Hedenquist, J.W.[1*] & Taran, Yu.[2]
[1]Earth Sciences, University of Ottawa, Canada
([*]hedenquist@aol.com)
[2]Instituto de Geofisica, UNAM, Mexico D.F., Mexico

Hypogene advanced argillic alteration, typically quartz-alunite with halos of kaolinite ± dickite and roots of pyrophyllite-diaspore, forms in the epithermal environment from condensates of magmatic vapor that contain SO_2 and HCl, derived from an underlying intrusive source. The most aggressive, nearly isochemical leaching of the host rock by the most acidic condensate, commonly pH~1, leaves a residual silica that recrystallizes to quartz closest to the flow channel, in the core of alteration; the alteration flares upward along feeder structures, and if a lithologic unit is intersected, the alteration forms a sub-horizontal blanket, termed a lithocap. Where subsequently mineralized, the residual quartz, commonly with a vuggy texture, has higher Au (and Cu) grades than the halo of quartz-alunite. Tonnage in these high-sulfidation systems may develop within the sub-horizontal lithocap, although the highest grades are in the structurally controlled feeders.

Our modelling of the condensation of a typical volcanic vapor and its cooling and reaction with a felsic rock reproduces the alteration pattern observed along structures and in lithocaps that may host high-sulfidation deposits. The modelling indicates alumino-silicates (pyrophyllite, diaspore, locally andalusite) are stable only at higher temperatures at depth; at lower temperatures and more shallow depth, Na- and K-alunite become stable, eventually followed by residual quartz at higher condensate:rock ratios (>10:1). The reason for this transition, and the upward flare (widening) of the zone of alteration along structures, is related to the increased reactivity of HCl and H_2SO_4 acids as the temperature decreases; only quartz, pyrite, anhydrite and native S are stable below ~200°C, hence the abundance of quartz residue. As a further check on the modelling, the calculated composition of the condensate after reaction with fresh rhyolite and the alteration minerals to 100°C is similar to acidic springs, with pH~1, that discharge around active volcanoes, e.g., Satsuma Iwojima, Japan.

It is observed that the most extensive lithocap alteration, residual quartz and/or quartz-alunite, is commonly offset from the surface projection of the causative intrusion, the latter associated with porphyry deposits. This is caused by a combination of two factors. There is typically lateral flow of acidic condensate away from the high-temperature vapor plume that forms directly over the intrusion, caused by hydraulic gradients at shallow depths if there is a volcanic edifice at the surface. As a result of this lateral flow, the most intense and abundant advanced argillic alteration that forms at lower temperatures may occur away from the near-surface projection of the intrusion. The potential for lithocap alteration to be offset from the intrusion must be determined when exploring for high-sulfidation ore, since the highest grades are commonly related to structures that are proximal to the underlying intrusion. In addition, defining the likely location of the source intrusion will help the explorer to efficiently assess any potential for deeper porphyry-style mineralization.

The porphyry to epithermal transition in atypical late Neoproterozoic REE-Au-Ag-Te occurrences

Tuduri, J.[1*], Dubois, M.[2], Try, E.[2], Chauvet, A.[3], Barbanson, L.[4] & Ennaciri, A.[5]
[1]ENAG – BRGM School, Orléans, France ([*]j.tuduri@brgm.fr)
[2]LGCgE and Université Lille1, France
[3]UMR 5573, Université de Montpellier II, France
[4]ISTO, Université d'Orléans, France
[5]Reminex, Marrakech, Maroc

The Neoproterozoic terranes of the Eastern Anti-Atlas ranges (Morocco) host numerous precious and base metal deposits. The Kelâa M'Gouna showings are found at the interface between i) a basement made of Cryogenian detrital sediments intruded by early Ediacaran granodiorite plutons and ii) a late Ediacaran upper unit composed of lava flows and caldera-related ash-flow tuffs associated with cogenetic granites.

We proposed a two-stage formation model: **Stage I** is related to high-temperature hydrothermal system. Alteration structures are different if hosted by the basement or the volcano-plutonic unit, but supposed to occur during the same time with respect to fluid inclusions studies and mineral geochemistry. Within basement rocks, intense silicification produces the formation of a quartz-rich stockwork with F-Cl-rich amphibole, Cl-F-rich biotite, muscovite, scarce F-rich tourmaline and sulfides. Within the volcanic rocks a strong pervasive silicification is related to development of quartz, pyrite, F-rich tourmaline, F-rich phlogopite, Cl-F-rich apatite, andalusite, rutile, hematite, monazite, xenotime, thorite and uranothorite. Sulfides appear in both types and mainly consist of pyrite. Inclusions of chalcopyrite, pyrrhotite, electrum, galena, tetradymite and brannerite are observed in the stockwork, whereas inclusions of galena, coloradoite, hessite and altaite characterize pyrite of the pervasive alteration area. Fluid inclusions were used to constrain palaeohydrothermal conditions during **stage I**. Primary multiphase inclusions are composed of liquid, vapour and halite cube, as well as solids such as sylvite, calcite, $CaCl_2$. In addition, uncommon mineral inclusions that remain abundant have been identified such as titanite, hematite, magnetite, a refringent solid phase identified as andradite. Chalcopyrite and gold were observed in a multiphase inclusion. Multiphase inclusions have a high but very variable salinity (30 to 45 wt% eq. NaCl) and are characterized by homogenization by halite-disappearance. The large range of temperatures (150-400°C) related to an advanced argillic alteration is herein characteristic of alteration zones located in the upper part of Cu-Au porphyries and transition to high-sulfidation environments. **Stage II** is related to a low-temperature system characterized by epithermal structures such as veins and breccias. It begins by pervasive tourmaline-rich fractures and chlorite-rich breccias, then emplacement of adularia-, quartz- and chlorite-rich veins. Sulfides occur late in the core of previously formed quartz-adularia-chlorite veins by deposition of As- and Co-rich pyrite, minor chalcopyrite and precious metal (Au-Ag tellurides, electrum, Ag-telluride and Bi-telluride). Paragenetic study reveals that sulfides could coexist with iron oxides (hematite and magnetite). Microthermometric study shows lower salinity inclusions probably belonging to the H_2O-NaCl-$CaCl_2$ and the absence of multiphase inclusions. Homogenisation temperatures are ranging between 120 and 300°C. Thus, stage II appears as a transition from stage I and corresponds to a low sulfidation epithermal style deposit.

The study of the Kelâa M'Gouna showings reveals that late-Neoproterozoic hydrothermal activity may provide atypical ore systems: a REE-Au deposit related to an advanced argillic alteration telescoped by an iron oxide, Au-Ag-Te low sulfidation epithermal deposit.

Re-examination of sulfidation state of the Victoria gold deposit, Northern Luzon, Philippines

Tanaka, T.[*], Imai, A. & Watanabe, K.
Dept. of Earth Resources Engineering, Kyushu University, Fukuoka, Japan ([*]takahiro-tanaka@mine.kyushu-u.ac.jp)

The Victoria epithermal gold deposit is located in the Mankayan mineral district, northern Luzon, Philippines. The Mankayan mineral district is known as a porphyry copper-type hydrothermal system. In the Mankayan mineral district, the Victoria gold deposit is adjacent to the FSE porphyry copper-gold deposit and the Lepanto enargite deposit. Although, it is considered that the Victoria gold deposit has no relationship to FSE porphyry copper-gold deposit and the Lepanto enargite deposit [1]. Sphalerite, galena, chalcopyrite, tetrahedrite and native gold/electrum occur as the principal ore minerals in the Victoria deposit [2]. Thus, it has been recognized as a low-sulfidation epithermal deposit by geologists of Lepanto Consolidated Mining Company [3]. Additionally, Sajona et al. (2002) classified it as a carbonate-base metal low-sulfidation epithermal deposit [1].

However, mineralogical and fluid inclusion studies in this study indicate that some veins at the Victoria deposit consist of high-sulfidation veins and intermediate-sulfidation assemblage. Especially, colusite, enargite and luzonite often occur in quartz veins and pyritic sulfide veins at the southern portion of the Victoria deposit. Bismuth and Tellurium minerals are also observed in quartz veins at the southern potion of the Victoria deposit. Further, the assemblage of bornite-chalcopyrite-pyrite is often observed at the deeper levels. Homogenization temperatures of fluid inclusions in the quartz veins, which have the assemblage of bornite-chalcopyrite-pyrite, range from 230 to 280°C. These results indicate that (1) part of the Victoria veins are formed in a high-sulfidation condition (Fig. 1); (2) Bismuth, Tellurium and Selenium bearing ore fluid might be derived from a magmatic source located at the southwest and deeper portion of the Victoria deposit.

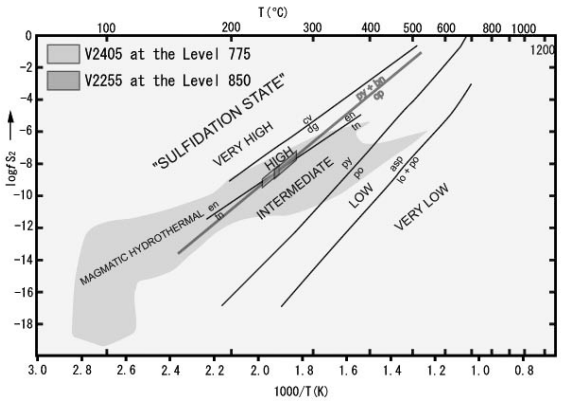

Fig. 1: LogS_2 - 1000/T diagram, showing sulfidation state of the Victoria deposit (modified after Einaudi et al. [4]).

Furthermore, melting temperatures of fluid inclusions in the quartz veins, which have the assemblage of bornite-chalcopyrite-pyrite, show two trends. This result may indicate that the Victoria veins formed by two different hydrothermal fluids.

Convention* (GEOCON '98), 211-219. [4] Einaudi, M.T. et al. (2003) *Soc. Eco. Geo. Spc. Pub.*, **10**, 285-313.

Hydrothermal alteration, fluid inclusions and stable isotopes (O, H) in a porphyry and related epithermal system of the Palaeogene volcanic belt of the Alp-Carpathian Orogen (Velence Mts., W-Hungary)

Molnár, F.[1*], Bajnóczi, B.[2], Pécskay, Z.[3], Prohászka, A.[1] & Benkó, Zs.[1]
[1]Dept. of Mineralogy, Eötvös Lorand University, Budapest, Hungary ([*]molnar@abyss.elte.hu)
[2]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary
[3]Institute of Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary

The calk-alkaline andesitic intrusive-volcanic complex of the Velence Mts. is located within the Palaeogene Volcanic Belt of the Alp-Carpathian system. This belt is situated on a displaced fragment of African Plate origin which has escaped into the Carpathian realm from the highly compressive Alpine collision zone during the Late Oligocene-Miocene. This belt is the host of the world class Cu-porphyry-Cu-Zn-skarn-epithermal Cu-Au ore complex at Recsk (Ne-Hungary). The underexplored mineralization of the intrusive-volcanic complex in the Velence Mts. bears several similarities with Recsk.

The outcrops of volcanic rocks in the Velence Mts. are strongly altered lava and pyroclastic units in an erosional remnant of a stratovolcano with about 10 km diameter. The topographic high areas form an E-W trending zone in the volcanic structure and consist of vuggy silica bodies. Geophysical surveying and drillings found a diorite intrusion at about 600 m depth under the central part of the volcanic structure. The diorite intrusion shows K-metasomatic (K-feldspar and biotite) and superimposing propylitic (actinolite-epidote-chlorite) alteration. Stockwork mineralization in the intrusion consists of early brittle-ductile K-feldspar-quartz-biotite and magnetite-chlorite and late brittle quartz-calcite-pyrite-chalcopyrite-bornite-Pb-Zn-sulphide, as well as the latest barren calcite-zeolite veins. The transitional zone between the porphyry and epithermal mineralization is characterised by illite alteration with increasing amount of kaolinite towards the epithermal zones. In the high temperature (300 to 400°C) advanced argillic alteration zones around brecciated vuggy silica bodies topaz and zunyite occurs together with pyrophyllite, diaspore and kaolinite. These zones probably indicate major upflow zones of magmatic volatiles with high fluorine contents causing formation of topaz and zunyite instead of andalusite. Vuggy silica bodies with more peripheral position have pyrophyllite/diaspore-kaolinite alteration halo. Na-enriched alunite containing APS mineral inclusions is ubiquitous in late infillings of vuggy silica. Marginal zones of the epithermal system lack of vuggy silica and silicified zones show illite, illite-kaolinite or illite-dickite alteration along major fault and breccia zones. Strong pyritization (oxidised to ochre in most areas) is characteristic to vuggy silica and occurrences of enargite is also detected. K-Ar ages for K-feldspar, illite and biotite+amphibole from the porphyry intrusion (29-32 Ma) are essentially identical with those for illite and alunite in the epithermal zones (31-33 Ma).

Fluid inclusion data indicate high temperature boiling producing high salinity-high density magmatic brine and low density vapour during the variation of pressure between hydro-lithostatic conditions at the level of intrusion. Mixing of both types of magmatic fluids with meteoric water is supported by variation of fluid inclusion salinity and stable isotope (O, H) data for biotite, amphibole, chlorite, illite, kaolinite, pyrophyllite and alunite from the subvolcanic to the volcanic level and to the peripherial zones.

Tracing low sulfidation systems from their roots down to foothills - example from the Kremnica ore and industrial minerals fields (Slovakia)

Koděra, P.[1*], Lexa, J.[2], Fallick, A.E.[3], Biroň, A.[2], Gregor, M.[1], Uhlík, P.[1] & Kraus, I.[1]
[1]Dept. of Geology of Mineral Deposits, Comenius University, Bratislava, Slovakia ([*]kodera@fns.uniba.sk)
[2]Geological Inst., Slovak Acad. of Sci., Bratislava, Slovakia
[3]Scottish Universities Environmental Research Centre, UK

Deciphering paleohydrology of epithermal systems is critical for determining the location of boiling, precipitation of metals and distribution of zones of alteration that may represent economic ore and industrial mineral deposits. Neogene Kremnica system is an excellent example of a classical low-sulfidation Au deposit, accompanied by several economic accumulations of K-bentonite, bentonite and zeolite.

The ore deposit is hosted by andesitic rocks, situated on marginal faults of a resurgent horst in central part of a volcanotectonic graben. Mineralization is contemporaneous with uplift of the horst and emplacement of rhyolitic rocks S of the horst in the graben. Wallrock alteration includes adularia, illite or I/S and kaolinite. Mineralogical and fluid inclusion data indicate multistage filling of veins with at least two episodes of boiling at different temperatures and paleodepths. Boiling was responsible for Au deposition and adularia-illite alteration. Kaolinite represents a later overprint on mineralised structures, resulting from penetration of subsurface water acidified by condensation of H_2S and CO_2-bearing vapour released by boiling. Individual parts of the vein system originated from low-salinity (<2 wt% NaCl eq.) fluids showing decrease in temperature from 270 to 150°C in the N-S direction due to decreasing erosion level (~350 to 50 m). Fluids were isotopically homogenous (~ -3.5 ‰ $\delta^{18}O$) mostly of meteoric origin affected by isotopic reequilibration with country rocks.

Less mineralised S section of the vein system was emplaced in rhyolite domes and volcanoclastic rocks, filling the graben. This area also hosts the industrial mineral deposits. Regional I/S alteration (incl. K-bentonite deposits) next to veins probably result from lateral outflow of hydrothermal fluids into permeable pumiceous/glassy volcanoclastic rocks as indicated by their similar $\delta^{18}O_{fluid}$ compositions and paleotemperatures (135-190°C – concordance of fluid inclusion data, oxygen isotope and I-S geothermometers). A local elevation with blocks of silicites resting on breccias cemented by quartz and kaolinite is interpreted as an ancient hot-spring system. S and SE parts of the area host numerous bentonite (smectite) deposits, representing altered tuffs and glassy marginal breccias of rhyolite domes. There is not a continuous decrease of expandability and paleo-temperatures between areas with I/S and smectite alterations (I/S has rarely >45% of smectite layers), which is probably a consequence of a hidden fault, dividing relatively subsided and uplifted parts of the area. Bentonite is often interlayered with limnic/lacustrine silicites representing the former paleosurface. Silicites result from episodical inflow of groundwater enriched in silica due to decomposition of volcanic glass. Oxygen isotope values of both smectite and silicites show decreasing temperature from N to S-SE as the result of paleoflow of heated groundwaters and/or recrystallisation during shallow burial. Smectite crystallinity (crystal size distribution) well correlates with their $\delta^{18}O$ values as the result of decreasing temperature (70 to 15°C based on isotopic equilibrium with meteoric water). Silicites give slightly higher temperatures (80 to 30°C), while some correlation between crystallinity and $\delta^{18}O$ also exists. Smectite alteration changes into zeolite alteration with clinoptilolite and mordenite towards depth probably due to diagenesis and thermal effect of rhyolite extrusives.

Phreatomagmatic breccia at the Pb-Zn-Ag Trepča deposit, Kosovo

Strmić Palinkaš, S.[1*], Palinkaš, L.A.[1] & Molnar, F.[2]
[1]Institute of Mineralogy and Petrography, Dept. of Geology, University of Zagreb, Croatia ([*]sabina.strmic@inet.hr)
[2]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary

The Trepča Pb–Zn–Ag deposit (42.9°N, 20.9°E) is located in the Kopaonik block of Western Vardar Zone, Kosovo. The mineralization is represented by skarn and hydrothermal parageneses. Skarn paragenesis comprises prograde (hedenbergite) and retrograde mineral assemblages (ilvaite, magnetite, pyrrhotite, arsenopyrite, pyrite, quartz and carbonates). The economically important sulfides, such as galena and sphalerite, are associated with hydrothermal stage superimposed onto the skarn mineralization [1].

The mineralization is spatially and temporary related to Tertiary postcollisional magmatism. Recrystallized Triassic limestone with paleokarst features represents the principal host rock. The limestone is placed within the core of an anticline and covered by Triassic schist. A nearly circular volcanic pipe transects the limestone-schist contact along the crest of the anticline. The volcanic pipe consists of trachytic core and breccia mantle. The core, with the form of steeply dipping inverted cone, is intensely hydrothermally altered into the mixture of K-feldspar, quartz and muscovite. Sanidine phenocrysts comprise sanidine relics accompanied with various micas and quartz. Breccia mantle is composed of angular to subround fragments of country rocks (limestone, schist), fragments with magnetite core and pyrite rim, and round clasts of trachyte. The contact between breccia and the wall rocks is sharp and sporadically branches into lateral fractures, filled with rock flour ("milled matrix, fluidized breccia") or with angular fragments ("jigsaw-fit breccia"). The breccia pipe is exposed at all horizons of the deposit, from the surface (+860 m above sea level) downwards to Horizon XI (+ 15 m above sea level) and its downward termination is not observed. An intimate relation of breccia with trachytic dyke suggests that phreatomagmatic explosions were controlled by direct contact of magma with an external source of water.

The contact between the breccia and host limestone is marked by presence of low saline (~ 4 wt.% NaCl equ.) and moderate temperature fluids (T_H = 275-290°C). Stable isotopes of carbonates point to the influence of magmatic fluids ($\delta^{13}C$ = -2.8 ‰; $\delta^{18}O$ = 12.5 ‰). Fluid inclusions preserved within recrystallized limestone fragments display moderate salinity (13-14 wt.% NaCl equ.) and T_H up to 340°C. Decreased $\delta^{13}C$ (-4.3 ± 0.1 ‰) and $\delta^{18}O$ values (13.0 ± 0.4‰) suggest recrystallization under influence of magmatic CO_2. Fragments composed from magnetite core and pyrite rim occur mostly in the upper part of the breccia pipe. Textural features suggest that fibroradial magnetite, accompanied by mixture of quartz and carbonates, was formed as retrograde alteration of hedenbergite under increased oxygen fugacity:

$$3CaFe^{2+}Si_2O_6 + 3CO_2 + ½O_2 \rightarrow Fe^{2+}Fe^{3+}{}_2O_4 + 3CaCO_3 + 6SiO_2$$

Increased oxygen fugacity is attributed to the opening of the system during the phreatomagmatic explosion. Once formed breccia pipe had served as a sink for invasion of groundwater into the system and initiated the retrograde stage. Furthermore, opening of the system decreased the pressure and amplified the sulfur release. The occurrences of pyritic rims point to the sulfur fugacity increase:

$$Fe^{2+}Fe^{3+}{}_2O_4 + 3\ S_2 + 8\ H^+ + 8\ e^- \rightarrow 3\ FeS_2 + 4\ H_2O$$

Isotopic composition of pyrite ($\delta^{34}S$ = 3.1± 0.7 ‰) supports a magmatic source of sulfur.

Te and Se mineralogy of Paleozoic epithermal Au deposits of the Ural - Mongolian belt

Plotinskaya, O.Yu.[1*], Kovalenker, V.A.[1] & Seltmann, R.[2]
[1]Institute of Ore Geology, Petrology, Mineralogy, and Geochemistry, Russian Academy of Sciences, Moscow, Russia ([*]plotin@igem.ru)
[2]Natural History Museum, CERCAMS, London, UK

Although most of the known epithermal deposits were formed during Mesozoic or Cenozoic eras, there are numerous sites of Paleozoic age. Among these, the best examples are in the epithermal-porphyry province of the Kurama ridge (Middle Tien Shan) and the recently discovered Birgildinsk-Tominsk ore district in the South Urals. The first area is a part of C_3-P_1 Andean-type continental margin while the second one is supposed to be located within D_3-C_1 island arc. In the present study two epithermal orefields, Kochbulak-Kairagach (Kurama) and Bereznyakovskoe (Urals), are considered as most remarkable due to their variable telluride-selenide mineralogy.

The Kochbulak and Kairagach deposits (estimated reserves 120 and 40 t of Au, respectively) are located in the same volcanic structure and have been formed within the same ore-forming system [1,2]. Au-Ag-Cu-Bi-Te-Se mineralization is confined to veins and dissemination zones accompanied by quartz-sericite wall-rock alteration. The deposits are characterized by similar mineralogy. Among tellurides, calaverite, altaite, hessite, and tetradymite are most widespread in both deposits; at Kairagach selenides and sulfoselenides of Bi and Pb are common, while at Kochbulak only various Bi and Pb telluroselenides and sulfotelluroselenides are typical. At both deposits the native gold assemblages change from Au+calaverite+altaite to Au+petzite±hessite and, finally, to Au+hessite±petzite, accompanied by increase of Ag contents in native gold and correlating with temperature decrease, pH increase and fO_2 drop during each ore stage [3].

The Bereznyakovskoe orefield includes several small deposits with a total Au potential of 50–100 t [4]. Mineralization is hosted by dacite-andesite tuffs interlayered with limestones. Wall rock alteration is represented by pyrophyllite-quartz alteration followed by argillic alteration [5]. Three ore stages were identified: pyrite, polymetallic (with enargite, fahlore-telluride, and gold-telluride sub-stages) and galena-sphalerite stages. The generalized sequence of gold-telluride bearing assemblages is as follows: native Te+sylvanite via krennerite+petzite and altaite+calaverite via Au+calaverite+altaite+coloradoite+tellurantimony to native Au+galena+antimonite and hessite+galena. The observed evolution was controlled by temperature decrease accompanied by drop in fS_2 and fTe_2. Selenides are absent except for galena-clausthalite [6].

Fluid inclusion data supported by mineral thermobarometry suggest Kairagach to represent shallower parts of the epithermal system than Kochbulak, while Bereznyakovskoe belongs to deeper parts of such system. At the same time, on a High to Low sulfidation line the Central Bereznyakovskoe establishes the highest degree of sulfidation, whereas its SE and North periphery, as well as Kochbulak and Kairagach, belong to high-to-intermediate sulfidation types.

Trace elements and cathodoluminescence of quartz in stockwork veins of Mongolian porphyry-style deposits

Müller, A.[1*], Herrington, R.[2], Armstrong, R.[2], Seltmann, R.[2], Kirwin, D.J.[3], Stenina, N.G.[4] & Kronz, A.[5]

[4]Institute of Geology SB RAS, Novosibirsk, Russia
[5]Geowissenschaftliches Zentrum Göttingen, Germany

In this study, results are presented from a comprehensive study of quartz from mineralised A-type and other associated veins of the late Devonian Central Oyu Tolgoi and early Carboniferous Zesen Uul porphyry copper-gold deposits in the south Gobi region of Mongolia. The investigated A-type veins, which are considered to have formed during the early stage of stockwork formation, show complex growth structures with multiple overprinting and replacement revealed by cathodoluminescence (CL) imaging. Electron probe microanalysis (EPMA) was then used to determine quartz trace element chemistry (specifically Al, K, Ti, and Fe). The use of backscattered electron imaging helped to establish the paragenetic relationships between ore mineral assemblages and different quartz generations. Finally fluid inclusion microthermometry was carried out on recognized quartz generations.

The study of the Central Oyu Tolgoi and Zesen Uul Cu-Au porphyry systems shows that despite differences in the alteration and mineralisation styles, the CL features of the different quartz generations are generally similar. Four major quartz crystallisation stages Q1 to Q4 were identified in the central mineralised stockworks of both deposits namely:

Q1 occurs in barren A-type veins and as massive silicification of the host rocks. Q1 is brightly luminescent with high Ti contents, indicative of crystallisation temperatures greater than 600°C. This quartz stage forms more than 90 vol.% of the quartz mass of the stockworks in each deposit.

Q2 is mineralised, occurring as dull luminescent quartz with high and variable Al contents together with high K values in places. Q2 quartz precipitated from a fluid with a low but fluctuating pH. This onset of high and variable Al and K in quartz is indicative of the onset of sulfide mineralisation.

Q3 is largely barren of mineralisation and forms dull to non-luminescent quartz with low Ti, Al, K, and Fe contents. Q3 stage fluids had moderate salinities.

Q4 formed dull luminescent quartz with high and variable Al and Fe contents hosted in calcite vein breccias which in places have associated sulfides.

The distinct trace element signature of each of the individual quartz generation reflects the variability of fluid temperature and acidity at different stages of the evolution of the magmatic-hydrothermal system. CL patterns and related trace element variations seen in this study of the Mongolian porphyries appear identical to those described recently from other porphyry systems, despite major difference in formation time and geological setting. Just as paragenetic studies have long revealed consistent sequences of overprinting vein assemblages, trace element and textural studies of quartz, revealed by EPMA and CL, appear to support the idea that a common sequence of quartz crystallisation exists at least for the earliest vein stages (Q1-Q3). Detailed understanding of the strongly heterogeneous distribution of trace elements within a paragenetically complex series of quartz generations assists in understanding the processes involved in the early evolution and mineralisation in porphyry copper systems.

The discovery history of epithermal gold-silver deposits in the Haenam District, South Korea

Kirwin, D.J.[1*], Spadafora, M.J.[2], Sennit, C.M.[2], Kim, W.J.[2], Panther, C.[1], Forbes, M.[2], Rovillos, P.[2], Lograsso, J.[2] & Morales, N.[1]
[1]Ivanhoe Mines Ltd., Phathumthanee, Bangkok, Thailand

[2]Independent Consultants

Gold mining in Korea dates back more than 3,000 years and most primary production has been from mesothermal quartz vein deposits associated with Jurassic or Cretaceous granites. Initial interest in the prospectivity for epithermal precious metal deposits in South Korea commenced with the release of the Atlas of Mineral Resources by the United Nations ESCAP division in 1987. Detailed metallogenetic maps included in the Atlas showed both widespread, numerous gold occurrences and many hydrothermal clay deposits. While the clay deposits did not feature as gold occurrences, the alteration assemblages were described as being composed of silica, alunite, dickite and pyrophyllite. Furthermore many were hosted in Cretaceous to Early Tertiary volcanic rocks. A field evaluation of all the known clay deposits commenced in 1988 and this demonstrated that some of the clay deposits were indeed related to both high and low sulphidation epithermal systems, especially in the Haenam district in the south west part of the country. A field inspection of the Tongyeong gold-silver deposit which was still operational in 1988 also clearly confirmed the presence of an epithermal deposit in South Korea. Prospecting continued intermittently from 1988 to 1993 resulting in gold discoveries at the Seongsan and Gasado Island clay. The main vein at Gasado Island, called the Lighthouse vein was actually first recognized in 1988 from offshore while traversing the southern part of the island by boat. A very large prominent hill on the mainland, known as Ogmaesan comprises alunite-pyrophyllite-dickite-pyrite altered volcanics, however despite the intense high sulphidation alteration it appears to be unmineralised.

The epithermal potential of South Korea was followed up in earnest by Ivanhoe Mines (formerly Indochina Goldfields) from 1994 to 2000 and this lead to additional gold discoveries at Kohung, Dogcheon, Moisan, Eunsan and Chunsan; all in the Haenam district where there was no previous knowledge of precious metal mineralisation. Bonanza complex Au, Ag, Te, Se mineralization encountered at Eunsan was mined by Ivanhoe from 2001 to 2003 and subsequently by a Korean company who are currently mining at Eunsan and Moisan. The discovery of the epithermal gold-silver deposits in southwestern South Korea may be attributed to conceptual geological thinking, subsequent field validation, persistent and systematic prospecting by a team of dedicated field orientated geologists. It is concluded that additional epithermal gold-silver deposits will be found in the southern part of South Korea.

Native minerals found in the Baogutu gold deposit, west Junggar (Xinjiang, NW China)

An Fang & Zhu Yongfeng*
School of Earth and Space Sciences, Peking University, Beijing, China (*yfzhu@pku.edu.cn)

The Sb-bearing minerals, usually coexisting with native gold, are common in Sb-Au or Au-Sb hydrothermal deposit. Most of the Au-Sb hydrothermal deposits are mesothermal or epithermal, hosted in black shale or in limestone, as these rocks could contribute enough sulfur [1,2]. Relatively alkaline and slightly reducing hydrothermal conditions provided by limestone favor transportation of Au and Sb are essential for the formation of Au-Sb deposits, while decrease of pH is the major controlling factor for co-precipitation of stibnite and native gold [3]. Sulfur activity might play an important role in the co-precipitation of native gold and antimony minerals (stibnite, berthierite) in the intrusion-related gold system [4]. Native antimony generally coexists with native gold or aurostibite in gold deposit [4]. It is scarce to find native antimony coexisting with stibnite, because their stable fields are separated by berthierite field. Here we describe antimony minerals (stibnite, ullmannite, native antimony, tetraedrite) coexisiting with native gold, found in the Baogutu hydrothermal gold deposit (west Junggar, NW China).

The west Junggar is an important constituent of the central Asian metallogenic region [5], which is characterized with occurrence of several ophiolite belts, contacting with the Lower Carboniferous volcanic-sedimentary strata (LCVS) via faults. The LCVS is mainly composed of coarse tuff sandstone with alternating layers of tuff, tuff siltstone with basalt and siliceous locally. Post-collisional granitic plutons with ages of 295-310 Ma [6] intruded into the LCVS.

One medium-sized copper deposit formed in the porphyry body. Molybdenite separated from this porphyry copper deposit was dated to be 310Ma by Re-Os method [7]. The Baogutu gold mine, occurring 15km SW from the porphyry copper deposit, is a typical hydrothermal gold deposit hosted in the LCVS. The tuff and tuff siltstone are the wall-rocks of most gold-bearing quartz-sulfide veins. Most of the gold-bearing quartz-sulfide veins are lensoid or ribbon-like. Some veins reach 400 m in depth with length of 10m to 150 m and thickness of 0.5m to 3m in plane. More than twenty gold-bearing veins are exposed on the surface, while the buried lodges are the major ore-bodies mined presently. The NNE-trending faults (F_4) controlled the distribution of the gold-bearing quartz-sulfide veins and diorite dykes, while the F_5-F_6 faults cut through most of these veins and dykes.

The ore-forming process of the Baogutu gold deposit can be divided into three paragenetic stages based on the cross-cutting relationships and mineral assemblages. Gold-bearing fine-grained quartz-sulfide veins, formed at stage II, cross-cut the coarse-grained quartz-sulfide veins formed at stage I. Native antimony-bearing calcite veins, formed at stage III, always cut through the mineral assemblages formed at stages I and II.

Hydothermal alteration related to the formation of the Pb-Zn-Ag deposit Crnac, Mts. Rogozna

Borojević Šoštarić, S.[1*], Palinkaš, L.A.[1] & Neubauer, F.[2]
[1]Dept. of Mineralogy and Petrography, University of Zagreb, Croatioa (*sborojsost@geol.pmf.hr)
[2]Dept. of Geography and Geology, University of Salzburg, Austria

Pb-Zn-Ag deposit Crnac, Western Vardar zone is a structurally controlled deposit, composed of vein type mineralization hosted by Jurassic amphibolites terminating into overlying serpentinites of the same age, and listwaenite type of mineralization developed along serpentinite-amphibolite interface (Fig. 1).

Ore is deposited subsequent to injection of the quartz porphyry dykes into the Jurassic amphibolites and serpentinites at 28.9±0.3 Ma within several stages: *(i) porphyry stage* commencement with the pervasive propylitic alteration within amphibolites and quartz porphyry dykes, causing break down of amphibole and formation of a chlorite-epidote-actinolite-magnetite mixture, whereas some of the plagioclase are altered to albite-oligoclase. *(ii)* Priori and synchronous with the deposition of the *pre-ore stage*, composed of pyrite, arsenopyrite, pyrhottite, quartz and kaolinite, pervasive sericitization (sericite-quartz-pyrite assemblage) affected host amphibolites and quartz porphyry dykes, and is dated at 28.6±0.5 Ma. Pervasive and veinelets type silification is also widespread within amphibolite hosts, whereas kaolinitization predominantly occur as veins banding or breccia clasts within veins and listwaenite type of mineralization. Kaolinite is also found within the matrix of the quartz porphyry dykes. Magnetite-pyrite intergrowth occurs at the closing stages of the pre-ore deposition. *(iii) Syn-ore stage* deposited massive galena and sphalerite together with tetrahedrite, chalcopyrite and stefanite, as massive veins bending or listwaenite breccia matrix. *(iv) Post-ore stage* deposited predominantly carbonates banded with negligible amount of pyrite, arsenopyrite or galena. Open space filling in vugs, cavities and geodes, colloform and comb textures are often found. Within host amphibolites and quartz porphyry dykes carbonatization is recognized as vinelets and matrix infill.

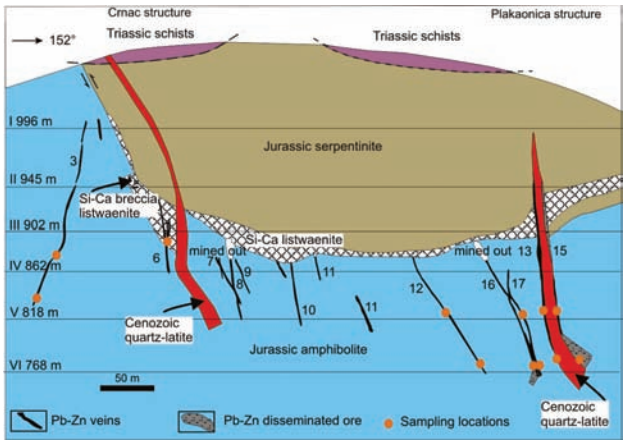

Fig. 1: Geological cross-section of the Crnac Pb-Zn-Ag deposit (modified after [1]).

The origin of hydrothermal fluids in the Kumarlar Pb-Zn veins, Çanakkale, NW Turkey

Bozkaya, G.[1*] & Celik, S.[2]
[1]Dept. of Geological Engineering, Cumhuriyet University, Sivas, Turkey ([*]gbozkaya@cumhuriyet.edu.tr)
[2]Dedeman Mining Group, İstanbul, Turkey

Kumarlar (Çanakkale) lead-zinc mineralization is the typical example of lead-zinc deposits occurred in the Tertiary volcanic rocks, outcropped in the Biga Peninsula [1]. Ore veins along the fault zones in the tuffs contain mainly galena and sphalerite, and minor amounts of pyrite, chalcopyrite, fahlerz (tennantite), marcasite, chalcosine, covelline, bornite, tenorite and quartz. Fluid inclusion and stable isotope (O, S) studies were investigated on the sulfur and quartz minerals, to determine of the origin of hydrothermal fluids.

T_{FM}, Tm_{ICE} and T_H values, measured during fluid inclusions within the quartz, indicate the presence of $CaCl_2$ and $MgCl_2$ types of salts in the mineralizing hydrothermal solutions. The salinity of the hydrothermal solutions is 15.8 (% NaCl *eqv.*) during sphalerite crystallization in the early episode of mineralization, while % 18.5 (% NaCl *eqv.*) during the quartz crystallization of the later episode of mineralization. T_H values, obtained from the fluid inclusions within the sphalerite and quartz crystals, show that the sphalerite and quartz were formed in the temperature ranges of 238.6-263.5 and 247.2-281.4 °C.

$\delta^{18}O$ values of water in equilibrium with quartz are in the range of -6.14 – 8.36 ‰ SMOW, and suggest that the ore fluids were originated from both meteoric and magmatic waters (Fig. 1a). Relatively higher temperature values are found in quartz with probably magmatic origin, collected from deeper parts of the veins. In contrary, the lowest values are detected in quartz with meteoric origin, collected from shallow parts of the veins. In other words, $\delta^{18}O$ values increase with the increasing temperatures (Fig. 1b).

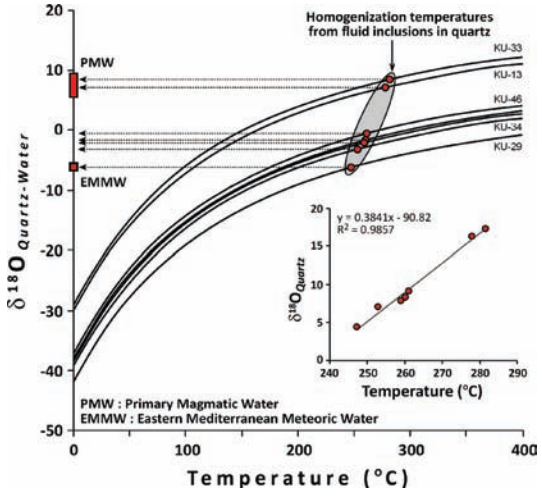

Fig. 1: (a) Oxygen isotope vs. temperature curves of the quartz samples, calculated from quartz-water fractionation [2]. **(b)** Regular variations of oxygen isotope and temperature values in quartz.

$\delta^{34}S$ values of galena (-10.41 to -6.28, mean -7.6 ‰) suggest that the sulfur was reduced from sulfate (SO_4^{2-}) from the sea water or sulfate minerals in the sedimentary rocks by bacterial or inorganic processes. According to sulfur isotopic fractionation during the reduction sulfate in closed systems and age curves of sulfur isotope in marine sulfates [3], sulfur could be leached from the Triassic sedimentary basement rocks.

A statistics-based method for the short-wave infrared (SWIR) spectral analysis of altered rocks: an example from the Acoculco caldera, eastern Trans-Mexican Volcanic Belt

Canet, C.[1], Arana, L.[2], González-Partida, E.[3], Pi, T.[4], Prol-Ledesma, R.M.[1], Franco, S.I.[1], Villanueva-Estrada, R.E.[1], Camprubí, A.[4] & López-Hernández, A.[5]
[1]Instituto de Geofísica, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, México D.F., Mexico
[2]Posgrado en Ciencias de la Tierra, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, México D.F., Mexico
[3]Centro de Geociencias, Universidad Nacional Autónoma de México, Campus Juriquilla, Santiago de Querétaro, Qro., Mexico
[4]Instituto de Geología, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, México D.F., Mexico ([*]camprubitaga@gmail.com)
[5]Gerencia de Proyectos Geotermoeléctricos, Comisión Federal de Electricidad, Morelia, Michoacán, Mexico

We propose a simple graphic and statistical method for processing of SWIR reflectivity spectra of alteration minerals. It generates a classification of the spectra according to its shape and absorption features, thus obtaining groups of spectra equivalent to mineral assemblages. It also permits to select a reduced number of samples for further mineralogical verification. This method uses the SWIR spectra without hull subtraction. The first step is to normalize the spectra reflectivity to 100 % at maximum. In order to reduce the reflectance dataset, a decimation filter is used, obtaining one value each 10 nm. Subsequently, a cluster analysis, using as input data the decimated reflectance values for each sample, results in a dendrogram that allows deducing assemblages of SWIR active minerals.

The effectiveness of this methodology is illustrated with a study of the Acoculco Caldera, which is a geothermal prospective area. Two major zones of alteration have been recognized: an upper of ammonium illite, and a lower with epidote-chlorite-calcite. Four additional assemblages have been deduced: (a) buddingtonite and (b) smectite, in the recent volcanic sequence, and (c) calcite marble and (d) granitic rocks, in the Mesozoic basement. The upper alteration zone reaches a depth of 500-600 m, affecting most of the caldera sequence. It consists in a pervasive ammonium-argillic alteration of ignimbrites and dacitic lavas. Although ammonium illite is the main alteration mineral, kaolinite, buddingtonite and smectite locally occur at depths up to 300 m. The occurrence of ammonium silicates suggests temperatures above 200ºC. There is a correspondence between the abundance of ammonium minerals and the total nitrogen content of the rocks. The highest value (0.653 N wt.%) corresponds to a sample rich in buddingtonite. Ammonia probably derived from the organic matter-rich Mesozoic sedimentary series underlying the caldera.

The Zn-Pb-Ag skarns of Zacatepec, Northeastern Oaxaca (Mexico): a study of mineral assemblages and ore-forming fluids

Canet, C.[1], Romero-Guadarrama, J.A.[2], Sánchez-Vargas, L.I.[2], Camprubí, A.[3*], Castro-Mora, J.[4,5], González-Partida, E.[6], Martín Romero, F.[3], Prol-Ledesma, R.M.[1] & Linares-López, C.[1]

[4]Posgrado en Ciencias de la Tierra, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, México D.F., Mexico

[5]Facultad de Ingeniería, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, México D.F., Mexico

[6]Centro de Geociencias, Universidad Nacional Autónoma de México, Campus Juriquilla, Santiago de Querétaro, Qro., Mexico

The Zn-Pb-Ag skarns of Zacatepec are located in the eastern Sierra Madre del Sur, southern Mexico. They are hosted by the Cuicateco Terrane, which is composed of deformed Jurassic and Cretaceous volcanic and sedimentary rocks deposited in an arc environment, which also hosts several precious- and base-metal epithermal deposits and Cu-Mo occurrences. The mineralization occurs as irregular masses along the contact between Cretaceous limestones and Tertiary porphyritic dacites. Over widths of few decimeters, an epidote-rich ($Ep_{44–97}Czo_{01–55}Pie_{00–03}$) endoskarn is developed. For the most part, the mineralization consists in skarns of calcic garnet ($Adr_{62–22}Grs_{78–38}$) with disseminated hematite. Calcic garnets show chemical oscillatory zonation. Skarns rich in calcic clinopyroxenes ($Di_{28–54}Hd_{22–55}Jh_{07–32}$) locally occur, farther from the porphyry contact. As a result of a retrograde mineralizing event, the above assemblages are locally silicified, and chamosite and ore minerals (sphalerite, galena and chalcopyrite with subordinate amounts of scheelite) deposited. The iron contents in sphalerite range between 5.0 and 9.4 mol % FeS. A later association of bismuth sulfosalts consists of vikingite and an Ag-Bi-S phase akin to the aikinite group. Locally, magnesian skarns develop and are composed of almost pure diopside ($Di_{98–100}Hd_{00–01}Jh_{00}$), clinochlore, chrysotile, and vesuvianite that is extremely rich in Ti (6.48 to 7.93 wt. % TiO_2). The magnesian skarns have the highest metal grades, up to 595 g/t of Ag in an ore-rich sample. After weathering of the ores, botryoidal crusts of supergene minerals as smithsonite, rosasite and hemimorphite developed. Microthermometric studies of fluid inclusions were carried out in calcite, calcic garnet, quartz and sphalerite. Homogenization to the liquid phase occurred between 335º and 470ºC. Salinities were calculated assuming a H_2O-NaCl system and range from 11.7 to 16.0 wt % NaCl eq. The temperature of formation of the prograde skarn, calculated from microthermometric data, for an assumed pressure of 500 bar, ranges between 470º and 510ºC. A slight increase in fO_2 caused the formation of garnet form after clinopyroxene. The formation of the retrograde assemblage implies a temperature drop down to 350º to 405ºC coupled with a great increase in fO_2. These changes can be explained by boiling followed by mixing with cooler and dilute meteoric water.

Occurrence of the colusites-(Sn) at the ore-body „T“ of the Bor copper deposit (Serbia)

Cvetković, L.[*], Pačevski, A. & Tončić, T.

Faculty of Mining and Geology, University of Belgrade; Serbia

RBB – Cooper Mines Bor, Serbia

([*]cvetkovicljub@yahoo.com)

The ore body „T“ is the newly discovered one which is located in the central part of the Bor copper mine, in the vicinity of the ore bodies F1, F2 and famous Tilva Roš. It belongs to the massive-pyrite ore bodies group, passing gradually into the stockwork and porphyry-copper types, at the outer parts. The most abundant copper minerals are chalcocite-digenite and some less covellite, followed by lesser amounts of enargite, bornite and chalcopyrite. Galena and sphalerite appear in very small amounts, in thin veinlets which intersect all previously formed mineral aggregates. The gangue minerals are silicifying quartz, veinlets of anhydrite, gypsum and calcite, as well as the traces of fluorite

Common microscopic investigation of the samples of the drilling-cores from this ore-body revealed the frequent presence of the minerals of the colusite group, which occur in single grains, or in rare aggregates, up to 0.5 mm approximately. They appear in irregularly shaped and oval grains, or rare in deformated crystals, displaying moderate reflectivity and creamy-yellowish colour of the reflected light. Sometimes, a weak anomal anisotropy of these grains could be observed. The grains-aggregates of colusite usually overgrowth the covellite grains, or are embeded in the chalcocite-digenite aggregates. These minerals are accompained by the single grains-crystals of a mawsonite-like mineral, occurring in traces

The minerals of the colusite group in this ore-body were analysed by SEM-EDS by using JEOL JSM-6610LV instrument located at the Belgrade University, Faculty of Mining and Geology. The analyses yielded the compositions of investigated minerals, whose calculated formulae ranged from

$$Cu_{24.93}V_{1.72}As_{4.63}Sb_{0.20}Sn_{0.84}S_{31.86}$$ to

$$Cu_{23.74}V_{2.03}As_{3.85}Sn_{2.16}S_{32.21},$$

what confirmed that the most of the present colusites belong to the stannocolusite variety. Also, the analyse of the single-grain occurring mineral gave the formula $Cu_{15.99}Zn_{1.87}Fe_{3.87}Sn_{3.90}S_{24.39}$, what verify the presence of the mineral stannoidite. This is the first appearance of this mineral in the Bor copper mine and in Serbia, generally.

Illite and kaolinite in the Coranda low sulphidation type epithermal deposit, Apuseni Mts., Romania

Gál, Á.[1*], Kristály, F.[2], Szakács, A.[3], Molnár, F.[4] & Weiszburg, T.G.[4]
[1]Dept. of Mineralogy, Babeş-Bolyai University, Cluj-Napoca Romania ([*]agi.gal@ubbcluj.ro)
[2]Inst. of Mineralogy and Geology, University of Miskolc, Hungary
[3]Dept. of Environmental Science, EMTE-Sapientia University, Cluj-Napoca, Romania
[4]Dept. of Mineralogy, ELTE University, Budapest, Hungary

The Coranda (Certej deposit) low sulphidation type epithermal ore deposit is located at the southeastern part of the Neogene Brad-Săcărâmb inter-mountain basin, NW from the more famous Săcărâmb ore deposit, in the Apuseni Mts., Romania.

Polarizing optical microscopy observations and X-ray Powder Diffraction investigations were performed on whole-rock specimens. Interstratified smectite content was tested by powder specimen ethylene-glycol saturation. Most of the samples with >10 Å basal spacing values did not show any interstratified smectite content. Samples showing high degree of sericite – quartz phyllic alteration were selected for Scanning Electron Microscopy (SEM) and Energy Dispersive Spectrometry (EDS) investigations. Kaolinite group minerals are associated to these types of phyllic alteration products, with degree of crystallinity varying on a large scale. Peak broadening is directly proportional with the value of basal spacing. Mica-type, dioctahedral clay mineral ($d_{(060)}$~1,500 Å) was detected with ~10.040 Å basal spacing during random powder specimen diffraction. This phase is intrinsically associated to ~7,400 Å halloysite with poor degree of crystallinity. Characteristic paragenesis is given by sanidine (adularia), pyrite, anatase and jarosite (Fig. 1). Aluminium-phosphate-sulphate minerals occasionally occur, with cationic and anionic substitution between large limits and micrometric scale.

Thermal Analysis with simultaneous Differential Thermal Analysis (DTA), Thermogravimetry (TG) and Derivative Thermogravimetry (DTG) revealed the devolatilization of clay minerals in more small reactions. DTA at 126°C and 185°C is with two-stepped DTG, and at 595°C and 713°C with continuous weight loss and no DTG peak.

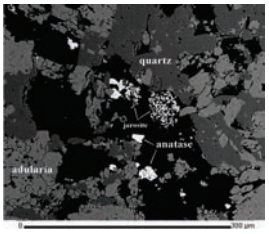

Fig. 1: General composition of phyllic alteration paragenesys (Back-scattered electron image, 40kv, 15nA).

K-deficiency and absence of other cations and smectite layers suggests the presence of NH_4 in the interlayer space. Higashi [1] gives a correlation of 0.1 – 0.15 NH_4 ratio in the interlayer for 10.040 Å spacing. EDS investigation proved the absence of Fe, Mg, Ca and Na from the illite. The intrinsic intergrowth of halloysite – illite, and K-deficiency of the mica structure is supported by the double Si+Al/K ratio of analyzed spots compared to the theoretic value.

Anatase is mostly present in euhedral or anhedral grains, no shift in composition towards Fe-Ti oxides is observed. Pyrite shows strong alteration, and the presence of a secondary, micrometric unaltered generation is characteristic.

Low-sulfidation Eusan (Se-type) and Moisan (Te-type) epithermal gold-silver deposits, Korea

Kim Chang Seong, Choi Chang Seong[*] & Koo Minho
Dept. of Earth and Environmental Sciences, Korea University, Seoul, Republic of Korea ([*]seongyu@korea.ac.kr)

The epithermal gold–silver deposits of the Haenam-Jindo Basin, located on the south-western margin of the Korean Peninsula, occur within the Cretaceous calc-alkaline volcano-tectonic depressions and calderas, confined to rifts within magmatic arc environment. Veins of the Eunsan and Moisan deposits are mostly hosted by felsic pyroclastic rocks. The ore mineralogy of these veins is characterized by the dominance of silver-arsenic-antimony sulfosalts with silver selenides and tellurides over argentite. However, mineralogical differences between the Eunsan (e.g., naumanite and aguilarite) and Moisan deposits (e.g., petzite, sylvanite, frohbergite, goldfieldite, native tellurium, altaite, tellurobismuthite and mackayite) appear to reflect their intrinsic geochemical characteristics.

The K–Ar ages of adularia from the Eunsan deposit and adularia and sericite from the Moisan deposit are 75.0 ± 1.6, 74.7 ± 1.6 and 75.1 ± 1.6 Ma, respectively [1]. The similarity of these ages, combined with the close proximity and similar geochemical characteristics of the deposits, indicates that the mineralization occurred as part of a single hydrothermal system. Based on their ore and gangue mineralogy, geochemical signatures and stable isotope data, the Eunsan (Se-type) and Moisan (Te-type) veins might have resulted from different parts of the same geothermal system. The Eunsan and Moisan deposits were formed at shallower crustal levels (<0.5 kbar) and relatively lower temperature (<300°C) conditions from the hydrothermal fluids containing large components of less-evolved meteoric waters.

The systematic mineralogical and geochemical differences can be explained by variations of the physicochemical conditions existed during the gold-silver deposition. The alteration, ore and gangue mineralogies of the Au-Ag deposits are typical of the adularia-carbonate-sericite (low-sulfidation) class of volcanic-hosted epithermal deposits. This implies that the physicochemical conditions of the Moisan deposit exhibit mineral assemblages deposited closer to the heat source than those of the Eunsan deposit.

Biely vrch Au-porphyry deposit, Slovakia: a new economic mineralization type in the Carpathian volcanic arc

Koděra, P.[1*], Lexa, J.[2], Bakos, F.[3], Biroň, A.[2], Fallick, A.E.[4], Fuchs, P.[3], Hanes, R.[3] & Žitňan, P.[3]
[1]Dept. of Geology of Mineral Deposits, Comenius University, Bratislava, Slovakia ([*]kodera@fns.uniba.sk)
[2]Geological Inst., Slovak Acad. of Sciences, Bratislava, Slovakia
[3]EMED - Slovakia, s. r. o., Banská Štiavnica, Slovakia
[4]Scottish Universities Environmental Research Centre, UK

Biely Vrch deposit represents a new economic Au-porphyry type of mineralisation discovered recently in Slovakia by EMED Mining company. The deposit is located in the central zone of the Neogene Javorie stratovolcano and shares many properties typical for Au-porphyry deposits. Mineralization extends to a depth of at least 450 m. Resource estimation stands at 140.2 Mt geological resources (JORC inferred category) with average grade 0.57 g/t Au using 0.3 g/t cut-off [1].

Parental diorite to andesite porphyry stock 300x400 m in diameter and surrounding andesite are affected by extensive alteration. Intermediate argillic (IA) alteration (Ill-Sme, Ill, Chl, Ep, Py) variably overprints earlier high-T K-silicate (Kfs, Bt, Mag) and Ca-Na silicate (An-rich Pl, Act) alteration in deeper levels of the system. Propylitic alteration represents outer zone of the system (Ill-Sme, Chl-Sme, Chl, Qtz, Py). Ledges of advanced argillic (AA) alteration (Kln, Dic, Prl, Alu, Dsp, vuggy Qtz) are the youngest stage of alteration, probably related to a younger intrusion at depth. Alterations are accompanied by several generations of hydrothermal-explosive breccias and veinlets. They involve the oldest Bt-Mag veinlets (EB-type) associated with K-silicate alteration and several generations of widespread Qtz veinlets including A-type (Qtz ± Bt-Mag) and later banded veinlets. Younger Py veinlets (± rare Ccc, Mrc, Gn, Sp, Mo) and coeval IA veinlets (Chl, Ill-Sme, Py) are affiliated to IA alteration. Carbonate-zeolite and AA veinlets are the youngest veinlets types. Gold grains are of high fineness (875-994) and occur next to Qtz veinlets in altered rock with Ill, Ill-Sme, Chl and Kfs, sometimes attached to sulphides or Mag [2].

Vapor-rich fluid inclusions (FIs) dominate in vein quartz, locally accompanied by Fe-rich brine inclusions (>70 wt% total salts, Th > 600°C). They are interpreted to result from fluid immiscibility of hot magmatic fluids associated with shallow emplacement of dioritic magma. Vapor FIs also dominate in later quartz veinlets with banded texture, derived from former silica colloid due to rapid fluid decompression. Rare associated liquid-rich FIs (mostly 0-5 wt% NaCl eq., Th 230–260°C) represent a later fluid, likely resulting from condensation of the low density fluid and associated with IA alteration [3].

Oxygen isotope data from vein quartz (7.6-12.4 ‰ $\delta^{18}O$) indicate a strong magmatic signature of associated fluids. Ill-Sme equilibrium fluids (-0.5 to -0.1 ‰ $\delta^{18}O_{fluid}$, -76 to -87 ‰ δD_{fluid}) were rich in meteoric component. Fluids in equilibrium with Kln and Prl (2.1 to 5.2 ‰ $\delta^{18}O_{fluid}$, -55 to -84 ‰ δD_{fluid}) and S isotope data of Alu ($\delta^{34}S$ 10.6-15.6) are consistent with magmatic-hydrothermal source of these latest fluids and S [3].

Gold was introduced into the system probably in bisulfide complexes in vapor during the emplacement of quartz veinlets and precipitated due to reaction of fluid with Kfs (effective H^+ sink) and Fe-oxides (effective for de-sulfidation) in the regime of rapid fluid decompression. Several Au generations with different fineness point to multiphase introduction of Au and its remobilisation mainly during the stage of AA alteration.

Mineralogical, petrological and fluid inclusion study of the Brehov ore deposit (Eastern Slovakia)

Molnár, F.[1], Molnár, L.[1*] & Bačo, P.[2]
[1]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]luismoloar@gmail.com)
[2]Štátny geologický ústav D. Štúra, Košice, Slovakia

We have analyzed drillcore (VSB-2 and VSB-2a) and surface samples from the buried base metal ore deposit near Brehov. The samples were divided into four lithological groups: rhyodacite, hydrothermal breccias, pyroclastics, diorite. The rhyodacitic samples are heavily altered to illite-sericite, while kaolinite is the product of steam heated acid-sulfate alteration in pyroclasics. The ore forming minerals occur in stockwork and veins (sphalerite, galena, pyrite, hematite). The gangue minerals are quartz together with barite in pyroclastics and rhyodacite and with calcite in diorite. Results of fluid inclusion study which was carried out on quartz samples show that boiling occurred at different depths of the same palaeohydrological system, and thus the 10 wt% NaCl boiling curve can be fitted to the location of samples from various depths. This data shows that we can count about 200 meters of erosion in relation to the paleogroundwater table. Compared to the Tokaj Mts., the age of the volcanic rocks and mineralization fits into the trend observed in the Tokaj Mts., where hydrothermal centres exposed on the surface are progressively younger towards south. Fluid inclusion data for the Brehov deposit show similar salinity as fluids in the transitional zone between the porphyry and epithermal mineralization in the Zlatá Baňa stratovolcano. According to these results, a base metal sulfide rich low sulphidation type epithermal mineralisation is present near Brehov and the hydrothermal system can be connected to the subvolcanic diorite intrusions of the area.

Variety in texture and chemical composition of pyrite from the Čoka Marin polymetallic deposit, Serbia

Pačevski, A.* & Šarić, K.
Faculty of Mining and Geology, University of Belgrade, Serbia
(*aleksandar.pacevski@gmail.com)

The Čoka Marin polymetallic (Cu-Au-Ag-Zn-Pb) deposit belongs to the world-class Bor ore district which is situated in eastern Serbia. This ore district is one of the major ore deposit clusters along the Late Cretaceous Banat-Timok-Srednogorie belt with abundant porphyry-copper and associated high-sulfidation epithermal deposits [1]. The Čoka Marin deposit consists of three volcanic-hosted orebodies which are composed predominantly of pyrite and barite. Other common minerals in the deposit are enargite, luzonite, chalcopyrite, bornite, sphalerite, galena and marcasite. The deposit contains relatively high contents of Au and Ag, however, native gold (enriched in silver) is the only mineral of these precious metals and it rarely occurs. This deposit shows many features typical for high-sulfidation epithermal deposits.

Pyrite from the Čoka Marin deposit displays great variety in texture and minor and trace element contents of Cu, Pb, As, Ag, Sb. It occurs mainly as fine- to coarse-grained, with a grain size from 50 μm to 5 mm and variable crystal shapes from irregular to idiomorphic. Irregular pyrite masses often admixed with minor amounts of other minerals are also common. Then, pyrite partly occurs as spongy pyrite, generally showing a yellow brown color (due to minor contents of Cu), framboidal pyrite and colloform pyrite. Pyrite replacement of phenocrysts in the volcanic rock and some ore minerals (luzonite and enargite) was also noticed. Pyrite oolits and the distinct shapes of pyrite which could be interpreted as pyritized microfossils, suggest that the mineralization was partly hosted by the sediment rocks. Chemical zoning and variable contents of Cu, As, Pb, Ag, and Sb, measured by Electron Microprobe Analysis (EMPA), are generally present in all textural varieties. Copper is almost always present in pyrite in concentrations up to 8 wt.% Cu. Solid solution of Cu in pyrite was proved by EMPA, micro-Raman spectroscopy and X-ray diffraction [2]. Pb-bearing zones (up to 7 wt.% Pb) in pyrite frequently occurs (Pačevski et al., in prep). These zones often contain minor amounts of As (up to 2.5 wt.%), sometimes Cu and Ag, and rarely Sb. Arsenian pyrite (3-4 wt.% As) occurs in colloform forms and replacement textures. Silver is occasionally present in the studied pyrites, with concentrations up to 1 wt.% Ag. Sector zoning in some pyrite grains is caused by silver distribution.

Regarding that pyrite is generally the most abundant sulfide in the ore deposits and that this mineral represents a waste component during a mine processing, incorporation of Cu, Pb, Ag and As as trace and minor elements in pyrite could have implications for utilization of the ores and for environmental questions. Further, as the Čoka Marin deposit shows general features of the high-sulfidation epithermal deposits, this study emphasizes the question about variety of pyrite texture and minor and trace elements contents in pyrites from this important type of the deposits.

Relationships of rhyolite magmatism and epithermal systems in the Central Slovakia and Tokaj Mts. regions of the Western Carpathians: K/Ar dating of volcanic and hydrothermal processes

Pécskay, Z.[1], Lexa, J.[2*] & Molnár, F.[3]
[1]Institute of Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary
[2]Geological Inst., Slovak Academy of Sciences, Bratislava, Slovakia (*geoljalx@savba.sk)
[3]Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary

Middle-Upper Miocene (Sarmatian-Pannonian) low to intermediate sulfidation epithermal systems of Central Slovakia (Banská Štiavnica, Kremnica, Pukanec, Nová Baňa, Banská Belá) and the Tokaj Mts. region (Telkibánya, Füzérradvány, Mád) are variably hosted by andesitic and rhyolitic volcanic complexes. While in Central Slovakia rhyolitic volcanism concludes evolution of major andesitic stratovolcanoes, in the Tokaj Mts. rhyolitic and andesitic volcanic formations alternate in the bimodal type of suite, often with well defined rhyolitic eruption centers of the dome/flow type.

In Central Slovakia, epithermal systems evolved at horst-related fault systems that post-date andesitic volcanism, rhyolite dykes are emplaced along the same faults and such dykes are affected by adularization and/or argillization. K/Ar ages of rhyolites (whole rock, groundmass, biotite) and early epithermal mineralization (adularization) overlap in a narrow interval of time and are coeval at all mentioned districts (Table 1).

In the Tokaj Mts., there are several stages of andesitic-rhyolitic volcanic activity and related hydrothermal mineralization (Table 2). Hydrothermal activity occurred in three major periods between 12.5 – 12.2 Ma, 11.9-11.5 Ma and around 10.9 Ma. In studied areas andesites are altered and pre-date rhyolite volcanic activity that appears to be coeval with epithermal systems.

Apparently, high-level rhyolite magma chambers, rather than andesitic ones, play an essential role in evolution of epithermal systems of the Western Carpathians. K/Ar ages of hydrothermal activity in the Central Slovakia Volcanic Field and in the Tokaj Mts. overlap, implying interval 12.5 – 11.0 Ma as a peak period of hydrothermal activity in the Western Carpathians. This suggests that large scale regional processes have also been involved in development of hydrothermal systems in addition to the local volcanic/magmatic control. Considering that faults controlling hydrothermal fluid flow are equivocally N-S oriented in both districts, this regional factor appears to be the extension that developed due to the coeval westward subduction in the Eastern Carpathians.

Native copper ore-bearing formation

Rudenko, K.V.[1*], Derevska, K.I.[2] & Shumlyanskyy, V.O.[3]
[1]Institute of Geological Sciences of National Academy of Sciences of Ukraine, Kyiv, Ukraine ([*]rena-li@ukr.net)
[2]National Museum of Natural History of National Academy of Sciences of Ukraine, Kyiv, Ukraine
[3]Institute of Fundamental Studies of National Academy of Sciences of Ukraine, Kyiv, Ukraine

Native copper ore-bearing formation in basic volcanic rocks and sedimentary rocks, which associated with them, is well known. The oldest occurrences of it are deposits in Western Australia with age near 3000 Ma. Native copper occurrences of Kola Peninsula are associated with basalts, trachybasalts, tuffolavas, tuffs and tuffites of Proterozoic [1]. There are two Riphean examples of this formation in North America: the Michigan ore district (1640-880 Ma) [2], which is the most well known representative of this formation, and area of native copper mineralization in North Western part of Canada (1200 Ma). Native copper deposits and occurrences were discovered in basalts and tuffs, which are referred to Vendian continental flood basalts, of the Volyn region in Ukraine (550 Ma). Paleozoic native copper ore-bearing formation occurrences were reported in basic volcanic rocks of the Kuznetst Alatau (Russia), the Novaya Zemlya, in basic mandelstones in Europe and in upper part of Yunnan flood basalts (China). Mesozoic native copper occurrences known in trap of Western Siberia and in basic volcanic rocks of the Novaya Zemlya, the Korean Peninsula and in other regions. There are some examples of Cenozoic representative of native copper ore-bearing formation, which are situated in Peru, Azerbaijan, the Solomon Islands. The modern native copper-bearing lavas, which erupted from Kilauea (Hawaii), was reported in 1963 [1,3,4].

In addition, native copper ore-bearing formation of Volyn region is considered in detail below. Within the Volyn region, sedimentary rocks of the Riphean polesie are altereted to medium catagenesis substage while Vendian continental flood basalts of the Volynian series that overlie Polesie sediments have experienced chlorite-zeolite alternation that corresponds to an early catagenesis. Alterations of basalts, which related to impact of meteoric water on the hot lava flows, are presented by development of palagonite, opal, and oxidation of magnetite. These processes led to initial phases of copper release and to formation of copper aggregates and of palagonite. Further alteration of the Volynian flood basalt is replacement of low-temperature mineral associations by moderate-temperature ones. This might be caused by the heating due to magma intrusion at the end of flood basalt sequence formation. Underground waters resided in the Riphean sedimentary series are considered as ore-forming solutions. After these alterations, almost all areas were subjected to the hydrothermal stage. The richest native copper mineralization localized in the chloride-analcime-quartz zone.

Progressive oxidation of magma in gabbro-granodiorite intrusives in the Cretaceous-Paleogene Inner Zone batholith of southwest Japan - very pure magnetite formation

Yamaguchi, Y.[1*] & Kawakatsu, K.[2]
[1]Dept. of Geology, Shinshu University, Matsumoto, Japan ([*]yoshia_ygutti@d4.dion.ne.jp)
[2]Kakogawahigashi High School, Kakogawa, Japan

Cretaceous-Paleogene granitoids (62-75Ma) [1] of the central San-in district are exposed in large batholiths, composed of various rock-types ranging from gabbro through granodiorite to granite. Small masses of gabbro-granodiorites (0.5-10 km), from which samples were collected for this study, are early-stage intrusives exposed in the Mizawa-Nita area. Field observation shows that, in the intrusives, gabbroic magmas multiply injected into granodiorite magmas and mixed with it and partially mingled to form numerous mafic microgranular enclaves. The intrusive rocks typically contain magnetite (Magnetite-series granitoids) [2], and magnetite is mined from the weathered parts of some intrusives. Very pure magnetite (< 0.02 Wt% TiO_2) commonly occurs coexisting with titanite and quartz under a highly oxidized condition [3].

Pyrrhotite, an early Fe-bearing phase, is found in various occurrences: 1) sulfide inclusions in amphibole; 2) discrete sulfide grains among amphibole and plagioclase; 3) corroded sulfides included in magnetite. On the other hand, magnetite is not early phase.

Initially, just after the mafic magma injection, amphibole began to crystallize together with plagioclase and sulfide, and continually crystallized to form strongly patchy zoning from brownish green pargasitic core to pale green actinolitic-hornblende rim, with a systematic decreasing in $Fe^{2+}/(Fe^{2+}+Mg)$ [4]. Correspondingly, the progressive increase in Fe^{3+}/Fe^{2+} induced the precipitation of magnetite around amphibole. Although this initial magnetite phase (> 1.0 Wt% TiO_2) coexisted with ilmenite, the further continuing Fe^{3+}/Fe^{2+} increasing of the residual magma led to depletion of ilmenite to develop magnetite-titanite-quartz assemblage. Magnetite decreased here in TiO_2 (< 0.02 Wt% TiO_2).

Crystallization trends of these sulfide, amphibole, and oxide indicate that this hydrous mafic magma was progressively oxidized during crystallization on cooling. Some possible mechanisms have been previously proposed for the progressive oxidation of magma during crystallization: 1) hydrogen evolution hypothesis, involving oxygen liberation from the evolved high H_2O/FeO felsic magma at shallow place near the chamber roof; 2) assimilation of oxidized country rocks; 3) oxygen liberation in response to transformation of sulfur species from SO_2 to H_2S on cooling of originally SO_2-rich hydrous magma [5, 6].

The late-stage magnetite formation corresponding to the simultaneous decreasing in Fe^{2+} during amphibole crystallization were likely related to progressive oxidation of iron in magma by sulfur species conversion. Transformation of sulfur species from SO_2 to H_2S probably causes oxidation of iron in the minerals in this hydrous magma on cooling, as suggested in previous models for large sulfur supplies and magma oxidation in subduction related magmatisms [5, 7, 8].

Metal sulfide minerals from deep-seated granitic geothermal reservoir

Yanagisawa, N.
Institute for Geo-Resources and Environment, AIST, Tsukuba, Japan (n-yanagisawa@aist.go.jp)

At Kakkonda geothermal area, Iwate prefecture, north-eastern of Japan, there is a 80MW geothermal power plant using high temperature fluid from the reservoir at the boundary between Quaternary Kakkonda granite and Pre-Tertiary formations about 3km depth. Metal sulfide minerals deposited at production wellhead and pipeline from fluid. These sulfide minerals were collected and analyzed [1].

The scales are classified into two types based on sulfide mineralogy, which are Pb-Zn rich type and Cu rich type. Pb-Zn rich scale is found in Well-19 located at the marginal part of the Kakkonda granite as shown in figure 1. It is mainly composed of amorphous silica, galena (PbS), Sphalerite (ZnS) and Pyrite (FeS_2). Cu-rich scale is found in Well-13, located at the central part of the Kakkonda granite. It is mainly composed of amorphous silica, chalcocite (Cu_2S), bornite (Cu_5FeS_4), loellingite ($FeAs_2$) and native antimony (Sb). It is also rich in Au, Ag, As, Cr, Ni and Mo compared to Pb-rich scale. On progress of production the fluids from deep reservoir suffered by the fluid of shallow reservoir and meteoritic water. And mineral assemblage of scales of Well-13 changed to tetrahedrite ($Cu_{10}[Fe,Zn]_2[As,Sb]_4S_3$). But the ratio of metal composition is almost constant. The metal contents of the scale in Well-22 show intermediate features between the two types of scales.

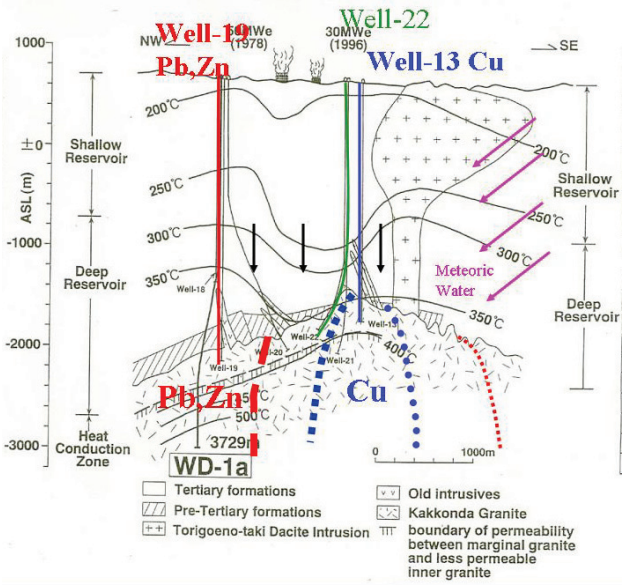

Fig. 1: Schematic geothermal cross-section of the Kakkonda geothermal system including well name and metal in precipitated sulphide and brine in granite.

The brine of WD-1a at 3.7km depth, into Quaternary Kakkonda granite rock underlied Well-19 is rich in Pb and Zn and similar composition as the Well-19 scale [2]. Therefore, deep reservoir of Kakkonda field evolves with mixing the fluid of shallow reservoir and the brine of occurred in the Quaternary Kakkonda granite. Then, the existence of both Pb-Zn rich scale and Cu rich scale is a characteristic feature of Kakkonda geothermal and this fact suggest to have similar zoning as found in Porphyry Copper Zoning.

Te-bearing gold-silver-basemetal mineral deposit of Arinem, Western Java, Indonesia

Yuningsih, E.T.[1*], Matsueda, H.[2] & Rosana, M.F.[3]
[1]Graduate School of Science, Hokkaido University, Sapporo, Japan ([*]etintiny@yahoo.com)
[2]Hokkaido University Museum, Hokkaido University, Sapporo, Japan
[3]Faculty of Geology, Padjadjaran University, Bandung, Indonesia

The Arinem area is located in a part of the Sunda-Banda magmatic arc (well known as gold copper belt) within the Indonesia archipelago at the southern margin of the Sundaland and the Eurasian plate (Fig. 1). The mineralized body is in form of quartz vein trending N140-160ºE for about 5,900m long and 3-5m width, exposed at elevation 365-530m above sea level. The ore body is hosted in andesitic lava, breccias and tuff of the Oligocene-Middle Miocene Jampang Formation. The pyroclastic host rocks mainly suffered of propylitic and argillic alterations and are characterized by the occurrence of chlorite, sericite, kaolinite, and in place by carbonate. Outcrop and drill core samples containing gold-silver are intimately associated with basemetal minerals of copper, lead and zinc. K-Ar dating of sericite associated with the quartz vein indicates a Late Miocene age (8.8±0.3 Ma) for the ore mineralization.

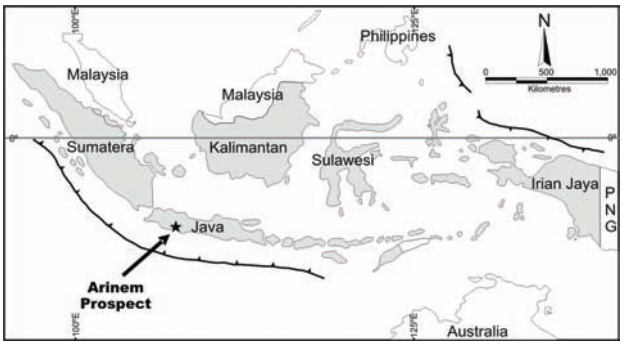

Fig. 1: Map of the Indonesia region, where the location of the Arinem prospect is also indicated by the star with black arrow.

The ore mineral deposition could be categorized into three stages, where stages I and II are Au-Ag bearing, and stage III is barren. The ore mineral assemblages of the deposit consist of sphalerite, galena, chalcopyrite, pyrite, marcasite, arsenopyrite with a little amount of pyrrhotite, bornite, calcocite, covellite, hematite, argentite, electrum and sulfosalt minerals of enargite and tennantite. Some of Te-bearing minerals such as hessite, tetradymite, stutzite, petzite and altaite are observed in the mineralization stage II. The deposit is characterized by low iron content in sphalerite, ranging from 0.25-4.71 wt%. Gold is detected in petzite with the ranges of 14.32-18.32 wt%, while in some hessite and altaite grains up to 1.77 and 0.55 wt%, respectively. Otherwise, up to 1.31 wt% selenium element is detected in tetradymite.

Fluid inclusion studies for quartz of the stages I and II reveal the homogenization temperatures with the ranges of 176.6-325.1ºC and 156.9-311.8ºC, and with the low salinity of less than 4.3 wt% NaCl equiv. in both. Based on the microscopic observation of the occurrences of inclusions there are some boiling phenomena observed. They also tend to show a slight cooling of ore-forming fluids through stages I to II. In the decrease of temperature, it might be followed by both decrease of sulphur fugacity and increase of tellurium one.

Considering the preliminary stable isotopic studies of sulphide and quartz minerals from the deposit, it might be suggested that the mixing of magmatic ore fluids with meteoric water caused the ore precipitation in underground beside of boiling.

Franklin-type mineralization in the Zambesi Metamorphic Belt (Zambia): the Star Zinc and Excelsior willemite prospects

Boni, M.[1*], Terracciano, R.[1] & Gleeson, S.A.[2]
[1]Dipto. di Scienze della Terra, Università di Napoli, Naples, Italy ([*]boni@unina.it)
[2]Dept. of Earth & Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

The Zambian willemite (Zn_2SiO_4) deposits occur in Proterozoic metasedimentary carbonate rocks (Kabwe and Lusaka areas). The Star Zinc and Excelsior prospects (Lusaka area), discovered in the early twenties and since then subjected to sporadic exploration [1], are hosted in the highly metamorphic lithotypes of the late Proterozoic Zambezi Supracrustal sequence, deposited in a transtensional basin formed during the oblique collision of the Kalahari and Congo cratons. In these prospects willemite occurs epigenetically along joints and fissures in the Cheta and Lusaka Fms, consisting mainly of limestone and dolomite marbles, with minor quartz-muscovite schists and feldspathic quartzite. On a local scale, the willemite ore displays open-space filling, colloform and vuggy textures. Structural analysis suggests that mineralization is hosted by two main sets of fractures trending E-W and N-S, the latter being compatible with the Riedel shears related to the pan-African Mwembeshi dislocation zone (a major geotectonic boundary between the Lufilian Arc and the Zambezi Belt).

Willemite is associated with specular hematite and replaces the Zn-spinels franklinite and gahnite. Calcite commonly replaces willemite. The Zn-Be bearing sulfosilicate genthelvite [$Zn_4Be_3(SiO_4)_3S$] occurs as a minor mineral in irregular aggregates and may contain micrometric inclusions of Fe-Sr-Ba-Fe sulfates. Fluorapatite is also recurrent in the mineral association. Thermometric analyses of willemite inclusions from both prospects result in the following homogenization temperatures: Th: 160-250 °C, and salinities: 8 to 16 wt% $NaCl_{equiv}$. Even if these temperatures are still well below those reached during the regional metamorphism of the Zambezi belt, they point to a hypogene-hydrothermal origin for the willemite concentrations. A preliminary crush leach fluid inclusion study was carried out on two calcite and one willemite sample from Star Zinc and one willemite sample from Excelsior. The samples were analysed for F^-, Cl^-, Br^-, SO_4^{2-}, Na^+, K^+ and Li^+. Two samples (one calcite, one willemite) contained Br above the detection limit. These samples have Cl/Br (molar) ratios of 54 and 230 respectively; this suggesting that the fluids that formed these samples may have ultimately derived their salinity from evaporated seawater.

The origin of this peculiar type of willemite-franklinite-gahnite mineralization in the Lusaka area is still unclear. However, the existing concentrations could represent a metamorphosed occurrence derived from primary sulfide ores (now completely disappeared), as those occurring in the Nampundwe massive sulfide deposit SW of Lusaka. If this is the case, the seawater signature has not been lost during metamorphism. The zinc spinels franklinite and gahnite are commonly associated with willemite in several other hypogene nonsulfide zinc deposits. The typical occurrences are in the Franklin Marbles of the Middle Proterozoic Grenvillian basement in North America, with the best example represented by the Franklin-Sterling Hill deposit. In the latter, the franklinite-gahnite-willemite ore association is considered as having been originated by amphibolite-granulite facies metamorphism from a previous zinc sulfide/nonsulfide mineralization.

Genesis of supergene Co and Cu deposits in the Katanga Copperbelt (DR Congo)

Decrée, S.[*], Dewaele, S., Mees, F. & De Putter, Th.
Royal Museum for Central Africa, Tervuren, Belgium & GECO project, Belgium ([*]sophie.decree@africamuseum.be)

The Katanga Province (DR Congo) hosts world-class cobalt and copper deposits, accounting for 49% and 5% of the world reserves, respectively [1].

Heterogenite (CoOOH) and malachite ($Cu_3(OH)_2(CO_3)$), the most ubiquitous oxidized ores, ultimately derived from the oxidation of primary sulfides, which occur as stratabound deposits within fine-grained Neoproterozoic metasediments.

The oxidation and weathering processes are economically significant since they strongly concentrate Co and Cu in the oxidized part of the mineralization.

In the Katanga deposits, heterogenite is concentrated as "cobalt caps" along the top of silicified dolomite inselbergs (Fig. 1) [2]. Malachite is mostly present under the cobalt cap (Fig. 1), as thick nodular precipitates filling voids and cavities [3]. Geochemical data suggest that heterogenite forms in (sub)surface oxidizing conditions, whereas Cu tends to migrate downward and to precipitate as malachite in slightly deeper conditions, probably at or near the fluctuating water table.

Heterogenite caps can therefore be considered as residual deposits, similar to lateritic iron deposits and Mn-ore occurring in the southern part of Katanga [4,5].

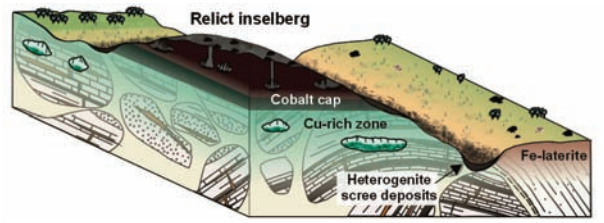

Fig. 1: Sketch diagram illustrating the settings of the Co, Cu and Fe supergene ores in the Katanga Copperbelt [2].

These residual deposits have been dated to the Pliocene (based on field observations, Ar-Ar dating and U-Pb dating) and resulted from: (i) regional Mio-Pliocene uplift, creating conditions favorable for massive erosion and for oxidation of the sulfide ores; and (ii) humid climate conditions, favoring element mobilization. This process results in a vertical gradient of the oxidized ores (Co on top of Cu) that all form in shallow supergene settings: residual surface caps, weathered rock impregnation and infilling of voids and cavities.

Eventually, part of these deposits were dismantled and accumulated in valleys and along foot slopes (as scree, Fig. 1), because of erosion and valley incision during the Quaternary.

The syngenetic-epigenetic baryte-phosphate-bearing Pb-Zn deposit Sekarna (Tunisia), in the stratotype area of the K/P boundary

Dill, H.G.[1*], Botz, R.[2], Dohrmann, R.[1] & Weiss, W.[1]
[1]Bundesanstalt für Geowissenschaften und Rohstoffe, Hannover, Germany ([*]dill@bgr.de)
[2]University Kiel, Germany

The El Kef area (official stratotype of the K/P boundary), Tunisia, is host of complex metallic and non-metallic mineralization at Djebel Sekarna, encompassing syn(dia)genetic shale- and carbonate-hosted Zn-P and epigenetic Pb-Zn-Ba ores in Cretaceous and Paleogene rocks. Geological, mineralogical, and chemical studies including C- and O isotopes analyses resulted in a subdivision of this mineralization into 8 distinct stages.

Stages 1 and 2 (late Cretaceous to early Paleogene) are representative of syn(diagenetic) shale- and carbonate-hosted sulfidic and siliceous (Fe)-Zn-P mineralization deposited in shallow marine to slightly brackish sediments. The presence of zinc and iron-bearing calcite is indicative of poorly-aerated conditions. Kaolin-group minerals prevailing over smectite may be taken as proximity indicators relative to the Kasserine Island. The El Haria Formation, a regressional facies, is interpreted as a large inner ramplike shelf deposit. Limited water circulation during deposition of this Formation resulted in anoxic conditions and the formation of ZnS and FeS_2. The REE patterns of apatite of the Métlaoui Formation leave little doubt that the phosphorites in the district are of lower Eocene age, similar to other phosphorites in the Mediterranean region. Stages 3 to 5 (early Eocene) are represented by epigenetic sulfidic and sulfatic (Fe)-Zn-Pb-Ba mineralization that formed at temperatures as high as 170°C/200°C. Stage-5 barite-bearing Pb-Zn mineralization differs from the predecessor stages by elevated Sr contents accommodated in the barite lattice to form celestobaryte. The epithermal (to mesothermal) carbonate-hosted hydrothermal celestobaryte Zn-Pb mineralization evolved from seawater that underwent evaporation and precipitated from brines circulating down to a considerable depth into the carbonate platform. Stages 6 and 7 (late early Eocene) include non-sulfidic Zn-(Pb) mineralization that formed at temperatures as high as 60°C, transitional from hypogene into supergene conditions ("epithermal calamine deposits"). Stage 8 represents alteration of the pre-existing mineral assemblages in the course of the Holocene weathering.

The distribution of the syn(dia)genetic shale- and carbonate-hosted mineralization in the Late Cretaceous and Paleogene rocks is controlled by planar structural elements of sequence stratigraphic relevance distribution of the mineralization. The Similar planar structural elements delimit the epigenetic vein- and replacement-type ore mineralization in their vertical extension to the lower Eocene. The Cretaceous through Paleogene aquatic system is characterized by a poisoning of the sea with base metals, mainly Zn, and the atmosphere was choked with clouds of fine-grained volcanic ejecta. Both processes contributed to the build-up of Zn-(Pb) deposits and uneconomic bentonitic clay deposits around the K/P boundary. Ore mineralization in the El Kef area is a multiple-phase process which reached its climax during the early Eocene. These inorganic concentration processes resulting in the formation of mineral deposits had obviously also a negative effect on the long-term course of regional Earth's biological history during the late Cretaceous to early Eocene period with lethal consequences for some species. The inorganic and organic data reveal that such extraordinary metallogenetic processes close to the K/P boundary in its stratotype area in Tunisia were "strictly terrestrial".

Mineralogy and geochemistry of the Black Reef Au mineralization at Consolidated Modderfontein, East Rand, South Africa

Gauert, C.D.K.[1*], Deacon, J.[1] & Fuchs, S.[1,2]
[1]Dept. of Geology, University of the Free State, Bloemfontein, RSA ([*]Gauertcdk@ufs.ac.za)
[2]Inst. für Kristallogr. und Materialwiss., Leipzig University, Leipzig, Germany

The Proterozoic Black Reef Formation (BR) is a widespread, thin, small pebble unit at the base of the Transvaal Supergroup, locally occurring in well–defined, deeply scoured channels and gullies deeply eroded into the footwall. In the East Rand, Randfontein and Klerksdorp areas the unit contains considerable gold, minor uranium as well as associated platinum group element (PGE) mineralization, being exploited extensively since the 1930s and renewed since 2002. Its economic importance is indicated by Gold One Ltd. quoting a probable reserve of 5.4 Mt of ore at an average grade of 6.1 g/t for its Modder East Mine (2009) and Pamodzi Gold's total measured and indicated resources of 13.22 Mt at a grade of 4.23 g/t for 2007 [1].

Deposition of the BR was characterized by previous workers as having occurred under fluvial to shallow marine conditions. Of the three BR facies types at Consolidated Modderfontein on the East Rand, the pyrite-rich 'blanket facies' and the 'basal channel facies' [2] contain most of the gold and have the highest amount of heavy minerals (Fig. 1).

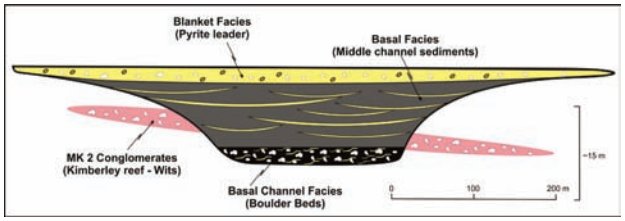

Fig. 1: Schematic section through an incised Black Reef Channel at the Consolidated Modderfontein Mine (Modified after Barton & Hallbauer [2])

Gold occurs in the form of free gold and as inclusions in pyrite, as well as refractory, 'invisible' gold in (arseno-) pyrite and submicroscopic gold particles with carbon. Detrital and heavy minerals comprise compact, concretionary rounded and porous rounded pseudomorphic pyrite [2], zircon, chromite, Ni-Co-Fe-sulpharsenides, cobaltite, gersdorffite, rutile, arsenopyrite, uraninite, and rare galena and sphalerite.

Electron microprobe analyses (EMPA) reveal true fineness values of free gold between 793 and 851, and its Hg content between 0.20 and 0.85 wt%; the pyrite mineral chemistry reveals minor As and Pb, as well as traces of Ni and Cu. Ongoing EMPA, nano-SIMS, and PIXE investigations try to fingerprint the gold chemistry in order to distinguish its provenance as derived from reworked upper Wits Reefs or from different gold deposit types in the 'hinterland'.

Mechanisms contributing to the gold mineralization in the BR are probably a combination of a) detrital processes as evidenced by sediment structures and rounded grains, b) hydrothermal processes as illustrated by several later stages of epigenetically formed pyrite, and c) low-grade metamorphic processes indicated by the paragenetic sequence.

Uranium mineralogy – a critical parameter for successful mining

Kinnaird, J.A.*, Nex, P.A.M., Freemantle, G.G. & Youlton, B.J.
EGRI, University of the Witwatersrand, Johannesburg, South Africa (*Judith.Kinnaird@wits.ac.za)

Southern Africa is a world-class uranium province, with an age span of deposits from Archaean to Recent. The current demand for uranium, together with a rising commodity price and a projected increase in world requirements, has rejuvenated project development. The potential to mine lower U grades makes it imperative to understand uranium deportment and the mineralogist is vital in providing relevant information.

Primary deposits include Cambrian uraniferous leucogranite sheets in Namibia that are typified by the Rössing deposit. Other similar deposits are being developed nearby. The typical cut-off grade was >350 ppm U but has been reduced as price for the commodity has increased. The main U-bearing mineral is uraninite, although refractory betafite occurs locally, while whole-rock values of < 40 ppm may be accounted for by zircon, monazite or xenotime.

In the Witwatersrand Basin, detrital uraninite was transported into the Basin together with detrital gold and other heavy minerals and preserved in quartz-pebble conglomerates. Fluvial transport of detrital uraninite was possible because of the anoxic atmosphere in the Archaean. Uranium was subsequently remobilized and concentrated during circulation of hydrothermal fluids. Where uraninite is produced as a by-product of gold mining the grade may be as low as 0.01%. From ~2200 Ma, when an oxidising atmosphere formed, uranium could dissolve in surface waters, be transported in solution, and subsequently precipitated. In South Africa, Karoo-age sandstones formed in river channels where oxidising surface water interacted with local reducing conditions and uraninite was deposited in sandstone layers. Surficial U has been deposited in the last 5 Ma in near-surface valley-fill sands and gravels in arid areas of Namibia. Carnotite was precipitated in association with calcite and halite in early Tertiary sediments, while near-surface gypsum is sourced from sea-mist, rather than from the fluids that formed the carnotite. The gypsum may prevent the efficient processing of surface material because gypsum reacts with sodium compounds during alkaline leaching and forms calcium carbonate and sodium sulphate in solution, which inhibits U leaching.

For all types of deposits, it is imperative to know the size and association of the uranium-bearing minerals as a guide to milling and liberation. In primary deposits, very small uraninite grains hosted by magnetite or biotite would be difficult to process, whilst minerals such as brannerite, davidite and betafite do not yield their uranium during conventional processing. For secondary deposits, it is vital to understand the relationship between carnotite and clay minerals so as to develop successful metallurgical processing, whilst the accessory minerals dictate whether an acid or alkaline leach is appropriate. Automated scanning electron microscopy has provided valuable information on the mineralogy of uranium deposits towards efficient and cost effective processing.

Archean chromitites and PGM from the Northern West African Craton (Amsaga, Mauritania)

Berger, J.[1*], Diot, H.[2], Féménias, O.[3] & Lo, K.[4]
[1]Université Libre de Bruxelles, Brussels, Belgium (*juberger@ulb.ac.be)
[2]Université de Nantes, France
[3]IAMGOLD corporation, Mali
[4]Université de Nouakchott, Nouakchott, Mauritania

The Amsaga area in the Northern West African Craton consists of Archean TTG series and greenstones belts with ages ranging from 3.5 to 2.7 Ga [1,2] and almost no thermal or magmatic overprint since the end of the Neoarchean era. Chromitites are hosted within ultramafic-mafic complexes that are mainly composed of serpentinised and carbonated spinel-peridotites, werhlites, pyroxenites, leuco-/mela-metagabbros and metabasalts, which show evidence of a peak granulite facies metamorphism with subsequent retrogression into amphibolite and greenschist facies conditions. These complexes occur as tectonic slices in the greenstone belts and might consequently be interpreted either as pretectonic continental intrusion or relics of the Archean oceanic lithosphere. Three deformation phases can be distinguished on the field. D1 is evidenced by low-angle foliation planes and down-dip mineral lineations, probably formed during an early thrusting event. Foliation planes were subsequently verticalised during formation of straight folds with subvertical axial planes (D2) and steeply plunging mineral lineations. Late strike-slip shear zones (D3) have generated folds with vertical axis and subhorizontal lineations that are clearly evidenced in the surrounding BIFs.

Chromitites are either present as pods enclosed in serpentinites or as distinct layers in serpentinised peridotites. Chromites usually form more than 90 vol.% of the samples; the remaining silicate matrix being composed of serpentine, Cr-chlorite, talc or Cr-pargasite. Late hydrothermal events have led to the formation of a (Fe-Cr)-enriched rim around primary spinel grain. This rim also contains chlorite and sulphides inclusions. Preliminary SEM investigations have shown that pargasite-chromitites are rich in base metal sulphide inclusions (mainly pentlandite and chalcopyrite) and contain sperrylite ($PtAs_2$) with sub-micrometric inclusions of Pd, Rh, Ir arsenides and Bi-bearing phases within Ni sulphide grains. The external position of PGE-hosting minerals within chromite grains suggests that the crystallisation of PGM is not synchronous with the early magmatic formation of the chromites but rather results of the PGE remobilisation, either during the granulitic metamorphism or during the late-stage hydrothermal events.

A structural, metallogenic and lithological analysis for gold exploration in the Manica - Mutare - Odzi greenstone belt, West Mozambique and East Zimbabwe: field evidences from Fair Bride mine

Mondlane, S.* Jr., dos Muchangos, A. & Fumo, S.M.
Geology Department, Eduardo Mondlane University, Maputo, Mozambique (*salmond@zebra.uem.mz)

The Manica - Mutare - Odzi (MMO) greenstone belt of West Mozambique and East Zimbabwe is a late Archaean linear structure (anastomosing, transcrustal, first order shear zone [1]) that formed around 2,74 Ga. The ENE - trending belt is roughly synformal, with ultramafic metavolcanic rocks along the margins and coarse clastic metasedimentary rocks in the core. Volcanism was associated with emplacement of early granites. Shear zones commonly separate individual lithological packages. Lithological units are intensely folded and a regional penetrative foliation has developed. Fold axes generally plunge shallowly either to the east or to the west and parallel the regional mineral lineation. To the east, the belt is bound by N-S trending Proterozoic gneisses of the Bárue Complex and quartzites and pelites of the Frontier Formation.

The MMO greenstone belt has produced c. 84 tonnes of Au [1]. Historically Au has been produced mainly from shear zone hosted deposits (ave. grade 12.36 g/t), faults hosted deposits (ave. grade 23.51 g/t) and quartz vein deposits (ave. grade 10.07 g/t). Most of these deposits are steep and strike E-W to NE-SW.

Recently, old deposits have received special attention by mining companies. This is the case of Fair Bride, a deposit located on the southern limb of the MMO greenstone belt, in highly sheared and vertically folded metavolcanic mafic and ultramafic rocks in contact with metassediments of Shamvaian age. This sheared contact is reportedly associated with significant mineralization of gold in late quartz-sulphide veins. The Fair Bride gold deposit is an epigenetic quartz vein associated with sulphides in a hydrothermal system that generated different types of alteration, namely, carbonitization, silicification, chloritization, sulphidation and alkaline metassomatism that precipitated gold in BIFs and quartzites. This deposit is a result of reactivation of the shear zones and remobilization of ancient deposits by thermo-tectonic and magmatic events during late Archaean.

Our study established the metallogenetic and lithological setting of gold deposits in the MMO greenstone belt. The main mineralogical paragenesis at Fair Bride consists of arsenopyrite + chalcopyrite + pyrite + pyrrhotite ± gold ± galena ± magnetite. Gold is disseminated within idiomorphic arsenopyrite, suggesting a single source of the mineralizing fluids.

Microscopic and spectroscopic studies of Pb-Zn deposits along Red Sea coast, Egypt

Hassan, M.S.
Central Metallurgical R & D Institute, Helwan, Egypt
(hassan_mervat@yahoo.com)

Recently, due to new extraction technologies, there has been a marked revival of interest in the geology and exploration for non-ferrous deposits in the world. Along Red Sea Coast of Egypt, there are a number of the oldest mining districts in the world. Significant occurrences of non-ferrous Zn-Pb-Cu ores were exploited from the Um Ghieg, Zug El-Bohar and El Russa mines. Lead and zinc mineralization in the Miocene sedimentary sequences is the most promising locality for production of these minerals in Egypt. Non-ferrous zinc-Pb minerals (carbonates, silicates, and oxide) found at these historical mining areas was characterized. Mineral abundance has been evaluated on the basis of petrographic studies using optical microscope (thin polished sections), scanning electron microscope (SEM+EDX), backscattering and secondary electron modes, as well as Infrared spectroscopy.

Nonsulfide zinc phases are fine-grained and dominated by hemimorphite ($Zn_4Si_2O_7(OH)_2 \cdot H_2O$), hydrozincite ($Zn_5(CO_3)_2(OH)_6$) and smithsonite ($ZnCO_3$). Lead phases occur as cerussite ($PbCO_3$) and rare anglesite ($PbSO_4$), whereas iron oxyhydroxides and oxides (mainly goethite and hematite) derived from the oxidation of pyrite are commonly present in "limonitic" boxworks and in small concretions with amorphous manganese minerals. Remnants of the primary ore, mainly sulfides (sphalerite, galena and pyrite/marcasite) and barite were detected. Infrared spectra of lead-zinc minerals were discussed from the structural point of view. The paper is a part of systematic studies of vibrational spectra of minerals of secondary origin in the oxide supergene zone.

Pan African sinistral transpression regime in southern Eastern Desert of Egypt: structural control on gold mineralization

El Amawy, M. & Zoheir, B.*
Dept of Geology, Faculty of Science, Benha University, Benha, Egypt (*basem.zoheir@gmail.com)

The Neoproterozoic (720-750Ma) Allaqi-Heiani ophiolitic belt in the extreme southern Eastern Desert of Egypt is a major ductile shear zone that comprises anastomosing WNW- trending sinistral transpression zones against older shelf metasediments (Pre-Pan African?). These zones are delineated by discontinuous mylonites, subhorizontal stretching lineations, steep and high strained slices of ophiolites. Along the belt, ophiolitic slices are progressively curved southeastward and merged into the N-S sinistral Hamisana shear zone, suggesting structural continuity of a major transpression corridor. Field studies revealed four episodes of deformation, namely: an early pure-wrenching along the WNW-trending Allaqi-Heiani belt and formation of tight and intrafolial folds. In the course of a second deformation episode, transpression preceded and N- to NNE-dipping anastomosing shear planes and SW-vergent folds developed. These two events represent a single progressive phase of shortening due to a major E-W sinistral simple shear. Consistently, the E-W shortening was accelerated during the third deformation expisode, particularly in the eastern part of belt, in response to deflection into the N-S Hamisana shear zone and exhumation (re-emplacement) of ultramafic rocks under oblique convergence in a generally NNW- trending pop-up structure. During the last (fourth) deformation episode, the entire pattern was re-oriented in a north-trending flower structure. The exhumed belt was then fragile and brittle deformation prevailed during the emplacement of syn- to late orogenic granitoids.

Along the Allaqi-Heiani belt, distribution of gold mineralization is controlled by the WNW-transpression between the highly sheared ultramafic derivatives and related pelagic sediments and wherever syn-orogenic granitoids are tapered along the transpressive planes. Gold occurrence is also markedly traced along the NNW-SSE transpressive planes either developed between the highly sheared ultramafics and ophiolitic metagabbro or as sigmoidal lenses of ultramafics re-emplaced within the highly sheared mélange matrix in a pop up structure. These two settings refer to formation of mineralized shear zones in the frontal, low displacement parts of the transpression system. Finally, a third occurrence is confined to brittle shear zones, developed later in the deformation history contemporaneous with the intrusions of acidic dykes and granitic offshoots, commonly along the ENE-WSW trend.

Geochemical trends within Madagascar chromite ores

Merlini, A.* & Grieco, G.
Dept. of Earth Sciences, University of Milan, Italy
(*anna.merlini@unimi.it)

The most important chromitite deposits of Africa are mainly located in South Africa, in the well known Bushveld complex, nevertheless Madagascar hosts some important chromitite deposits making Madagascar the world's 10th largest chromite producer.

Kraomita Malagasy, the state-owned mining company, produces a chromite concentrate grading between 48 and 50 wt% Cr_2O_3 with 0.002 to 0.003 wt% P_2O_5 and lumpy chrome ore grading from 42 to 44 wt% Cr_2O_3.

Since strong quality parameters are required for the commercialization of both concentrate and lumpy products, a detailed chemical and textural analysis of such mineralization was focused on understanding quality profile of these ores in ordrer to maximize future exploitation that strongly depends on chemical and textural features of the ore itself.

Mineralized regions present different geochemical and textural features that strongly influence explotaition and developing of chromite mining industry of Madagascar.

The main chromitite ores are located in Andriamena, Befandriana and Tamatave regions and are related to Archean basic-ultrabasic intrusions set in the central zone of the island.

The Andriamena complex, located in the southern end of the Tsaratanana Mineral Field, has been the leading chrome producing region for the last decades. In Andriamena complex most of chromite production comes from three mines: Ankazotaolana, Bemanevika and Telomita.

Ankazotaolana mine is characterized by a series of ultramafic lenses hosted by a gneissic rock of Archean age. Chromitite shows values of Cr_2O_3 wt% between 35 and 40 with a Cr/Fe ratio up to 2.7. Bemanevika mine, characterized by a series of parallel lenses at different depth, shows Cr_2O_3 content close to 40 wt% and a Cr/Fe ratio of 2.3. Recent estimates predict 2.6 Mt of reserves for this area. Telomita mine, recently reopened to increase the production of Kraomita Malagasy, is characterized by Cr_2O_3 content similar to that of Ankazotaolana and a Cr/Fe ratio of 2.2.

Befandriana district represents another strategic zone where chromitite lenses, ranging from few meters up to 10 meters in thickness, are highly massive, with Cr_2O_3 close to 53 wt% and Cr/Fe ratio close to 2.6.

Tamatave district was the first to be exploited in the ’60 of last century and is characterized by highly deformed and metamorphosed chromitite lenses located in two main sites: Ambodiriana and Ranomena. Tamatave chromitites show a low Cr_2O_3 content, close to 30 wt% and a Cr/Fe ratio lower than 1.5.

Comparison of geochemical and textural chromitites features of all analysed regions highlighted, some important differences among the ores that need to be considered for the future developing of chromite mining industry in Madagascar

In general chromite ores of Madagascar show a trend of decreasing Cr_2O_3 content from north to south, related to differences in ore genesis, which strongly affects ore quality for exploitation. Andriamena chromitites show an average good quality, but with differences between mines. Befandriana ores show the best quality due to their massive texture together with high Cr_2O_3 content of chromite. Chromitites from Tamatave are absolutely unsuitable due to the low Cr_2O_3 content of chromite. On the other hand a surplus value of Tamatave chromitite is the presence of Platinum Group Minerals (PGM) mainly laurite or complex solutions observed both included in chromite grains as well as in the matrix.

Carbonate mineral-chemistry in Late Archean to Early Proterozoic banded iron formations: a proxy for the evolution of ocean chemistry and implication for metal concentrations

Morgan, R.[1*], Orberger, B.[1], François, P.[1], Hofmann, A.[2] & Rosière, C.A.[3]
[1]Université Paris Sud 11, Paris, France
([*]rachael.morgan@u-psud.fr)
[2]University of KwaZulu-Natal, South Africa
[3]UFMG, Minas Gerais, Brazil

The geochemistry of sedimentary carbonates provides important clues about the evolution of the ocean, atmosphere and biological conditions during Archean and Early Proterozoic times. The geochemistry of carbonates associated with mineral deposits may also be of importance for tracing the origin of economic metal (e.g. U, As, Au etc) bearing fluids i.e. marine, diagenetic, hydrothermal or metamorphic, since pH and the HCO_3^- content of the mineralizing fluids can significantly influence metal concentrations. We investigated carbonate mineralogy and chemistry in carbonate facies BIFs and associated cherts from two well preserved shallow-marine successions: the 2.7 Ga old Spring Valley Member (SVM), Manjeri Formation (Belingwe Greenstone Belt, Zimbabwe), and the 2.4 Ga old Gandarela Formation (Minas Supergroup, Brazil).

The SVM is an oxidised (Fe-oxides) and a reduced (Fe-sulphides) chert facies, representing respectively, distal and proximal, marine-hydrothermal chemical precipitates [1]. Both facies contain early diagenetic ankerite, siderite and as a late precipitate, calcite and secondary euhedral ankerites. Au and U mineral inclusions were observed in these carbonates. SVM carbonates are significantly richer in FeO (~20 wt.%) and poorer in MgO (~8 wt%) than the Gandarela carbonates (~8 and 20 wt.%, respectively). The latter consists of primary massive bedded Fe-dolomites alternating with beds of banded chert Fe-oxide and Fe-dolomite and secondary euhedral Mg-siderite [2]. Our samples show that the late Archean (2.7 Ga) shallow environment may have been richer in dissolved Fe2+, reflecting acidic and reducing conditions in agreement with the general model for the evolution of the Archean ocean. However, in the Early Proterozoic (2.4 Ga) the ocean evolved to conditions more favourable (kinetics?) for Mg-carbonate precipitation. In the (Late) Archean, primary carbonates may have acted as a trap for Au, Ag (and possibly U) and further studies are currently being undertaken in order to provide more evidence for this model. In both formations, calcite replaces in part the primary carbonates, resulting in the liberation of noble trace metals, which may allow for their transport and economic concentration.

U-mineralization in Tranomaro, Madagascar

Ramdohr, R.[1*] & Evstigneeva, T.[2]
[1]Consultant Geologist, Bonn, Germany
([*]reinramdohr@yahoo.com)
[2]IGEM RAS, Moscow, Russia

The Tranomaro U-Th is located in the SE of Madagascar, ca. 80 km from Fort Dauphin. In this region there is a sequence of ~ NS striking, steeply dipping highly metamorphosed rocks (granulite facies, i.e. ca. 750 degrees C and 5 kbar pressure) consisting of granite-gneiss, leptinites (migmatites), marble, and magnesium skarn . High grade mineralized zones contain 4,329 ppm U or 11.25 lbs/metric ton U_3O_8.

Magnesium skarns formed at the contact “granite – dolomitic marble”. The metasomatic zoning from magmatic rock to dolomitic marble is determined by Fe- and Al- mobility decreasing: granite (pegmatite) → spinel-pargasite-anorthite-fassaite skarn → pargasite-anorthite-fassaite skarn → pargasite-fassaite and pargasite-diopside skarn→ spinel -pargasite-fassaite skarn→ pargasite -diopside and diopside-pargasite skarn → spinel -calcite-forsterite skarn. The spinel-anorthite-fassaite, spinel-fassaite, diopside and spinel-calcite-forsterite skarns were formed during the magmatic progressive stage. The postmagmatic regressive stage is represented by calcite-bearing skarns with pargasite that replaces clinopyroxene.

The possible source of Th and U could be the granitic magma. Geochemical mobility of these elements determines their concentration in pargasite-fassaite and pargasite-diopside skarns with moderate alumina and ferrous monoclinic pyroxenes. It is necessary to note that the largest thorianite crystals of South Madagascar were found in phlogopite magnesium skarns.

Uranium generally occurs as uranothorianite, hosted in North-South trending pyroxene-rich skarn units. Uranothoriante, $(Th,U)O_2$, the main U-bearing mineral, is characterized by Th:U ratio varying from 0.5 to more than 30. The most typical value Th:U in uranothorianite from Tranomaro is close to 3:1. The central part of some grains is richer in Th in comparison with the border. There are two types of (Th,U)-oxide: a) separate $(Th,U)O_2$ grains with Th:U ~ 3:1, and b) very tiny grains $(U,Th)O_2$ with Th:U ~ 1:2 or 1:3. Uranothorianite of first type seems to be the primary mineral of magmatic origin (source - granites). Th-Uraninite is the product of secondary processes (hydrothermal, metasomatic etc.). It is associated with other Th-bearing minerals (monazite, thorite etc.) generally enriched in Ce and La.

Th- and Th-bearing minerals are monazite, Ce-Nd-Th phosphate (often with Si); Th-bearing apatite; $ThSiO_4$ (very rare). These minerals form small grains, 0.n – n microns in tiny fractures or jointly zones, and are common in many samples.

Th content in rocks is determined as sum “Th in Th-oxide” + “Th in other minerals (monazite, apatite etc.). This is responsible for Th:U ratio variations, often noted in probe analyses Tranomaro.

Spanish sepiolite deposits

García-Romero, E.[1*] & Suárez, M.[2]
[1]Dpto. Cristalografía y Mineralogía, Fac. C.C. Geológicas, Universidad Complutense de Madrid, Spain ([*]mromero@geo.ucm.es)
[2]Area de Cristalografía y Mineralogía, Dpto. de Geología, Universidad de Salamanca, Spain

Spain is the world leader in sepiolite production. Madrid hosts the world's largest sepiolite deposit with reserves estimated over 15 Mt of high quality material. The main Spanish producer is TOLSA (300 kt of sepiolite in 2008), which mines the main deposits, located in the Madrid basin (Vicalvaro, Madrid, and Cabañas de la Sagra, Toledo). SEPIOLSA produced 164 kt in 2002, from the deposits of Paracuellos del Jarama and Barajas (Madrid) and BENESA 70000 tpa in Valdemoro (Madrid). Another important deposit currently under exploitation is located in Orera, in the Calatayud basin (Zaragoza). MYTA produced 131 500 t from this deposit.

The Madrid Basin is a Tertiary basin developed during the Alpine orogeny. The Miocene sediments of the Madrid basin display a concentric facies distribution pattern. Close to the margins of the basin there are detrital sediments corresponding to alluvial fan systems. These sediments are predominantly arkosic to the NW and S, and litharenitic to the NE and E. Transitional facies correspond to mud flat environments between the detrital and lacustrine sediments. The lacustrine sediments are mostly evaporites. In the northern and southern margins of the basin, arkose sands dominate gradually passing to carbonatic paleosols and clays in the distal facies of the alluvial fans and in the lacustrine systems. These clayey facies include the important Mg-rich clay deposits.

At least seven layers (≥ 1 m thick) of lacustrine sedimentary rocks containing sepiolite can be recognized in the Vicálvaro-Barajas area east of Madrid [1]. The layers are up to 7 m thick in places, with a virtual pure sepiolite composition. The Vicálvaro sepiolite deposit covers a 7.5 km^2 area elongated in NW-SE direction (5 km long and 1.5 km wide), with maximum thickness 12-15 m in the center and progressively decreasing towards the borders of the deposit. Clay layers with variable colors dominate in this unit, intercalated with carbonates (marly mudstones, marls, dolostones, and limestones). In the southern area of the Madrid basin (Cabañas de la Sagra, Toledo) the sepiolite is located in an arkosic unit, (distal parts of alluvial fans). Clayey levels consist almost exclusively of sepiolite and trioctahedral smectites, with variable ratios between pure end members. At the top of the unit sepiolite is associated with dolomite and chert.

The deposit in Orera in the Calatayud basin (Zaragoza) currently exploited by MYTA develops in the marly-carbonate transitional facies of the Calatayud Tertiary lacustrine basin. It corresponds to an alluvial fan marginal deposit which during late Miocene closed a valley producing a lake in which sepiolite was formed. Sepiolite clays and sepiolite-palygorskite clays also occur in the Cuesta facies of the Duero Tertiary basin, and in Lebrija (Sevilla).

The sepiolite from Madrid basin has specific surface area ~270 – 330 m^2g^{-1}, and fibres longer than 10 μm in places Sepiolite from Calatayud has also high specific surface area (~270 m^2g^{-1}) and the size of the fibres is medium, generally smaller than 11 μm in lengh. The contribution of external and microporous surface area is similar in both cases.

[1] Leguey, S. et al. (1995) in Churchman, G.J., Fitzpatrick, R.W. & Eggleton, R.A. (eds.) *Clays: Controlling the Enviornment*. Proc. 10th Clay Conf., Adelaide, Australia, 1993, CSIRO Publishing, Melbourne, Australia, 383-392.

Distribution of layer charge of smectites in the Miloan bentonites, Aegean Greece

Christidis, G.E.[*], Makri, P., Pogaridou, E., Theodoridou, G. & Kantsou, P
Dept. of Mineral Resources Engineering, Technical University of Crete, Chania, Greece ([*]christid@mred.tuc.gr)

Layer charge is a fundamental property of smectites which controls cation exchange capacity, ion exchange selectivity swelling and rheological properties. Within this context, determination of layer charge and charge distribution within a bentonite deposit is of particular importance because a) it can shed light on the formation mechanism of the bentonite and any possible subsequent modifications, and b) it controls the variability of bentonites in various industrial applications. This knowledge, in turn, can assist in an understanding why production of Na-activated smectites from Ca-Mg smectites usually yields unpredictable results.

Layer charge and charge distribution of smectites was studied in three bentonite profiles in Eastern Milos. The two profiles were 120 x 30 m long, whereas the third one was 200 x 45 m long and has been affected by contemporary solfatara spring activity along a NE-SW trending fault. The bentonites formed by submarine alteration of Lower Pleistocene pyroclastic flows. The deposits consist of Ca-smectite (60-95%) with subordinate quartz and/or traces of opal-CT. Minor calcite, kaolinite and K-feldspar are present in places. Determination of layer charge was carried out according to [1]. Briefly, the less than 2 μm fractions were separated by settling, saturated with K and dried on glass slides to make oriented clay mounts, which were subsequently saturated in ethylene glycol vapour at 60°C for 16 hours. The layer charge and charge distribution of smectites was determined by means of the LayerCharge program [1]

Although mineralogy is similar in the three profiles, the layer charge distribution follows different patterns. The first profile is characterized by a high charge anomaly (layer charge > 0.50 eq/phuc) in the lower WNW sector whereas the remaining profile is characterized by smectites with intermediate layer charge (layer charge 0.43-0.47 eq/phuc). The second profile is dominated by gradual increase of the layer charge towards the top of the profile, from 0.41 eq/phuc at the bottom, to 0.48 eq/phuc at the top. Moreover tetrahedral charge tends to increase towards the top of the profile. The third larger profile is dominated by a high charge bentonite layer ~ 12 m thick at the bottom (layer charge > 0.5 eq/phuc), followed by a thick layer > 30 m thick with layer charge 0.44-0.47 eq/phuc, which does not display certain trends. In the area affected by the solfatara spring activity the layer charge decreases (0.41-0.42 eq/phuc).

The different distribution patterns of layer charge in the three profiles reflect different evolution of the bentonites. In the first profile the high charge smectites are attributed to hydrothermal alteration which postdated the formation of bentonite and are associated with fine-grained K-feldspar and kaolinite. The distribution of layer charge in the remaining profiles reflects the geological environment during bentonite formation. The formation of low charge smectites in the vicinity of the solfatara spring is also attributed to contemporary hydrothermal alteration and intensive leaching of the original smectites

Sustainable use of fines from the sand and gravel industry

Schmitz, M.*, Röhling, S. & Dohrmann, R.
Federal Institute for Geosciences and Natural Resources, Hannover, Germany (*martin.schmitz@bgr.de)

In 2008, some 260 million tons of sand and gravel were produced in Germany [1]. During processing sand and gravel are split into different grain size fractions. Fines are separated by washing and screening and usually dumped as water-sediment suspensions in tailing ponds close to the quarries. Up to now fines are rarely used in industry, e. g. as aggregates to produce bricks and tiles [2]. Pflug (2001) estimates that about 50 million tons of fines are produced in Central Europe every year [3]. The aim of the study is to determine the qualitative potential of fines from the processing of sand and gravel in Germany for applications in the brick and tile industry.

Fines were sampled in 28 sand and gravel pits all over Germany. After the particle size analysis the mineralogical and chemical composition of the fines were determined in the laboratories of the German Federal Institute for Geosciences and Natural Resources. As a result, 12 samples with an average grain size >200 µm, low clay mineral content or high concentrations of carbonates were rejected due to the fact that they cannot be used in the brick and tile industry.

The mineralogical composition of the remaining 16 samples is presented in Table 1. Four samples are dominated by kaolinite (samples 1, 7, 11, 16) and one by illite/muscovite and an expandable mixed-layer mineral (sample 4). In general, the selected samples consist of different mixtures of quartz, feldspar and a wide variety of clay minerals, carbonates, and oxides (Table 1).

Table 1: Simplified mineralogical composition of selected samples (I/Sm/M-L=illite/muscovite, smectite and mixed-layer minerals, K/Ch=kaolinite and chlorite; Q=quartz; F=feldspars; C=calcite and dolomite; Ox=Fe-oxihydroxides and Ti-oxides; O=others)

	I/Sm/ M-L	K/Ch	Q	F	C	Ox	**O**
1	15	35-40	35	10	-	<5	<1
2	15	5	45	15-20	10	6	<5
3	20-30	10-20	10-20	10-20	10-20	<1	<1
4	40-50	5-10	20-30	20-30	-	<1	<1
5	15	-	50	15-20	10-15	5	<1
6	15	5	40	30-35	5	<5	<1
7	15	30-35	40	10	-	<5	<1
8	25-30	20	15-20	25-30	<1	5	<1
9	20-25	5-15	25-30	15-25	-	<5	<1
10	10-15	5-10	70-75	5	-	<5	<1
11	-	55	40	-	-	5	<1
12	15	-	45	35	-	<5	<1
13	15	5	55	10-15	<10	5	<1
14	20	10	20-25	10-15	25-30	<5	<5
15	15-20	5-10	30-35	25-35	<5	<5	<5
16	25	45	20	10	-	<5	<1

The chemistry and the mineralogy of the fines reflect the composition of the source rocks the sediments derived from. A regional distribution of different qualities within Germany was not identified.

The ceramic properties of the samples will be discussed and the potential uses of fines in the brick and tile industry estimated.

Bentonite deposits of Hungary – a review of their mineralogy and geology

Kovács-Pálffy, P.[1*], Földessy, J.[2], Kónya, P.[1] & Bertalan, É.[1]
[1]Geological Institute of Hungary, Budapest, Hungary (*kovacs@mafi.hu)
[2]Dept. of Geology and Mineral Resources, University of Miskolc, Hungary

In the Hungarian part of the Pannonian Basin several bentonite deposits of some recent or historic economic importance are known (Mád-Sima, Mád-Újhegy, Istenmezeje, Komlóska, Pétervására, Salgótarján-Kazár, Budatétény, Sóskút, Egyházaskesző, Gérce). Some of these are being exploited in our present days. This summary gives details of their mineralogy, geochemistry and geology.

Most of these deposits are related to Neogene volcanic areas. These activities are marked partly by submarine pyroclastic accumulations and coeval andesitic lavas of Carpathian age (~17.5–16.2 My), followed by Badenian (~16.2–13 My) pyroclastics and associated basaltic, andesitic, rhyodacitic and rhyolitic flows. In the Late Miocene to Pliocene/Pleistocene period (~12–2 My in the western Pannonian Basin) alkali basalts have been produced, associated by lacustrine sediments.

The bentonites derive from different alteration styles of volcanic rocks:

- Primary, syn-volcanic bentonitisation: halmyrolitic and hydro-diagenetic (Tokaj Mountains), maar lake bentonites in W-Hungary (Egyházaskesző, Gérce).
- Secondary processes: these secondary bentonites are the results of intense argillization around hydrothermal centres in several parts of the Tokaj Mountains (Komlóska).
- Tertiary processes: are characterized by erosion and re-deposition in isolated marine gulfs and lagoons (e.g. Istenmezeje, Budatétény) or re-worked deposits in post-volcanic warm-water geyser lakes (e.g. Mád-Sima and Mád-Újhegy).

In general these bentonites are characterised by the dominance of the montmorillonite (Ca, Ca/Na, Fe), with small amounts of quartz, cristobalite, feldspars and biotite. Also in few cases are presents beidelite (Fe), kaolinite and mixed-layer clay minerals (rectorite) at Mád-Újhegy, and vermiculite/smectite at Egyházaskesző-Gérce.

Their swelling capacities vary in wide range, few bentonites are not activated (e.g. Kazár). Chemically these bentonites are resulted from argillization of rhyolitic-rhyodacitic, and basaltic pyroclastic rocks (Fig. 1).

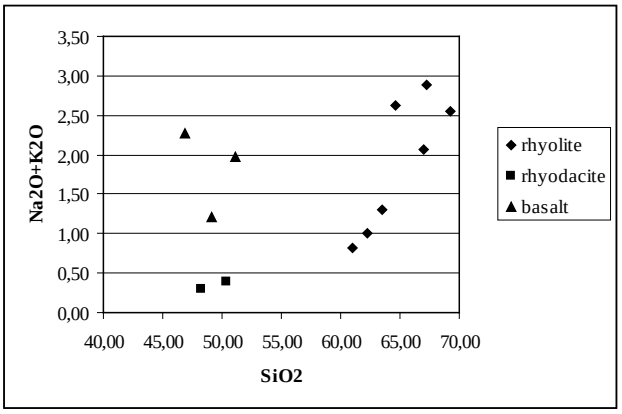

Fig. 1: Na_2O+K_2O vs SiO_2 diagram of bentonites from different pyroclastic rocks.

Natural pigments in clayey sediments of Kuprava pit in Latvia

Randers, M.[1*], Lūse, I.[2], Stunda, A.[3] & Karpovičs, A.[1]
[1]Dept. of Geography and Earth Sciences, University of Latvia, Riga, Latvia ([*]martins.randers@inbox.lv)
[2]Institute of Soil and Plant Sciences, Faculty of Agriculture, Jelgava, Latvia
[3]Riga Biomaterials Innovation and Development Centre, Riga Technical University, Latvia

Clayey pigments are relatively easy to obtain, therefore they have been used since prehistoric times for painting and decorating of bodies, ceramics, cave walls and temples. Despite utilization and research of natural pigments not much is known about their origin, chemical, physical and mineralogical properties.

There is a close link between colour of clay pigments and their mineralogical composition. Therefore aim of this study is to clarify which of the minerals represent clay colour in Upper Devonian clays of Latvia and possible new applications aspects. Study site is Kuprava clay pit in north-eastern part of Latvia where Devonian clays are exposed.

To determine mineral composition, X-ray powder diffraction method was used. Diffractometer X-ray tube operated at 40kV and 30mA, CuKα radiation, diffraction angle range 2° to 70° 2θ and step size 0.050° 2θ. For quantitative analyse data was processed using Quanto software. For granular composition of samples pipette method was used. Colour of all 70 samples was determined using Munsell colour scale, and 26 of them were chosen for detailed study.

Overall there were separated 19 different colour tones, ranging from purple and red tones to greyish. Reddish and gray clays have different mineral composition. Dominating minerals in all samples are illite (30–60%) and quartz (25–40%), in some samples amount of dolomite also is high (till 20%). Elevated amount of hematite and goethite were detected in red coloured samples. Grey and light coloured samples are sandier and there is higher amount of quartz, dolomite and kaolinite than in red samples. Red colouring minerals, like goethite or hematite, are present in all fractions, though amount of hematite, which gives intense red or purple colour tone to the sediments, is much higher in sand fraction, and amount of goethite is higher in clay fraction. Amount of goethite and hematite in red coloured samples is small, approximately 1–5% but such small amounts still is enough to colour clays red.

Results of this study show that colour of clays is mostly dependent on content of iron compounds, and role of other minerals is smaller. Grey clays do not contain ferric compounds, but have high amounts of quartz (35–40%) and dolomite (15–20%).

Results of this study further could be used for research on natural dyestuffs and cosmetics as well as other possible applications.

Acknowledgements: This work has been supported by the European Social Fund within the project „Support for the implementation of doctoral studies at University of Latvia”.

Palygorskite clays from Borshhovskoe deposit (Kaluga region, Russia): composition, crystal chemical particularities of clay minerals and colloidal properties

Bogrash, A.[1], Matskova, N.[1*], Zakusin, S.[1], Krupskaya, V.[1,2], Pokidko, B.[3], Voloshin, V.[4] & Krupnov, I.[4]

[1]Lomonosov Moscow State University, MSU, Moscow, Russian Federation ([*]nataliamatskova@hotmail.com)

[2]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry, Russian Academy of Science, IGEM RAS, Moscow, Russian Federation

[3]M.V. Lomonosov Moscow State Academy of Fine Chemical Technology, MITHT, Moscow, Russian Federation

[4]Lafarge Cement, Moscow, Russia

Palygorskite clays are used in various branches of industry, such as pharmaceutics, constructing, drilling, wine-making etc. Palygorskite clays as a component of drilling fluid are the main application. Clays can form a stable suspension with surplus water. Main technological characteristics of the raw clays are cation-exchange capacity, slurry yield with fixed viscosity etc.

Clays from production horizon of Borshhovskoe clay deposit (Kaluga region, Russia) were used as a test subject. Detailed research which includes study of relation between mineral composition, crystal chemical particularities and colloidal properties of clays should provide better exploitation of deposit and their proper use as a raw material.

The following methods have been used during this study: x-ray diffraction analysis, differential thermal analysis, near-infrared spectroscopy, middle-infrared spectroscopy, grain-size analysis, viscosity measurement (according to API requirements), and measurement of cation-exchange capacity. Characteristics of mineral composition and quantitative mineral analysis were carried out using the data received from XRD-analysis conducted in MSU. Thermal analysis was performed in MSU, infrared spectroscopy was carried out in MSU and Theoretical and Physical Chemistry Institute (Athens, Greece). Technological testing took place in MITHT.

Clays from different areas of upcoming quarry were studied during the research. It was found that clay composition varies from primary palygorskite to montmorillonite clays within the limits of deposit. Montmorillonite has quite stable composition while palygorskite has the complex one. NIR examination results clarified that palygorskite represents mechanical mixture of Al- and Al-Fe-varieties in different proportion with overall prevalence of Al-variety.

Testing the colloidal properties of clay suspensions has demonstrated generally good properties. The application range of these clays is determined chiefly by the quantitative ratio of clay and non-clay minerals, the suspension viscosity and the cation-exchange capacity. Standard technological tests require considerable amounts of time and sample volume. This work will underlie in development of express methods which could be used as fast and precise evaluation of the main characteristics of colloidal properties (used in grade of clay powder analysis) based on mineral composition and particularities of clay minerals structure.

Acknowledgements: Authors are grateful to Dr. G. Chryssikos and Dr. V. Gionis from Theoretical and Physical Chemistry Institute, National Hellenic Research Foundation, Athens, Greece for their kind help in NIR measurements. Authors wish to acknowledge “Lafarge Cement” company for providing samples from Borshovskoe deposit. The work was partially supported by the Russian Foundation for Basic Research, grant #09-05-00302 a and the National Hellenic Research Foundation.

Mineralogical characterization of talc from the Western Carpathians (preliminary results)

Čavajda, V.[1*], Uhlík, P.[1], Madejová, J.[2], Smolárik, M.[1] & Čaplovičová, M.[1]

[1]Dept. of Geology of Mineral Deposits, Comenius University, Bratislava, Slovakia ([*]cavajda@fns.uniba.sk)

[2]Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia

Several talc deposit are located in Slovak part of the Western Carpathians. The main deposits are evolved in Veporic unit (Early Paleozoic Sinec belt) and in Gemeric unit (Early Paleozoic Gelnica group). Most of talc occurrences in Slovakia belong to the deposits in association with Mg-carbonates [1]. Nowadays, a big talc deposit is opened in Gemerská Poloma. The objective of the study is mineralogical characterization of talc from Gemerská Poloma deposit and his comparison with talc from others areas (e.g. Hnúšta-Mútnik) and also investigation of structural order and crystal size. Research was performed on bulk rock and clay fraction (< 2 μm). Samples were studied by XRD, electron microscopy and IR spectroscopy.

Results from XRD quantitative mineral analysis by RockJock software [2], showed that amounts of talc from Hnúšťa-Mútnik samples vary from 85% to 1%. Samples from Gemerská Poloma contain 90-25% of talc. Other minerals are chlorite, quartz, magnesite, dolomite, biotite, muscovite (illite), and pyrite. The mean thickness of talc crystals from fraction < 2 μm was analysed by BWA technique (MudMaster software, [3]). It was indicated differences in mean thickness of talc crystals. Samples from Gemerská Poloma have bigger mean thickness (23,4 nm) than samples from Hnúšťa-Mútnik (15,6 nm). IR spectroscopy was used for partial crystallochemical characterization of the samples. The specific talc bands were significant in the samples with dominant amount of talc (e.g. OH-stretching band (Mg_3OH) at 3676 cm^{-1} and bending band at 669 cm^{-1}). Presence of small amount of Fe in the talc structure is probably determined by weak stretching band (Mg_2FeOH) at 3660 cm^{-1}. Stretching bands at 3571 and 3428 cm^{-1} were significant in samples with high amount of chlorite. Position of these stretching bands points out the presence of trioctahedral chlorite, probably clinochlore.

Talc samples are composed with platy crystals. Planar surface is almost isometric with dominant dimensions from 3 to 10 μm. The shapes of crystals are anhedral and subhedral according to SEM study.

Mineralogy of Devonian Timan bauxites

Vakhrushev, A.V.[1*], Kotova, O.B.[1] & Ozhogina, E.G.[2]
[1]Institute of Geology, Komi Science Centre, Ural branch of The Russian Academy of Sciences, Syktyvkar, Russia
([*]vahal@yandex.ru)
[2]Federal State Unitary Enterprise "N.M.Fedorovsky" All-Russian Scientific-Research Institute of Mineral Resources, Moscow, Russia

The mineralogical analysis of fine bauxite ores is recently considered as mandatory component of geological prospects because its results considerably supplement (including nanolevel of mineral formations) concentration techniques and volumes of separated effective mineral and its satellites, quality of mineral raw for further processing of the concentrate.

To evaluate technological characteristics of ore-bearing rocks it is first of all necessary to study in detail various lithotypes of ore-bearing rocks. Therefore we paid special attention to the technique of their material study.

Bauxites are rocks, which components are represented by fine minerals; the study of their mineralogical and physical-technical characteristics allow new look at problems of bauxite concentration.

The most promising new source of this raw in Russia is the Middle Timan group of deposits at the north-east of Komi Republic (reserves up to 200 m depth – more than 200 mln tons). The explored reserves of the Middle Timan are concentrated in the Vezhayu-Vorykva deposit (150 mln. tons).

The deposit includes three types of ores that are different by their lithologic and mineralogic features: hematite-boehmite, hematite-chamosite-boehmite, kaolin-chamosite-boehmite.

The content of boehmite (to 55-65%) often tends to the medium part of the bauxite member. The quantity of silica minerals (kaolin, chamosite and others) increases in top and bottom parts of the section (to 35-45%), but sometimes higher contents of kaolin are determined throughout the whole section.

The features of the mineral composition, as well as the degree of bauxite cementation, affect the degree of substance differentiation, which determines possible ways of concentration. Therefore both, discovery of distribution regularities (in the section or area) of bauxite lithological varieties, and determination of areas of bauxite development with predominance of various minerals, present interest for mapping of areas of concentrated ores development.

During the investigation of the Vezhayu-Vorykva bauxites the characteristic features of mineral composition and physical properties were determined. The high dispersity of the main bulk of composing minerals (mechanical mixtures with micron and sub-micron particle sizes) is characteristic for all the lithologic-mineralogic varieties. For example fine-crystalline boehmite with sizes <5-10 mcm is widely distributed; and also the considerable part of hematite and goethite is concentrated in the thinnest classes (<0.5 mcm). Often isomorphous substitution of iron oxide by aluminum is determined in goethite and hematite with formation of alumohematite and alumogoethite. The main silica minerals are kaolin and chamosite. The major part of chamosite is represented by a fine form; content of iron oxide reaches 10-15%. The X-ray amorhous phase is widely distributed, which is determined at comparison of various diagnostic methods (X-ray structural analysis, chemical analysis, IR spectrometry, Moessbauer spectroscopy).

Characteristics of smectite and palygorskite clays from the Dashkovskoe Industrial Deposit (Serpuchov Region, Russia)

Zakusin, S.V.[1*], Matskova, N.V.[1], Krupskaya, V.V.[1,2], Chryssikos, G.D.[3], Gionis V.[3] & Pokidko, B.V.[4]
[1]Lomonosov Moscow State University (MSU), Moscow, Russia

[3]Theoretical and Physical Chemistry Institute, TPCI, National Hellenic Research Foundation (NHRF), Athens, Greece
[4]M.V. Lomonosov Moscow State Academy of Fine Chemical Technology, (MITHT), Moscow, Russia

Palygorskite and bentonite clays are used in many industrial applications. The subject of this research was Dashkovskoe clay deposit (Moscow region, Serpukhov).

XRD analysis showed that samples contain palygorskite, montmorillonite, calcite, dolomite and quartz at various ratios (Fig. 1). Palygorskite is dioctahedral and Al-rich, with very minor FeIII substitution in M2 sites. The chemical composition of palygorskite in the different horizons of the Dashkovskoe deposit is found to be remarkably constant, despite the fact that this mineral is capable to exhibit large variations in the speciation of its octahedral sheet. This indicates that palygorskite was crystallized under the same chemical condition and deposited in sedimentary basin without transportation. Area of Dashkovskoe deposit is represented by a source of palygorskite for Moscow region.

The Dashkovskoe clay suspensions possess quite good structural-mechanical properties. All samples demonstrated pseudoplastic behaviour with Bingham yield value ranging between 1.9 and 9.5 MPa•s (Fig. 1). The best apparent viscosity (AV) and yield point (YP) have been found in the case of nearly 50/50 palygorskite and smectite mixture. This fact can be explained by the presence of optimal quantities of particles with different shapes in dispersion media. It is well known that palygorskite displays good stability in saline solutions and under high temperatures. This is especially important when using drilling mud with rotatory drilling of rocks bearing soluble salts. Thus combining smectite and palygorskite at a certain ratio not only allows acquirement of salt- and thermal-resistant mud but also significantly improves their rheological characteristics.

Identification and stabilization of clays for productivity/injectivity optimization in the hydrocarbon industry

Dormán, J.
New Technologies and R&D, MOL Hungarian Oil and Gas Plc, Hungary (jdorman@mol.hu)

Most of the sandstone type hydrocarbon bearing formations are severely contaminated by detrital clay minerals, which can cause severe formation damage and productivity impairment. Maximization of productivity of hydrocarbon producing wells or optimization of productivity/injectivity of underground gas storage wells require efficient preferably proactive formation damage control. The most common source of permeability damage in such wells is the destabilization and mobilization of fine particles with fluid flow (fines migration). Clay minerals are mostly prone to disintegration, mobilization and entrapment within the pore structure, causing permanent loss of permeability in case of improper drilling/completion fluid chemistry. In drilling/completion technology design and fluid chemistry optimization the need for characterization and determination of types and concentrations of mineral constituents of formation rocks, especially clay minerals (XRD, FTIR, CEC, etc.) are essential and inevitable and are routinely used to support advanced field practice.

Fluid flow in the porous formation is controlled at pore scale, while fines migration at micron-to-submicron scale, therefore extensive studies of pore structure/morphology and visualization, identification of potentially mobilizable particles and their typical position in the pore structure (SEM, ESEM) are also key issues in combating permeability reduction. Clay minerals commonly appear in a very complex coexistence with different detrital minerals.

Core flow studies (using representative core plugs) can efficiently support to evaluate the potential fluid chemistry/flow effects at semi-macro scale, but can't give direct answer for the effect of formation heterogeneity.

Potassium salts and selected cationic (organic) polymers of different molecular weight and other specialty additives are the key components of the new "fit-to-purpose" drill-in and completion fluids, which were formulated by complex engineering approaches. The main tasks in Hungary are to maintain formation integrity and to control formation damage in mostly under-consolidated, water-sensitive sandstone reservoirs.

The paper gives an overview of clay identification and stabilization techniques, results and illustrates their aspects in drilling/completion fluid design and successful field applications.

Evolution of boron and nitrogen content during illitization of bentonites

Środoń, J.
Institute of Geological Sciences, Polish Academy of Sciences, Kraków, Poland (ndsrodon@cyf-kr.edu.pl)

The contents of boron and nitrogen in illite-smectite clays from pyroclastic horizons of sedimentary rocks (bentonites) were studied using samples from different sedimentary basins, representing a complete range of diagenetic alteration. Bentonites were chosen to deal only with the authigenic clay, avoiding complications related to the recycled (detrital) clay material. The bulk rock chemical measurements, performed on raw rock samples in order to avoid any loss of exchangeable B and N, were referred to the contents of illite-smectite clays and to the content of illite alone, both measured by a combination of XRD and chemistry-based techniques [1].

The results indicate that the smectite illitization reaction in the studied range between 100 and <20 %S is not so much redistributing B and N present in the original smectite, but it is a net consumer of both boron and nitrogen from the pore waters.

Both B and N (as NH_4^+) are contained mainly in illite, so their contents in illite-smectite clay increase in more or less linear manner with progressing illitization. The content of N in illite layer is decreasing during diagenesis and the content of B is either decreasing or remains stable. In one diagenetic cycle bentonitic illite fixes up to 800-1000 ppm B and up to over 1% $(NH_4)_2O$, corresponding to over 20% of the fixed cation sites.

The studied rocks are different from regular sedimentary clays, because smectite in bentonitic horizons is not detrital but it crystallizes *in situ* during early diagenesis at the expense of volcanic glass. The conclusions drawn above refer only to this particular case. Similarities in diagenetic evolution of boron and nitrogen contents of illite, documented in this study, argue in favor of the kerogen as the dominant common source of both elements in sedimentary basins.

Reservoir properties dependence upon the compositional features of clay minerals

Kulyapin, P.S.[1*], Moiseenko, A.S.[2] & Strelchenko, V.V.[1]
[1]Well Logging Systems Dept., Gubkin Russian State University of Oil and Gas, Moscow, Russia ([*]pavel.kulyapin@gmail.com)
[2]Information and Measuring Systems Dept., Gubkin Russian State University of Oil and Gas, Moscow, Russia

Present-day core laboratories widely use the following method of clay content evaluation. The term “shaliness” is considered as an ability of rocks to contain particles with diameters d<0,01 mm, in the US laboratory practice d<0,001 mm. Hence, clay content is estimated by means of sieve analysis procedure.

Nevertheless, described approach eliminates the probability of fine-grained oxides and hydroxides of silicon and aluminum which aren’t related to clay minerals. Besides, clay fraction can be underestimated as the diameter of large kaolinite crystals exceeds 0,01 mm. Providing clay content is calculated thus-and-so, mistakes in formation evaluation are expectable.

Presence of certain clay minerals can indicate particular sedimentation conditions. Analyzing the alteration of clay minerals composition, it is possible to define depositional environments more exactly.

There is close correlation between depositional environments and natural radionuclide distribution. This fact is a basis for applying spectral gamma ray in order to determine clay mineral composition. Also, it is very helpful to estimate clay minerals content quantitatively using X-ray analysis, infrared spectroscopy or thermal gravimetric analysis.

Clay minerals impact on properties of oil and gas reservoir in a significant way. The study of clay minerals composition and estimation of their influence on physical and fluid-flow properties of rocks is a vital and high-demand task.

Clay minerals belonging to various groups affect reservoir properties differently. The estimation of a pore space filled by a clay material and the influence of certain clay minerals on filtration properties is applicable to drilling technology, formation evaluation and oilfield development. The information about clay minerals composition is used for adjustment of log-derived evaluation algorithms.

In the research the in-depth analysis of clay minerals is presented in scope of their effect on petrophysical properties of rocks. Also, the application of infrared spectroscopy for a qualitative and semi-quantitative estimation of clay minerals content is addressed.

Multi-constituent modeling of gasoline contamination in laboratory – sorption of light hydrocarbons by clay

Tóth, J.
New Technologies and R&D, MOL Group Exploration and Production Division, Budapest, Hungary (judittoth@mol.hu)

Petroleum hydrocarbons are common site contaminants, but little is known about their natural attenuation processes. Due to the diversity of hydrocarbon compounds a range of remediation technologies may be applicable. Volatilization and gas transport of VOCs are the bases for some remediation technologies (for example soil venting, air sparging, and soil vapor extraction), consequently knowledge of the volatility of hydrocarbon compounds is important for understanding their fate in subsurface media. In order to investigate volatility and sorption of light hydrocarbon compounds, a special column experiment was conducted in laboratory.

The volatile components of the used hydrocarbon could be transported only in one direction (upward through fillings), therefore the investigation of their sorption on natural clay and sand was possible. At the end of the experiment more than half of the initial fluid volatilized, due to the volatility of the individual constituents. The volatilization was very effective in the first year.

The sorbed HCs are mainly paraffins and aromatics, while napthenes rarely occur. After half a year, n-C_7 was found to be the lightest and C_{11} the heaviest constituent. The range enlarged continuously, it was possible to measure n-C_6 and C_{12} after one year, while at the end of the modeling n-C_5 and C_{15} were already measurable in clays. It was possible to detect sorbed HCs after half a year only in clay layers and in every sample at the end of modeling. Quantity of sorbed compounds decreased with growing carbon numbers. Models with clay-caps contained larger amounts of HCs also in deeper layers compared to their sandy pairs (totally three to six times more quantities). The reason for this is presumably the good sealing property of the clay, therefore volatilized components remained in the pores among sand particles or sorbed onto the individual constituents. Quantity of sorbed HCs is the greatest in the vicinity of the fluid phase. Fine tendencies, dependent on depth, can be seen mostly in case of cyclohexane, benzene, as well components with slightly larger carbon number (e.g. C_{10}, C_{11}, C_{12} and C_{13}). These clearly show the effect of less volatility.

By comparing the results of detailed analyses (GC, Rock-Eval, XRD), adsorption was the main sorption process.

On the basis of comparative assessment of the results derived from the analyses of samples from different phases (fluid, gas and solid), the best practice for identifying the source of a gasoline type contamination is a joint analysis of sorbed and free hydrocarbons of the soil samples, while the best way to monitor a contamination is to analyze free gas components. It is worth applying the analyses together, because a different range of the initial fluid phase can be measured from the free gas and the sorbed phase. The ratio of the lightest hydrocarbons in the total amount of hydrocarbons may indicate the time when the contamination occurred.

Laboratory methods in evaluation of shale interaction with drilling fluids: effect of clay content and shale characterization

Gomez, S.
M-I SWACO, Houston, TX, USA (sgomez@miswaco.com)

The behavior of shale samples exposed to drilling fluids may differ significantly due to the rock characteristics. Type and amount of clay minerals, rock structure, distribution of minerals, and other geologic features are important elements that need to be integrated in the execution of successful testing programs. This paper includes the descriptions of different test methods used to evaluate the interaction between shale and drilling fluids and how the characteristics of the shale samples are used to select the experimental methods. Understanding and comprehending clay content and distribution in the shale samples is one of the most valuable steps before the testing. The response of clays with fluids can be manifested in swelling process, dispersion, propagation of fractures and other mechanisms. The type of response can be closely related to the type of clay. The rock structure and mineral distribution also play important roles. Presence of laminations, lenses, and just bulk structure may control, restrict or direct the areas where the fluids can interact with the clays in the rock. Compositional and structural variations in shale samples can be obtained from shale samples and constitute the base information for the selection of the laboratory tests for the drilling fluid design.

Clay minerals features application for reservoir pressure estimation

Deshenenkov, I.S.* & **Gorodnov, A.V.**
Gubkin Russian State University of Oil and Gas, Moscow, Russia
(*isd@post.com)

This research is devoted to the development of the abnormally high formation pressure (AHFP) zones determining innovative technique on well logging data. The method is based on changes in dependences of clays physical properties in AHFP zones. It takes into account the nonsteady thermal field in the borehole.

Normal pressure is formation pressure is due to the presence of fluids in pore spaces of the rock matrix. Abnormal pressure is any geopressure that is different from the established normal trend for the given area and depth.

AHFP represent a serious threat for the well and its staff maintenance while deep wells drilling and development. High technological and economic performance in drilling and deep wells development can be achieved in case of correct prediction and estimation of AHFP zones.

Abnormal pressure predicting methods in the thickness of sedimentary rocks are based on the pattern of rocks properties changes as a result of compaction in the process of sediments accumulation. Physical properties of pure clays, used as an indicator of pore pressure, are determined by its compaction degree. Clayed rocks containing deposits with AHFP are less sealed and have higher porosity in comparison with similar rocks with normal pore pressure [1].

Physical parameters depend on rocks density and as result porosity. This dependence of clayey rocks is the basis of various identifying and estimation by abnormal pressures methods.

There are following methods for AHFP zones predicting: equivalent depths method, «normally clay compacted curves» technique, compression curve method.

Factors determining changes in physical properties of pure clay rocks are changes of clay mineral composition and temperature. However, the impact of changes in clay mineral composition at depths of more than 2000-2500 m (in AHFP zones) is nonessential fact. A significant contribution to the calculation of reservoir pressure makes temperature [2].

Temperature correction is traditionally calculated on the geothermal gradient. Nevertheless, the real thermal field in the borehole can differ greatly from stationary geothermic data. Therefore, thermal field in the borehole was simulated. Also the distribution of the temperature over time after flushing out of well was surveyed within the radius of well logging methods study.

Authors investigate the thermal field formation in the vicinity of the borehole. Dynamics of the thermal field during drilling, well cleanout and well shutdown are studied. Temperature factor effects on the accuracy of abnormal pressure on well logging data calculation are determined. A modified «normally clay compacted curves» technique is developed. It involves the introduction of the correct temperature adjustment to electrologging curves before the line of normal clay compaction tracing.

Formation of thermal field in the vicinity of the borehole was investigated. Innovative method AHFP calculation, based on changes in dependences of clay physical properties in AHFP zones and taking into account nonsteady thermal field in the vicinity of the borehole, was developed. Maps of abnormal pressures and anomaly pressure coefficients in sediments of Bazhenov formation were charted.

Possibilities of gamma-ray log quantitative interpretation

Ezhov, A.K.* **& Lazutkina, E.N.**
Well-logging Systems Dept., Gubkin Russian State University of Oil and Gas, Moscow, Russia (*ejcyril@mail.ru)

Current work is devoted to studying of influence of separate clay minerals on collector properties and to definition of their maintenances according to gamma-ray log in complex of well-logging data.

On the basis of the revealed laws, petrophysical modeling of collectors and adaptive techniques of well-logging data interpretation [1] the algorithm of an estimation of kaolinite and hydromicas maintenances in structure of clay cement was developed (Fig. 1). In this work results of interpretation of Jurassic deposits of Tevlinsko-Russkinskoe field (West Siberia, Russia) are presented.

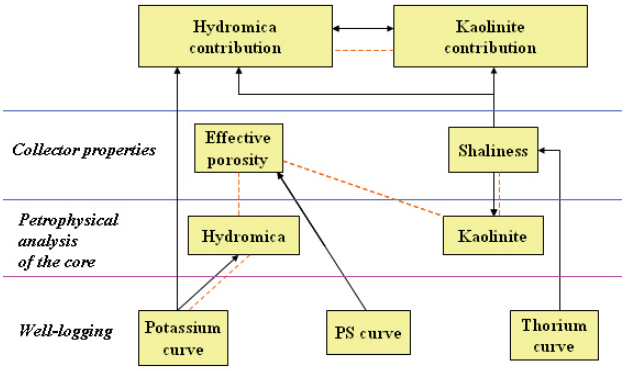

Fig. 1: The scheme of estimation of kaolinite and hydromica maintenances in cement of terrigenic collectors.

The ways of an estimation of kaolinite and hydromica maintenances in clay cement of collectors according to gamma spectrometry in complex of borehole surveys are offered. It's based on their interrelation in clay cement of terrigenic collectors.

It is revealed that character of ratio between contributions of hydromica and kaolinite in clay cement of terrigenic collectors is maintained for different adjournment of various deposits.

The specificity of clay minerals influence on the residual water layer formation

Petrov, A.N.
Gubkin Russian State University of Oil and Gas, Moscow, Russia (*al.n.petrov@gmail.com)

Clay minerals have specific features. A distinctive feature of all clay minerals is their high dispersity. High dispersion creates a well-developed specific surface area of rock (up to 800 m2/g for montmorillonite), which causes a high margin of free surface energy and the manifestation of molecular interaction forces in the surface layers. The most important physical-chemical characteristics of clay minerals is their ability to surface dissociation (formation of a water shell), the ability to anomalous high ion exchange (cation exchange capacity) [1]. Patterns of distribution of residual water saturation for the multimineral reservoirs are complex and nonlinear. Dispersion of clay material greatly affects the quantitative assessment, and even small admixture of chlorite or hydromica will make significant changes.

Appearance of reservoir nonuniformity on the dependence of residual water saturation from the total porosity due to clay minerals variation is discussed. The set of factors contributing to the heterogeneity of the matrix and cement composition and properties, defines the dynamic range of cement and matrix properties, which is why scatter points on the plane residual water saturation – total porosity appear. This means that, although the dependence between residual water saturation and total porosity, as well as other petrophysical relations, the "statistical" comparisons is not functional, but it is not in the full sense of statistics. The scatter of points in the field of correlation is due not only to measurement errors, but to the differences in petrophysical properties of clay minerals comprising the matrix and cement. Petrophysical informative field configuration have the degree of correlation and the scatter of points in the field of correlation. The most general definition of a complex manifold, regardless of the nature of the latter, will be the following: complex reservoirs are reservoirs, which are meaningless concepts conditioned values of petrophysical characteristics, or relevant testimony well logging techniques.

Filtration, capacity, and structure, water storage capacity and other petrophysical characteristics depend primarily on the content of clay minerals, their composition and morphology in terrigenous reservoirs. If no or little content in the carbonate rocks, silicate and iron cement quantity and composition of the clay material is a decisive factor in the separation of rocks on the reservoirs and non-reservoirs.

In conclusion, for reservoirs with multimineral composition, the dependence of residual water saturation from total porosity cannot be unambiguously determined. For each part of the reservoir, this dependence can vary, due to the heterogeneity of the mineral composition.

All types of reservoirs and their filtration-capacitive properties manifested in different kinds of dependencies residual water saturation – total porosity. With a fixed capacitance matrix of the diversity of these relationships is due to a variation of the properties of clay cement.

This heterogeneity of polymineral clay and other reservoirs can formulate, the most common definition of "complex" reservoirs, as such, which make no sense notion of fixed values conditioned volumetric or appropriate evidence of well logging techniques.

Burial diagenetic processes of clay mineral and non-clay mineral, and their relation to quartz cementation in sandstones of the Siri Canyon, Danish North Sea

Kazerouni, A.M.[1*], Friis, H.[1] & Svendsen, J.B.[2]
[1]Dept. of Earth Sciences, Aarhus University, Aarhus, Denmark
([*]afsoon.moatari@geo.au.dk)
[2]DONG Energy, Exploration and Production, Denmark

The deep marine sandstones in the Siri Canyon, Danish North Sea, have been reported to import significant amounts of dissolve silica from adjacent Palaeocene shales during early diagenesis, and the authigenesis of silica developed several morphologies in the studied sandstones. We have studied the diagenesis of one of these shales, the Sele Formation shale, to document the diagenetic steps which release silica and to evaluate the possible capacity and timing of silica export from the shale into the interbedded sandstones. Initially, the shales were rich in smectite and had variable admixtures of silicious fossils (diatoms, radiolarian and sponge spicules) and volcanic ash.

Depth dependant alteration of the various components in the shale, results in successive stages of silica-release. In shallow samples (<1700 m), the alteration of volcanic ash has already been completed. Released silica was partly consumed for the precipitation of smectite and zeolite. Opal-CT is not systematically related to volcanic ash, and some silica may have been mobilized and migrated into the interbeded sandstones. In addition, a major part of the biogenic silica has been transformed into opal-CT and partly to microcrystalline quartz. The microcrystalline quartz is an internal sink for dissolved silica, but the shale may also have been an active silica exporter during this transition.

With deeper burial (2000-2900m), opal-CT is fully transformed to microcrystalline quartz. During this phase, silica has been partly mobile and depending on the rate of dissolution compared to the rate of precipitation, silica may have been lost to sandstone cementation. Zeolite is also dissolved and mobilized silica may also have activated the shale as silica exporter.

At deep burial, iron-rich chlorite has replaced a minor part of smectite. The smectite to chlorite transformation released silica at the expense of iron. Therefore, a third phase of silica mobility was active. Microcrystalline quartz may have been an internal sink, but the shale would also be a potential silica supplier at this stage. At maximum burial depth (2900 m), the major part of the smectite is still not transformed, and the smectite to illite transformation has not yet been activated as a potential silica source. Early cementation by opal and microquartz depends on the supply of dissolved silica from a readily dissolvable source. The process starts with biogenic silica dissolution and supersaturation of pore fluids with respect to opal-CT and quartz. Relative rates of opal-A dissolution and opal-CT nucleation govern the extent to which silica activity is buffered and hence the possible silica flux into adjacent sandstones. With progressively less remaining opal-A, silica activity starts to decline and opal-CT nucleation becomes subordinate to growth. Precipitation of cryptocrystalline quartz began once the thermodynamic drive for the opal-CT became insignificant. Relative rates of opal-CT dissolution with respect to quartz nucleation and growth buffer the silica activity and the possible silica flux into adjacent sandstones. The early stages of the sandstone diagenesis are dominated by massive precipitation of opal cement and microquartz. This indicates a large flux of silica at the time of opal-A to opal-CT transformation and possibly at the time opal-CT to microquartz transformation. Therefore, the dissolution rate of precursor phases (biogenic silica, opal-A and/-CT) was fast enough to create a sufficient silica gradient to exports silica from shale to sandstone.

Molecular simulation of the hydration of methane confined in the clay interlayer or in nanopores between clay basal surfaces

Lu Xiancai[*], Zhang Lihu, Zhou Qing & Liu Xiandong
State Key Laboratory for Mineral Deposits Reseach, School of Earth Sciences and Engineering, Nanjing University, Nanjing, P. R. China ([*]xcljun@nju.edu.cn)

Methane hydrate is not only a potential energy resource, but also would be an ideal crystalline solid for gas storage. In general, the rate of nucleation and growth of the clathrate can be increased by operating at either higher pressure or lower temperatures, but such conditions may be undesirable for many applications. One of the alternative strategies to increase the kinetics of clathrate formation is to increase the interfacial contact between liquid water and the gas by inducing solid supports such as silica [1] to generate a thin, confined water layer in contact with the gas. The promotion mechanism of the clathrate nucleation and growth by mineral surface should be disclosed in order to understand the formation of methane hydrate in muddy sediments and in artifical conditions. In this study, molecular dynamic simulations have been carried out to investigate the formation and stability of methane hydrate in Na-smectite interlayer with different layer-charge distribution and water content, as well as in the nanopores with clay walls in various P-T conditions. In the simulation, the MD program Dlpoly and Clayff forece field [2] was employed.

The simulation results indicate that the methane clathrate can be formed in the interlay spaces under much higher temperature and lower pressure than that of the bulk hydrate. As methane molecules confined in the interlayer of clay minerals, most of the methane molecules are solvated by nearly 12-13 water molecules and coordinated with six oxygen atoms from the clay surface simultaneously. The methane molecules are generally trapped in the six-member rings through the strong H-bonds, which is exactly similar to the behaviors of K^+ or Cs^+ in montmorillonite interlayers [3]. The self-diffusion coefficients of the methanes in the newly-formed cages remarkably decrease from 0.452×10^{-9} m^2/s to 0.060×10^{-9} m^2/s at 277 K and 50 atm.

The layer-charge distribution displays remarkable effects on the stability of interlays hydrated methane complexes. A clay surface with negative charge sites is hydrophilic and present lowers surface affinity for methane moleculars. As the net layer charge is similar, the distance between negative charge sites and methane moleculars play important roles. It is disclosed that the tetrahedral negative charge site near the surface is hydrophilic and reduces the clay surface affinity for methane, which leads to less stability of hydrated methane complex in the smectite with tetrahedral substitutions. As Arizona-type montmorillonite has no tetrahedral negative charge site, the hydrated methane complex in it is more stable than other clays with tetrahedral charges.

The stability of the methane hydrates confined in nanopores with talc basal surface also shift to the higher pressure region depending on pore size when compared with those of bulk hydrates. The surface of the clay walls act as templates for the cystallization of methane hydrate, and a layer of methane hydrates are firstly formed, which is tightly contacting to the clay surface.

Increase of porosity in turbiditic sandstones by late-stage diagenetic formation of chlorite and kaolinite

Marchel, C.
Wietze E & P Laboratory - RWE Dea, Wietze, Germany
(christian.marchel@rwe.com)

Core material of miocene aged turbiditic sandstones, located in the Nile Delta area (Egypt), have been analyzed by means of thin-section petrography, scanning electron microscopy/ energy dispersive X-ray, petrophysical measurements, X-ray diffraction and IR-spectroscopy.

The sandstones vary from fine grained- to conglomeratic sandstones, representing ancient channel fill deposits. Values of porosity range from 2-32 % and permeability vary between 0.005 and 1100 mD. Eodiagenetic alterations are represented by moderate mechanical compaction and grain reorientation, calcite replacement of former aragonitic clasts and formation of anatase, siderite and pyrite. Early quartz precipitation occurs as quartz overgrowth. Mesodiagenetic alterations are mainly represented by illitization of smectites, quartz overgrowth, formation of chlorite and kaolinite and late-stage pore filling calcite.

Evolution of the reservoir quality has been controlled by both, eodiagenetic and mesodiagenetic processes, and shows that formation of secondary porosity plays an important role. Whereas primary porosity occurs mainly as intercrystalline macroporosity and takes 30 Vol.-% of total amount of porosity, secondary porosity comprises around 70 Vol.-% of total amount. The main part of secondary porosity belongs to intercrystalline micropores between chlorite and kaolinite. Investigations indicate that the formation of chlorite and also kaolinite proceeded at a late stage of diagenetic history, later than generally expected. It occurred via transformation of Fe-Mg rich detrital grains, fragments and clayey compound as well as precipitation within open pore space. This “late-stage formation” might be the result of rapid burial to greater depths and therefore decelerated mineral reactions. Thereby the detrital components stabilized the framework to a certain degree and prevented the sediment for strong mechanical compaction prior to the formation of chlorite and kaolinite. Thus, the new formed intercrystalline micropores increase the total porosity and also permeability of the reservoir section.

Structure of nanocrystalline phyllomanganates produced by freshwater fungi

Grangeon, S.[1], Lanson, B.[1*], Miyata, N.[2,3], Tani, Y.[2] & Manceau, A.[1]
[1]Mineralogy & Environments Group, Laboratoire de Géodynamique des Chaines Alpines, Université J. Fourier – CNRS, Grenoble, France ([*]bruno.lanson@obs.ujf-grenoble.fr)
[2]Institute for Environmental Sciences, University of Shizuoka, Japan
[3]Dept. of Biological Environment, Akita Prefectural University, Shimoshinjo-Nakano, Akita, Japan

Chemically reactive nanosized manganese dioxides are produced by a variety of living organisms including bacteria, fungi, and plants. The biotic oxidation of Mn^{2+} to Mn^{4+} is approximately two orders of magnitude faster than the heterogeneous oxidation catalyzed by mineral surfaces, thus supporting the currently held view that the biogenic route to Mn oxide formation prevails in nature. Vernadite, a nanosized phyllomanganate consisting of randomly-stacked layers of edge-sharing $(Mn^{4+}O_6)^{8-}$ octahedra [1], is the main biogenic Mn oxide, possibly with tectomanganates, such as todorokite. Phyllomanganates such as birnessite owe their surface reactivity to the presence of vacant layer sites and/or to Mn^{3+} for Mn^{4+} substitutions that confer to the layer a charge deficit up to three times higher than that of smectite. Vernadite has in addition high amounts of border sites because of its very small particle size. The ratio of external to internal Mn sites increases indeed when the crystal size decreases, and biogenic vernadite with a layer dimension of 60-70 Å [2] has approximately 20% of its Mn atoms exposed at the crystal border compared to ~0.4% for a birnessite layer ~300 Å [3]. Thus, organic pollutants can be degraded and trace metals taken up by vernadite in natural systems.

The production and sorption capacity of fungal vernadite are well documented, but progress in the interpretation and modeling of sorption data is limited by the lack of a comprehensive structure model. In the present study, chemical analyses, XANES (X-ray absorption near edge structure) and EXAFS (extended X-ray absorption fine structure) spectroscopy, and powder X-ray diffraction (XRD) were combined to determine the nature and amounts of structural defects in vernadite produced by three fungal strains. The fungi-mediated oxidation of aqueous Mn^{2+} produces layered Mn oxides analog to vernadite, a natural nanostructured and turbostratic variety of birnessite. The crystallites have domain dimensions of ~10 nm in the layer plane (equivalent to ~35 MnO_6 octahedra), and ~1.5-2.2 nm perpendicularly (equivalent to ~2-3 layers), on average. The layers have hexagonal symmetry and from 20 to 30% vacant octahedral sites. This proportion likely includes border sites, given the extremely small lateral size of the layers. The layer charge deficit, resulting from the missing layer Mn^{4+} cations, is balanced mainly by interlayer Mn^{3+} cations in triple-corner sharing position above and/or below vacant layer octahedra. The high surface area, defective crystal structure, and mixed Mn valence confer to these bio-minerals an extremely high chemical reactivity. They serve in the environment as sorption substrate for trace elements and possess catalytic redox properties

Oxidation of As(III) by β-MnO_2 in the presence of Fe(II) under acidic conditions

Gu, J.-D.[1*], Han, X.[1] & Li, Y.L.[2]
[1]School of Biological Sciences, The University of Hong Kong, SAR, China ([*]jdgu@hkucc.hku.hk)
[2]Dept. of Earth Science, The University of Hong Kong, SAR, China

Arsenite [As(III)] is a highly toxic inorganic pollutant and is mobile in sediments and aquifers because of its neutral, uncharged molecular state (H_3AsO_3) below pH 9.1 in soil-water environments. Oxidation of As(III) to the less toxic As(V) is always observed in aqueous environment containing Mn-oxides. Fe(II), which often co-exists with As(III) in groundwater, can also be oxidized by Mn-oxides; however, the contribution to As(III) oxidation by Mn-oxides has not been reported.

Effects of Fe(II) on As(III) oxidation at MnO_2-water interface under acidic conditions were investigated in this study and kinetic experimental results showed that oxidation of As(III) could be described by a pseudo-first order kinetic model and oxidation rate of As(III)/Fe(II) decreased with the increase of pH (2.0-5.0) in mono system. Competitive oxidation between Fe(II) and As(III) occurred on MnO_2 surface in the binary system, and the inhibitory effects of Fe(II) on As(III) oxidation decreased with the increase of Fe(II)/As(III) ratios. The inhibition could be attributed to the formation of Fe(III) compounds on the surface of MnO_2 and thus preventing the MnO_2 surface being accessible to As(III), and the produced Fe(III) compounds sequestered more oxidized As(V) with the increase of Fe(II)/As(III) ratios (Fig. 1).

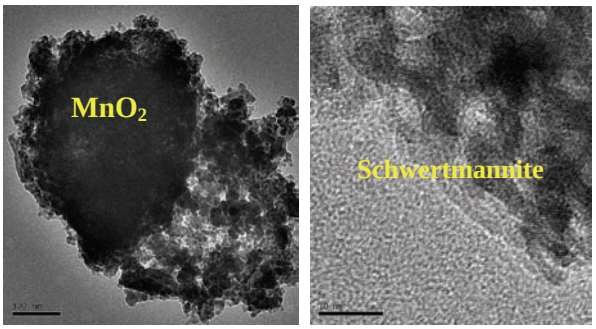

Fig. 1: Surface characterization of MnO_2 after the treatment with 15 mg L^{-1} Fe(II) at pH 3.0 and Precipitates formed around MnO_2 after the treatment of 20 mg L^{-1} As(III) at pH 3.0 with Fe(II):As(III)=1:1.

TEM results confirmed the formation of Fe compounds around or away from MnO_2 particles in both mono and binary systems, and schwertmannite particles were detected (Fig. 1) in the mono-oxidation of Fe(II) by MnO_2, while a new phase, most likely ferric arsenate ($FeAsO_4$) as confirmed by EDX was detected in the Fe(II)-As(III) binary system.

On the basis of the above results, mechanism involved in the process was proposed that competitive oxidation occurred between Fe(II) and As(III) on MnO_2 first and followed by the formation of Fe compounds around MnO_2, which inhibited oxidation rate of As(III) and Fe(II) in solution. Then, As(III), but not Fe(II) in the bulk solution, could slowly diffuse through the layer of the Fe(III) compounds and access the surface of MnO_2 for further oxidation, and some of the produced As(V) was released back into solution.

The present study suggested that the presence of Fe(II) played an important role in the oxidation of As(III) by MnO_2 on surface of minerals under acidic conditions.

Detailed crystal chemistry and iron topochemistry of naturally occurring asbestos (NOA): a first step to understanding their chemical reactivity

Pacella, A.[1], Andreozzi, G.B.[1*] & Fournier, J.[2]
[1]Dipto. di Scienze della Terra, Sapienza Università di Roma, Rome, Italy ([*]gianni.andreozzi@uniroma1.it)
[2]Laboratoire de Réactivité de Surface, Université Paris 6, 4, Paris, France

Five samples of naturally occurring tremolite asbestos (NOA) from Italy and USA were fully characterized by means of a well tested multi-analytical approach (ICP-MS, SEM, EMPA, FT-IR, MS, XRPD), with the aim to correlate crystal chemistry with chemical reactivity. Iron topochemistry was investigated in detail, due to Fe recognized contribution to aetiology of respiratory inflammatory diseases. The Italian tremolite samples have different Fe content (San Mango > Ala di Stura > Rufeno > Castelluccio Superiore), and the North American sample from Maryland shows a value almost double than the Italian ones. The bulk Fe^{3+}/Fe_{tot} ratio was quantified by Mössbauer spectroscopy, and the values obtained ranged from 6% Fe_{tot} (San Mango tremolite) to 24% Fe_{tot} (Mt. Rufeno tremolite). A possible site distribution of Fe was retrieved from combining chemical, spectroscopic and structural (Rietveld refinement) data. For all samples a substantial Fe^{2+} equidistribution was observed over M(1), M(2) and M(3) octahedral sites, whereas Fe^{3+} was only allocated at M(2). Results of EPR measurements on the Italian samples evidenced chemical reactivity (that is, HO° radical production) for all of them, with the highest value observed for San Mango sample and the lowest for Castelluccio Superiore sample. Notably, the HO° radical production resulted to be related to the Fe_{tot} content and, in particular, linearly related to the Fe population at [M(1) + M(2)] octahedra. Considering that Fe_{tot} population at M(2) > M(1) > M(3), that M(1) and M(2) have site multiplicity twice that of M(3) and are more exposed than M(3) on the external surface of the fibrils, the Fe at M(1) and M(2) sites has the highest probability to be involved in surface reactions.

Chemical composition of voltaite formed from flue gas of a coal-fired power plant

Gieré, R.[1*] & Williams, C.T.[2]
[1]Institut für Geowissenschaften, Universität Freiburg, Germany ([*]giere@uni-freiburg.de)
[2]Dept. of Mineralogy, The Natural History Museum, London, UK

Coal combustion facilities represent a major source of fine particulate matter (PM) in the atmosphere. We report results from analytical scanning electron microscope investigations on PM emitted from a commercial coal-fired power plant equipped with a stoker boiler. In an experiment designed to test the viability of co-combustion of coal and waste tires, two types of fuel were combusted: pure coal (a high-volatile *C* bituminous coal); and a mixture consisting of 95 wt% of the same coal and 5 wt% of shredded tires.

The samples were collected on borosilicate glass filters placed in the smokestack above all air pollution control devices. The filters remained overnight (12 h) in the stack (gas temperature: 183-195 °C; flow rate: 108±2 ML/h) and trapped the PM that would normally have escaped into the atmosphere.

As shown in a previous study [1], these fugitive particles are typically small (<2.5 µm) and consist of amorphous material and a variety of crystalline phases, including: lime [CaO]; mullite [$Al_6Si_2O_{13}$]; anglesite [$PbSO_4$]; anhydrite [$CaSO_4$]; gunningite [$ZnSO_4{\cdot}H_2O$]; and yavapaiite [$KFe(SO_4)_2$]. The filters, however, also contain crystals that are larger than 2.5 µm. These larger crystals comprise: millosevichite [$Al_2(SO_4)_3$]; meta-aluminite [$Al_2(SO_4)(OH)_4{\cdot}5H_2O$]; tamarugite [$NaAl(SO_4)_2{\cdot}6H_2O$]; and members of the voltaite group [$K_2Me^{2+}{}_5Fe^{3+}{}_3Al(SO_4)_{12}{\cdot}18H_2O$, where Me^{2+} = Fe^{2+}, Mg, or Zn].

The voltaite-group phases are present on the filters as euhedral, mostly twinned crystals, ranging in size from a few µm to ~100 µm across. The chemical composition of the voltaite phases was found to depend on the type of fuel used: combustion of the coal+tire mixture led to the formation of homogeneous voltaite, which contains almost equal molar amounts of ZnO and FeO and only small amounts of MgO. Combustion of pure coal, however, led to formation of strongly zoned voltaite, characterized by a Mg-poor core rich in FeO and ZnO and two surrounding growth zones. The outer growth zone is nearly devoid of Zn, but contains similar molar amounts of FeO and MgO. It is concluded that the voltaite phases, like all other sulfate phases, crystallized from the flue gas upon cooling.

Speciation of arsenic in brown-coal fly ashes from central Slovakia

Bolanz, R.M.[1*], Majzlan, J.[1], Jurkovič, L.[2] & Göttlicher, J.[3]
[1]Inst. of Geoscience, Friedrich-Schiller-University, Jena, Germany ([*]ralph.bolanz@uni-jena.de)
[2]Dept. of Geochemistry, Comenius University, Bratislava, Slovakia
[3]Inst. for Synchrotron Radiation, Karlsruhe Institute of Technology, Eggentein-Leopoldshafen, Germany

Neogeone brown coal seams in central Slovakia were contaminated by arsenic from volcanic-related hydrothermal fluids [1]. This coal is mined and burned for electric power generation until today. It contains on average 518 ppm As [2]. Fly ashes are disposed as waste products in uncovered ash impoundments where they interact with their surrounding environment. In 1965, an impoundment failure released approximately 1.5 million m^3 of As-rich fly ash into the Nitra river flood plain, thus contaminating 19,000 ha of mostly agricultural land. In our work, we investigated the speciation of arsenic in the fresh ash and in the 1965 ash mixed with soil. We combined graphite-furnace atomic absorption spectrometry (GF-AAS), electron microprobe analysis (EMPA) and synchrotron techniques (µXRD, µXRF, and µXANES) to identify the arsenic carriers. The completely digested samples revealed high As concentrations in the fresh ashes (1,411 ppm) and in the ashy soils (1,381 ppm). Sequential extractions after TESSIER et al. (1979) [3] hint at the affinity of As to Fe-Mn oxides and carbonates in the fresh ashes but only the affinity to Fe-Mn oxides in the ashy soils. In the fresh ashes, five constituents could be identified by EMPA and µXRD with the following average As_2O_5 concentrations: (i) Mineral fragments, mainly quartz and plagioclase, showed no As at all. (ii) Vesicular glasses are the main component of the fly ashes with 0.13 wt% As_2O_5. These particles hold presumably a considerable amount of the total As. The same counts for the unburned coal particles (iii) with 0.10 wt% As_2O_5. (iv) Spheroidal glasses are only accessory but reveal the highest As_2O_5 concentrations, on average 1.35 wt%. (v) Calcite veins occur sporadically in the unburned coal particles and contain 1.60 wt% As_2O_5. Within the ashy soils, the spheroidal glasses (0.44 wt% As_2O_5), unburned coal particles (0.46 wt% As_2O_5) and their calcite veins (0.33 wt% As_2O_5) reveal the highest As concentrations. Considering that the abundance of those ash-derived components is rather low in comparison to the fresh fly ashes, these components might have a subordinate role as As carriers in the soils. However, three additional constituents were identified in the ashy soils. Calcite grains and decomposing organic fragments show no As at all. Much more interesting is the matrix cementing the mineral grains. Although the As concentrations are rather low (0.05 wt% As_2O_5), the cement is ubiquitous and therefore carries the bulk of the arsenic in the ashy soils. The µXRF results show a strong spatial correlation between As and Ca in the fly ashes as well as As and Fe in the ashy soils. The µXANES-spectra reveal that most arsenic within the fly ash and ashy soils is bound as As^{5+}.

Composition and source of aerosols in Kraków (S Poland)

Wilczyńska-Michalik, W.[1*], Tyrała, L.[2], Borowiec, W.[3], Damrat, M.[2] & Michalik, M.[2]
[1]Inst. of Geography, Pedagogical University, Kraków, Poland ([*]wmichali@up.krakow.pl)
[2]Inst. of Geological Sciences, Jagiellonian University, Kraków, Poland
[3]Inst. of Geography and Spatial Management, Jagiellonian University, Kraków, Poland

High concentration of particulate matter (PM) in atmosphere in Kraków has always been a great concern of local and state authorities. Concentration of PM10 and PM2.5 in air often exceeds permissible values.

The study is based on single particles analysis. Morphology, chemical composition and size were determined using SEM-EDS method. Aerosols samples were collected on the Petrianov filters and transferred onto polycarbonate filters for SEM observations.

Quartz, feldspars and mica-like particles are abundant but irregular aluminosilicate particles of non-stoichiometric composition dominate. Spherical aluminosilicate particles are present in all samples. Carbonate particles (calcite, dolomite or non-stoichiometric Ca, Mg, Fe carbonates) are also common. Fe oxides, metallic iron, other metal-rich particles are present in numerous samples. Cr and Ni rich particles were noted only occasionally. Fe-rich particles are spherical or irregular. Na and Ca sulphates are common in numerous samples. Barite particles and Fe sulphate occur sporadically. Particles of mixed composition (sulphates and chlorides of Ca, Na, Mg, Fe) are abundant. Carbonaceous particles are relatively common in aerosol samples. Soot in form of fine-grained aggregates is a dominant type of the carbonaceous aerosol. Soot particles usually contain S and Cl. Biological particles (spores, pollen) are present in numerous samples. Seasonal variation in relative abundance of several types of particles is also determined. Soot and spherical aluminosilicate particles are very common in winter period (heating period) whereas biological particles occur in spring and summer. Composition and seasonal variation of aerosols is similar to those determined in earlier period [1].

It is difficult to distinguish anthropogenic and natural particles in the studied samples. A dominant part of aluminosilicate particles are devoid of characteristic features of their origin. Only in several cases morphology or composition of particles can be considered to be clear signature of their industrial origin (spherical aluminosilicate from coal fired power plants, spherical metallic Fe or Fe-oxide from power plants or iron metallurgy, Cr and Ni rich particles from metallurgical plants, soot from domestic furnaces).

The study of particles from local industrial sources (e.g. power plants, steel plant, cement production) indicates that local sources can be considered as very important. Transport and heating installations in private houses are an additional source.

Distant sources of aerosols are also significant but their role is difficult to recognize based on the obtained results.

Environmental study at a former military camp, Kiskunhalas (Hungary)

Baricza, Á., Pataki, A.*, Szabó, K.Zs. & Csaba, Sz.
Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (*bouboux@freemail.hu)

In our contribution we studied a former military barrack and yard in Kiskunhalas (Hungary) for a request to determine the local radiation and the level of radon because the owner wanted to reconstruct the building into a dormitory. Our goal was to make an assessment and ensure the probable radiation load.

During our in situ measurements we determined the gamma radiation with a gamma dozimeter in the three-storey building and in nine types of tiles used in the building. The results show the gamma radiation between 70-90±20 nSv/h in each floor and 123±32 nSv/h in the most active tile. We collected a gas silicate building material because indoor radon partially stems from the building [1] for measurements of HPGe gamma spectroscopy and defined the radium equivalent index (0.32) and Finnish activities (100 Bq/kg). We conducted relatively short-term indoor monitoring in building on 12 points by RAD7 and AlphaGUARD active detectors where the highest value was 111±42 Bq/m^3. The building isolation was unsatisfying; therefore, we took 2 drilling cores in the yard about 20 m from the building.

In course of labor measurements, we studied the collected soil samples in radon chambers and screened 4 samples in each drilling core for mineral separate to identify the potential radon sources. By the result of radon chambers, the highest radon activities concentration was 401±187 Bq/m^3 in a soil sample of one of the drilling cores derived from depth of 100-135 cm. The grain size distribution also indicates an anomaly here, being dominated by the courser grain size fractions. This layer also shows the highest U content (4.41 ppm) determined by gamma spectroscopy measurements. Scanning electronmicroscopy was applied to identify those grains which can be potential sources of radon. We have found grains of charcoal, coke and coal in all size ranges, which means that the examined particular layer contains allogenic materials, behind natural soil minerals, related to human activity. These organic substances easily include the Ra^{220} because this element can constitute strong complex with organic ligands [2]. To ensure that this soil sample has not any risk, we made a measurement in the soil with soil-gas probe. The result was 15500±1350 Bq/m^3 what corresponds to a medium risk [3]. The indoor radon and gamma concentration results show no any risk, neither the building material nor the drilling samples, except one soil sample. However, the risk is minimal because it is located deeply enough and has not a really high concentration of radon therefore the building studied is suitable for living.

Distribution of calcite and dolomite in alkaline lake sediments

Bozsó, G.* & Pál-Molnár, E.
Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Hungary (*bozso.gabor@geo.u-szeged.hu)

The major aim of the present study is to investigate the processes which determine the vertical distribution of calcite and dolomite in anthropogenic alkaline lakes of different hydrology. The distribution of dolomite and carbonate among hypersaline conditions is usually affected by evaporation, CO_2 concentration generated by root respiration and the chemical properties of rain and groundwater [1].

In harmony with our aims, samples were collected from the territory of the Fehér Lake (Hungary) at two sites during the spring of 2007. The profile K is situated on a saline meadow (temporarily inundated, desiccated during the summer), while the profile S1 was deepened at a fish breeding lake with a permanent water cover (drained only for a month in April). In case of both sites, a 4 m deep and 10 cm wide (diameter) undisturbed coring was made. The mineralogical analysis of calcite and dolomite was made with a DRON UM-1 type X-ray diffractometer equipped with a Cu tube, using 35 kV excitation voltage and 20 mA anode current.

The calcite and dolomite distribution in the two studied profile is very different (Table 1). Concerning the profile K, calcite appears below a depth of 55 cm; underneath, its quantity can be considered more or less constant (20-25 %) and its concentration decreases back to 0 only at a depth of 195 cm. The vertical distribution of dolomite in the profile K is not in a close relation with calcite, as it appears only below 145 cm and its maximum (42 %) is right at 195 cm. The vertical gradient of calcite and dolomite in the profile S1 is very different when compared to the profile K. The highest concentrations of calcite can be found between 0 and 40 cm (43-50 %), underneath its quantity continuously decreases but from 65 cm it settles at a fairly constant 15 % ratio. In case of the profile S1, the distribution of dolomite and calcite is very similar. In the upper 100 cm, the quantity of dolomite is around 18-20 %, and by increasing depth its ratio decreases gradually.

Table 1: The amounts of calcite and dolomite in the profiles

Depth (cm)	Profile "K"		Profile "S1"	
	Calcite (%)	Dolomite (%)	Calcite (%)	Dolomite (%)
0	0	0	50	18
40	0	0	43	18
55	16	0	20	18
65	24	0	15	22
95	25	0	0	20
145	15	27	18	15
195	0	42	15	15
295	28	25	15	0
345	25	10	15	0

Consequently, the distribution of calcite and dolomite in the profile K is affected by a strong leaching process, as both minerals appear only in the deeper-lying strata. The permanent water cover at the profile S1 inhibits leaching, thus dolomite formation can be observed also close to the surface layers. Based on our results, we claim that the distribution of dolomite formed in a lacustrine environment is primarily determined by the distribution of calcite and the prevailing hydrological conditions.

Geochemical atlas of soils and stream sediments of Santiago island, Cape Verde

Cabral Pinto, M.M.S.[1,2*], Hernandez, R.[1], Silva, E.A.F.[1], Silva, M.M.V.[2], Reis, P.A.[1], Rocha, F.[1], Dinis, P.A.[2], Inácio, M.[1], Prudêncio, M.I.[3], Marques, R.[3] & Patinha, C.A.[1],

[1]Geobiotec Center, University of Aveiro, Portugal
[2]Geociences Center, University of Coimbra, Portugal
([*]marinacp@ci.uc.pt)
[3]Nuclear and Technological Institute, Lisbon, Portugal

Climatic conditions and erosion are some of the natural problems of the Cape Verde archipelago. Furthermore, human influence on the surface environment has often proven to be inappropriate and pollutant. There is construction on soil fit for agriculture or forestry, dumping of solid or liquid materials in an inadequate manner, incorrect and intensive farming practices, the abuse of pesticides and fertilizers, watering with contaminated water, over-exploitation of aquifers in a manner that often leads to salinization. These factors cause innumerable consequences in terms of contamination of soil and both surface and subterranean water. Knowledge of the natural geochemical variability is essential for the proper resolution of economic, environmental, planning, medical and legal issues.

The need for building a database of georeferenced geochemical information that comprises the surface environment of the island of Santiago was the prime motivation for carrying out this study. A geochemical survey of 337 of stream sediment samples and 249 soil samples from the island of Santiago was conducted, following the guidelines of the International Project IGCP 259 not only at the sampling stage, but also in the subsequent stages of preparation, analysis, data treatment and mapping. Levels were determined, in the fraction < 2mm, of 36 elements: 9 major elements (Al, Ca, Fe, K, Mg, Mn, Na, P, Ti) and 27 trace elements (Ag, As, Au, B, Ba, Bi, Cd, Co, Cr, Cu, Ga, Hg, La, Mo, Ni, Pb, S, Sb, Sc, Se, Sr, Th, Tl, U, V, W, Zn), and total contents of REE.

Granulometric analyses were also carried out, and the mineralogical composition of about 25% of the soil and stream sediments samples was studied. 83 rock samples taken from various formations on the island of Santiago were also analysed, the levels of K_2O, Na_2O, $Fe_2O_{3(T)}$, MnO, Sc, Cr, Co, Zn, Ga, As, Br, Rb, Zr, Sb, Cs, Ba, Hf, Ta, W, Th and U and REE having been determined. The geochemical patterns obtained from spatial distribution maps were correlated with the nature of the parent rock, the soil type and also some sources of contamination. The interpretation of the results was carried out not only by observation of the geochemical maps, but also after statistical analysis of the data gathered, and supported by a wide range of available information. The use of Principal Component Analysis allowed associations between chemical elements to be perceived, whether geogenic or anthropogenic in origin. Spatial distribution maps of various multi-element indices of environmental importance were also drawn up, such as the Al/(Ca+Mg+K) Acidification Index, the Combi Index , the Environmental Risk Assessment Index, and the Enrichment/Contamination Indices for several groups of elements considered primary pollutant metals.

Control of pyrite oxidation for AMD by treatment agents

Choi, J.[1*], Ji, W.H.[2], Yang, J.S.[1], Lee, J.Y.[1] & Park, Y.T.[1]
[1]KIST Gangneung Institute, Gangneung, South Korea
([*]jchoi@kist.re.kr)
[2]MIRECO, Seoul, South Korea

In this study, several treatment agents have been applied to control acid mine drainage (AMD) from an abandoned coal mine in South Korea. Five natural minerals (calcite, dolomite, apatite, birnessite, smectite) and 3 chemicals (KH_2PO_4, MgO, $KMnO_4$) were selected as treatment agents for reducing the oxidation of the iron sulfide (pyrite) minerals which occur in the coal mine. For measuring the acid neutralizing capacity (ANC), net acid generation (NCG), and maximum potential acidity (MPA), ASTM D 5744-07 method was used. Among the treatment agents, both MgO and $KMnO_4$ showed a higher ability of reacting with the surface of pyrite.

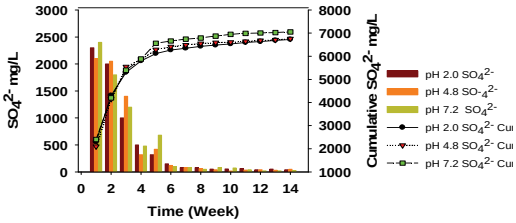

Fig. 1: The cumulative concentration of SO_4^{2-} at the coal mine.

The optimal conditions of coating with chemicals are 0.01 M $MgO+H_2O_2+NaOAc$ and $KMnO_4+H_2O_2+NaOAc$ at the initial pH of 6.0, respectively. Hydrogen peroxide and NaOAc were required to generate surface oxidation of pyrite and pH maintaining around 6.0, respectively.

Contamination level of arsenic and heavy metals, their bioaccessibility and risk assessment in the vicinity of the Songcheon and the Dongjung gold mines in Korea

Gold mining industry in Korea was most extensive during the early and middle 20th century, and most of gold mines have been closed during 1970s – 1990s without any environmental treatment of the mine sites. In this paper, two gold-silver mines, the Songcheon (SC) and the Dongjung (DJ) mines, were selected in order 1) to investigate the contamination levels and dispersion patterns of arsenic and heavy metals (Cd, Cu, Pb, Zn and Hg) in soils, crop plants and water in the vicinity of the mine sites, 2) to estimate the bioaccessible fractions of arsenic and metals in soils and plants by using the SBET (Simple Bioavailability Extraction Test), and the EHS (Extraction of Heavy metals in Stomach and small intestine) test, and 3) to assess human health risk for the residents around the mine areas.

Contamination levels of As and heavy metals in tailings, soils, sediment, water and crop plants were determined and plotted around the mine sites, and the pollution index (PI) of multi-elements in soil was proposed in this study. Arsenate was more predominant than arsenite in water collected near the SC mine sites and the concentration level of arsenate was higher than 50 μg/L. Arsenic concentration in the fingernails of the residents around the DJ mine was 12 mg/kg. The main contamination sources of As, Cd, Cu, Pb, and Zn are from tailings and their effluents according to ore and gangue mineralogy. The contamination level of Hg is almost negligible except for some mine tailings. The pathways of metals from tailings – agricultural soils - surface and ground water – annual crops - to finally human were suggested.

From the EHS test, bioaccessible contents of metals in soils and crop plants were determined and risk characterization was estimated. The hazard index (HI) value of the SC and the DJ mines was 16 and 46, respectively, and particularly hazard quotient (HQ) value of As of each mine was 15 and 23, respectively. The cancer risk for As of each mine was estimated as 2.7 E-03 and 4.0 E-03, respectively, which exceed the acceptable risk (1 in 100,000) for regulatory purposes. But the SBET results showed some different HI and cancer risk values of each mine.

Mineral composition of PM_{10} particles from the atmosphere near the coal mine power plant: Veliki Crljeni (Serbia)

Cvetković, Ž.[1], Logar, M.[2*] & Erić, S.[2]
[1]Geological Institute of Serbia, Belgrade, Serbia
[2]Faculty of Mining and Geology, University of Belgrade, Serbia
([*]milogar@eunet.yu)

This research contribution is a part of a one-year project to collect particles from the atmosphere in the vicinity of power plants and the surface coal mine in the Kolubara basin and to analyze their mineral composition. Air samples for PM10 (particles of the matter with aerodynamic diameter smaller than 10 microns) particles were collected on filter paper using an appropriate instrument during February and March 2007. Measured concentrations of PM10 are gravimetrically certain. Even though the average monthly concentration is 89.6 μg/m, 30.8% of measurements are above recommended daily limits of 120 μg/m3 for PM10.

SEM examination showed that the collected samples of dust from the surrounding coal mines and power plants consist largely of the association of minerals and waste particles from vehicle exhaust (Fig. 1). Mineral composition of PM10 particles is complex, heterogeneous and constantly changing. However, the association shown in the picture is characteristic and similar as those reported in the literature [1]. In addition to the minerals shown, almost always present are quartz and feldspars as confirmed by X-ray powder diffraction.

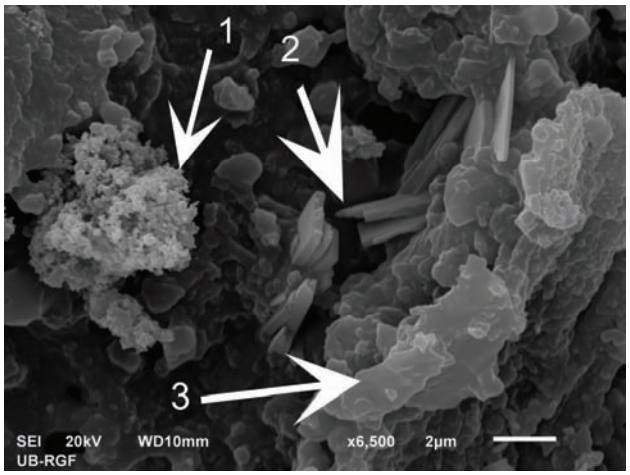

Fig. 1: Atmospheric particles (SEM): 1- particles from vehicle exhaust, 2- gypsum, 3- clay particles.

This paper shows that the concentration and mineral composition of atmospheric particles from the mine and the power plant is crucial for the fractions that are inhaled and for the identification of potentially hazardous components within the PM10.

Authigenic Fe-minerals as indicators of the Late Permian and Early Triassic depositional conditions (Velebit Mt., Croatia)

Fio, K.[1*], Posilović, H.[1], Sremac, J.[1], Vlahović, I.[2], Bermanec, V.[1] & Velić, I.[3]
[1]Faculty of Science, University of Zagreb, Croatia
([*]karmen.fio@geol.pmf.hr)
[2]Faculty of Mining, Geology and Petroleum Engineering, University of Zagreb, Croatia
[3]Croatian Geological Survey, Zagreb, Croatia

The uppermost Permian deposits in the Velebit Mt. area (Croatia) are characterized by the stratigraphic break caused by emergence and subsequent transgression which continued through the Permian–Triassic Boundary (PTB) into the Early Triassic. Two informal lithologic units can be distinguished – Transitional Dolomite (TD), relatively rich in fossils, and Sandy Dolomite (SD), characterized by recrystallized grains, scarce fossils, and enhanced input of terrigenous siliciclastic material [1,2].

Selected TD and SD samples were disintegrated, or cut and polished and analyzed by optical microscopy, SEM, EDS, and XRD. Preliminary studies of the authigenic Fe-minerals found in the TD and SD units have shown characteristic mineral associations connected to the changes in the depositional environment. Fossiliferous TD deposits contain randomly dispersed red hematite grains. Highly recrystallized SD deposits above the lithologic change only occasionally contain hematite. Further up in the SD unit, due to the increased siliciclastic input and scarce fossils after the PTB, iron oxides form hematite, identical as in the TD unit, and magnetite. Magnetite, in framboidal form, in places accompanied with larger cubic crystals, is confined to recrystallized calcite and do not appear in the dolomite. The interstices between framboid microcrystals are filled with calcite; some magnetite hexahedra intergrow with calcite rhombohedra or contain calcite crystals.

Fine granulation, random dispersion, and association with fossil remains imply early diagenetic origin of hematite, when pore waters were more oxygenated and iron migrated by diffusion and not by pore water flow. Magnetite was formed during late diagenesis when more oxygen depleted waters penetrated into the sediment and mobilized iron from hematite. Locally concentrated magnetite suggests ion migration with pore water flow. Mineral stability fields of hematite and magnetite in an iron–carbonate–water system display magnetite as dominant mineral at high pH and low Eh conditions. In the absence of oxygen and at the high pH, precipitation was driven through OH^- addition. As precipitation reduces OH^- concentration and lowers pH, a small amount of carbonates was dissolved and restored equilibrium conditions within a solution.

Ferromagnetic mineralogy of dust accumulated on *Nerium oleander* leaves in the cities of Praia, Cape Verde, and Coimbra, central Portugal

Gomes, C.R.[1,5*], Rocha, A.F.[2], Gomes, E.C.[3,5] & Pereira, A.[4,5]
[1]Centre for Geophysics (CG), University of Coimbra, Portugal
[2]Lousã Secondary School, Lousã, Portugal
[3]Geosciences Centre (GC), University of Coimbra, Portugal
[4]IMAR, University of Coimbra, Portugal
[5]Earth Sciences Dept., University of Coimbra, Portugal
([*]romualdo@dct.uc.pt)

Atmospheric dust particles are a mixture of organic and inorganic materials, components of natural and antropic origin. Some of the inorganic particles are ferromagnetic *s.l.* and easily identified by their magnetic properties. In the last decade, some studies have been done in order to characterize airborne dust particles and especially those accumulated on plant leaves, particularly *Nerium oleander* leaves, of the urban area of Coimbra. Magnetic parameters of leaves have been interpreted to characterize ferromagnetic structures, their composition, size and sources. In Coimbra these ferromagnetic particles have been attributed to the vehicular traffic. The main goal of the present study is to compare ferromagnetic mineralogy of urban dust accumulated on the *Nerium oleander* leaves samples from the cities of Praia and Coimbra. Sampling of *Nerium oleander* was done on the 10th and 11th of April 2009. The samples which were taken in Coimbra are from 12 of the most polluted sites, identified in previous studies. Magnetic parameters (isothermal remanent magnetization (IRM), at 1 T, -25 mT, -100 mT and S-ratios) of sampled plant leaves were measured and determined using a pulse magnetizer and a Minispin magnetometer (Molspin). The mineralogical characterization was performed by S-ratios and SEM with an integrated EDS microanalysis system. The size of particles on the surface of plant leaves is between 50 μm and less than 1μm. The IRM_{1T} values measured were normalized for leaf surface area and were in the range $125.00x10^{-6}$ - $844.00x10^{-6}$ A, for samples of Praia, and $24.00x10^{-6}$ - $310.00x10^{-6}$ A, for samples of Coimbra. Mean values are $342.00x10^{-6}$ and $85.80x10^{-6}$ A, respectively. Praia's mean value is 4 times higher than Coimbra's value. These different mean values can be interpreted considering that the SEM images show that the density of particles distribution is higher for samples from Praia, probably due to the drier climate in Cape Verde. These samples show essentially irregular and angular particles and rare spherical structures. The latter are relatively abundant in Coimbra. Some of these ferromagnetic particles from Praia samples (Fig. 1a) have a natural origin in Santiago Island substrate rocks, mainly in basalts. Irregular ferromagnetic particles are also present in Coimbra's samples (Fig. 1b) and they could be either anthropogenic or geogenic. These particles were identified as magnetite-like particles considering the S_{-300} values (0.98 from Praia and Coimbra's samples). Elemental mapping shows that Si, Ca, Fe, and Al are the most abundant elements on dust particles, reflecting the bedrock mineralogy and also the contribution of foreign dust, mainly from Sahara.

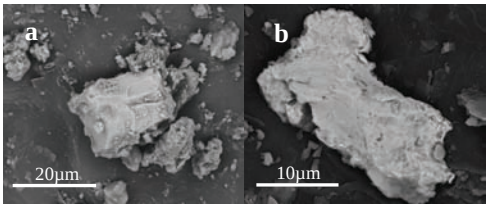

Fig. 1: SEM images of iron oxides from Praia a) (EDS: Fe, Ti, Si, Al, Mg, Ca) and Coimbra dust b) (EDS: Fe, C, Si, Ca).

Mineralogy and magnetic parameters of dust accumulated on *Nerium oleander* leaves in the city of Coimbra, central Portugal

Gomes, E.M.C.[1,2*], Saragoça, C.S.[2] & Gomes, C.S.R.[2,3]
[1]Geosciences Centre (GC), University of Coimbra, Portugal ([*]egomes@dct.uc.pt)
[2]Earth Sciences Dept., University of Coimbra, Portugal
[3]Centre for Geophysics (CG), University of Coimbra, Portugal

The purpose of this study is to characterize the mineralogy of urban dust accumulated on *Nerium oleander* leaves and to relate the mineralogical composition to magnetic parameters of leaves in order to recognize source origins.

Sampling of *Nerium oleander* leaves was done on the 4th of July 2007 in 122 sites in the urban area of Coimbra. Magnetic parameters (isothermal remanent magnetization (IRM), at 1 T, -25 mT, -100 mT and S-ratios) of sampled plant leaves were measured and determined. The IRM_{1T} values obtained were in the range $10.1x10^{-6}$-$172.2x10^{-6}$ $A.m^2$. Considering that IRM_{1T} values are proxies of pollution levels and allow the identification of pollution hot spots, plant leaves with higher values of IRM were used to study particles morphology, size, and chemical composition.

The mineralogical characterization was performed by S-ratios values and SEM with an EDS microanalysis system. Particle size on the leaves surface is between 50 µm and less than 1 µm. The major mineral components are quartz and phyllosilicates (mostly illite). Magnetite-like particles are also a major component. The S-ratios, S_{-25}, S_{-100}, and S_{-300} confirm the presence of these ferromagnetic structures. Less abundant mineral phases are calcite, calcium sulphate, and halite. Quartz particles are angular to subangular and range from 30 µm to less than 5 µm. Illite may appear covering spherical particles (Fig. 1a) or as aggregates exhibiting a vesicular texture. These aggregates reach 50 µm as maximum size. Individual grains are usually platy. The chemical composition of these clay particles includes Si, Al, K, Fe, Mg, and Na. Ferromagnetic particles are spherical to irregular. The mean size of these spherical particles is about 10 µm but the irregular ones can reach 30 µm. However, S-ratios indicate particles with diameter less than 10 µm. Some show cortical texture (Fig. 1b), with contours. Others seem to be built by stacking of tetrahedral and half-octahedral units. The X-ray analysis showed that these particles are composed of Fe, as a major element, with minor Ca, Cr, and Mn concentrations. Some particles, mainly aggregates, contain a group of elements in such proportions that cannot be attributed to a known mineral. These particles may show major concentrations of Fe, Cu, Ti, and Pt and minor Mg. Biological particles consist of pollen grains, sometimes covered by fine and ultra-fine mineral particles. Elemental mapping shows that Si, Ca, Fe, and Al are the most abundant elements on dust particles.

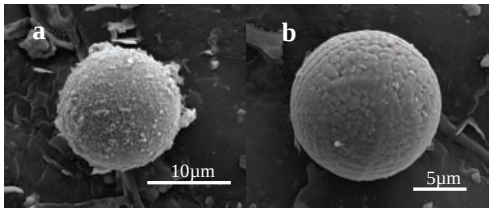

Fig. 1: SEM image of: **a)** illite covering a spherical particle (EDS: Si,Al,K,Fe,Na,Mg) and **b)** ferromagnetic dust particle (EDS: Fe,Cr,Mn).

Considering that Coimbra is a non-industrial city, located at about 40 km from the Atlantic coast, the main source of dust particulates found on *Nerium oleander* leaves surface may be substrate rocks, soil, and vehicular emissions. Quartz and phyllosilicates are terrigenous minerals. Most of the ferromagnetic particles are ascribed to the traffic pollution.

Environmental geochemical study at vicinity of a thorium anomaly in the Buda Mts. (Hungary)

Grosch, M.[1*], Müller, M.[1], Szabó, Zs.[1], Boros, Á.[1,2] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]hun.grosch@gmail.com)
[2]BGT Hungaria Environmental Technology Ltd., Budapest, Hungary

The thorium anomaly of Nagy Kopasz hill (Buda Mts., Hungary) has been studied since the 1950s. The former Mecsek Ore-mining Company heightened test trenches, prospect pits and drillings on the area. Study of the drilling cores and air borne gamma mapping showed a significant thorium anomaly, as well as rare earth element and Y indication [1,2]. Our major goals were to perform a pilot study by use of physical and geochemical methods on one of the prospect pits and its damp to assess the environmental impact of this portion of the thorium anomaly.

Based on in-situ gamma dose rate measurements, the dump showed maximum 2730 nSv/h, which is ten times higher than the average background value (70-90 nSv/h). Two soil samples were collected from the dump for additional laboratory investigations. Gamma-spectroscopy analysis was carried out, and thorium and uranium activity concentrations were determined, which show high content of thorium (max. 143±8 ppm), and low content of uranium (max. 0.26±0.02 ppm). Another part of the soil samples was sieved and divided into seven grain size fractions. Two grain size fractions were selected and grains were separated on the basis of morphology and color for scanning electron microscopy (SEM-EDS) study to define the content of thorium in the selected grains and identify minerals.

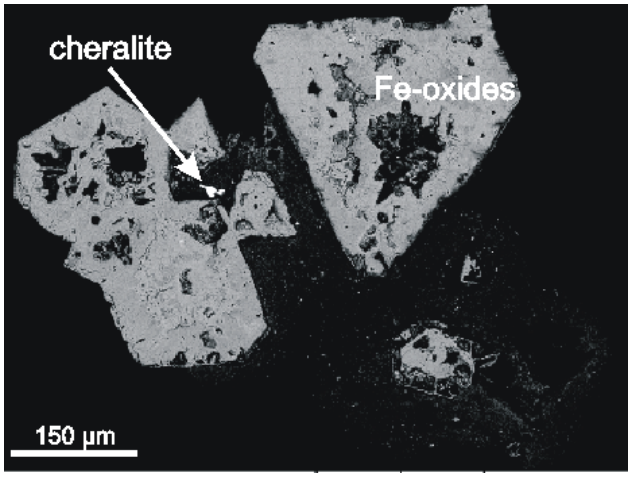

Fig. 1: SEM image with cheralite and Fe rich oxide minerals.

The high Th-bearing grains have been identified as mineral of cheralite (Fig. 1), which is always connected to the presence of Fe-oxide minerals and clay minerals. Due to the fact that the dump is rich in clay minerals, the local thorium anomaly does not mean a potential risk as it cannot be mobilized.

Environmental mineral formation in a Medieval (1664) bomb from Zrínyi-Újvár, Őrtilos, Hungary

Jánosi, M.[1*], Weiszburg, T.G.[1], Márialigeti, K.[2], Vajna, B.[2] & Négyesi, L.[3]
[1]Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary
([*]janosim@vipmail.hu)
[2]Dept. of Microbiology, Eötvös L. University, Budapest, Hungary
[3]Museum of Military History, Budapest, Hungary

The Hungarian Museum of Military History (Budapest) owns unexploded cast iron bombs, collected during the 2006 year excavations near Belezna and Őrtilos villages, on the banks of river Mura, at the scarcely surviving remnants of an adobe fortress (Zrínyi-Újvár, Novi Zrin). The castle was built in 1661 and was then demolished in 1664 during a Turkish siege.

The bombs were found fully intact, their internal parts communicated with the neighbouring soil/sediments only via a wooden plug, serving originally as fuse. Such bombs contained originally KNO_3, sulphur and charcoal. Recently two bombs were halved in order to perform combined mineralogical and microbiological studies for understanding the alteration processes of the original gunpowder filling.

In the larger bomb's half (external diameter 265 mm, Fig. 1 left) more or less concentric yellow, white and brown colour zones are visible, starting from the fuse. 6 subsamples were separated and studied by X-ray powder diffraction (XRD) and SEM+EDX. The yellow part proved to be jarosite. Both the c_0 unit cell parameter, 17.224(5) Å, sensitive for the large cation substitution, and the a_0 parameter 7.2998(6) Å, sensitive for the Fe-Al substitution indicate no Na, H_3O or Al in jarosite. SEM+EDX confirmed that observation, thus jarosite in the bomb is practically pure end-member jarosite.

The main mass of the bomb infilling is goethite. Other identified minerals are: rozenite, mohrite, siderite and sulphur, as relic of the gunpowder.

Fig. 1: Cut surface of the bombs, 265 mm diameter (left), 171 mm diameter (right).

In the smaller bomb's half (external diameter 171 mm, Fig. 1 right) goethite, jarosite and rozenite minerals and sulphur were identified. The bombs were exposed to oxygen, water and most probably, certain colonies of bacteria (utilising N and S), leading to the formation of the identified sulphates.

Secondary Sb mineral phases from abandoned Sb deposit Dúbrava (Slovakia)

Klimko, T.[*], Lalinská, B. & Chovan, M.
Dept. of Mineralogy & Petrology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
([*]klimko@fns.uniba.sk)

Secondary Sb mineral phases were studied as the products of oxidation of the sulphide minerals in the environment of mine tailings, dumps and soils at the abandoned Sb deposit Dúbrava in the eastern part of the Low Tatra Mts. in Slovakia. The mine tailings contain a high amount of toxic elements (up to 3.46 g/kg of Sb and up to 0.38 g/kg of As). The extent of the old dumps is also significant and contamination of the soils at the deposit is high (up to 9.62 g/kg of Sb and up to 0.93 g/kg of As). Therefore, these sites are significant sources of toxic elements (mainly Sb and As) that may migrate into the surrounding environment.

Pyrite, arsenopyrite and stibnite are the dominant primary sulphide minerals in the tailings and the soils. As a result of their oxidation, a high amount of secondary mineral phases with a variable content of Fe, Sb and As is created. From the mineralogical point of view, these phases are mostly Fe oxides/oxyhydroxides (ox./oxyh.), Fe(Sb) ox./oxyh. (Fe>Sb) and Sb(Fe) ox./oxyh. (Sb>Fe). Probably due to observed rapid decomposition of stibnite, these minerals often contain a high amount of Sb incorporated in their structures.

Besides, the main secondary products of sulphide oxidation in the environment of the tailings and the soils are weathering rims on the pyrite and the arsenopyrite crystals that are formed by Fe ox./oxyh.. The rims on pyrite have high content of Fe (up to 63.93 wt. %) and often significant content of Sb (up to 7.75 wt. %) and As (up to 3.63 wt. %). The rims on arsenopyrite contain up to 60.06 wt. % of Fe, up to 7.01 wt. % of Sb and up to 19.87 wt. % of As. Additionally, Sb as well as As binds in the oxidation rims with a concentration gradient from the edge of the rim to its contact with the primary sulphide.

However, the more important secondary min. phases in the process of distribution of toxic elements are the Fe(Sb) and Sb(Fe) ox./oxyh. with high content of Sb. These minerals are mostly created by crystallization from pore solutions in the environment of the tailings and the soils *in situ*. The crystals of Fe(Sb) and also Sb(Fe) ox./oxyh. are often chemically zoned, cracked and have sinter character. The WDS analyses proved increased concentration of Sb in the light zones, on the other hand decreased concentration of Fe in these zones. The content of Fe in Fe(Sb) ox./oxyh. is up to 62.82 wt. %, the content of Sb is up to 27.95 wt. % and As is up to 4.29 wt. %. Sb(Fe) ox./oxyh. have high content of Sb (up to 61.34 wt. %) and lower content of Fe (up to 27.22 wt. %). Content of As in these phases is usually low (up to 1.26 wt. %). In some cases, phases with significant content of Ca (up to 9.88 wt. %) were identified. In the environment of the old dumps the secondary Sb mineral phases are created by oxidation of the primary stibnite in the forms of thin films and crusts. The chemical composition of these phases correspondents to the minerals stibiconite (up to 69.50 wt. % of Sb) and romeite (up to 52.17 wt. % of Sb and up to 7.77 wt. % of Ca). This was also confirmed by XRD diffraction.

Observed results show the high affinity of As to Fe ox./oxyh. and a different behaviour of Sb, as it precipitates in the form of Sb(Fe) ox./oxyh. from pore solutions. Similar differences in As and Sb mobility were shown by sequence analyses of tailing material and stream sediments at the Dúbrava locality.

Unusual green Cr-rich smectite from Suweileh area, Jordan

Khoury, H.N.* & Al-Zoubi, A.S.Cr.
Dept. of Geology, University of Jordan, Amman, Jordan
(*khouryhn@ju.edu.jo)

In Jordan the green soft earthy volkonskoite is mainly associated with travertine of Pleistocene age. The chromium content in volkonskoite is responsible for the green color of the travertine. Volkonskoite exists as a filling material in cavities, voids, fractures and replacing pre-existing smectite.

A new green earthy clay locality is found in Suweileh Area, near Amman, Jordan. The green clay crops out at the surface and is found along bedding planes and filling voids and fractures in the limestone and phosphorite beds of Upper Cretaceous. The petrographic and mineralogical investigations have revealed that the green clay from Suweileh area is Cr-smectite with the structural formula: $(Ca_{0.30}\,Na_{0.23})\,(Al_{0.47}\,Cr_{0.63}\,Fe_{0.13}\,Mg_{0.66}\,Zn_{0.06}\,Ti_{0.03})\,(Si_{3.88}\,Al_{0.12})\,O_{10}\,(OH)_2$.

The infiltration of highly alkaline water through the combusted bituminous zone had led to leaching of Cr^{3+} and the precipitation of Cr-rich smectite in the Phosphorite Unit.

Suweileh volkonskoite is similar in structure and origin to that found in central Jordan [1].

Texture of calcium oxalates in human urinary stones

Kořistková, T.[1] & Leichmann, J.[2]
[1]Laboratory Specializing in Urinary Stones Analyses, Calculi®, Brno, Czech Republic (*calculi@calculi.cz)
[2]Dept. of Geological Sciences, Faculty of Science, Masaryk University, Brno, Czech Republic

We investigated the textures of urinary stones formed by calcium oxalate monohydrate (whewellite), calcium oxalate dihydrate (weddellite) and apatite. We selected two typical stones with different ratio of weddellite, whewellite and apatite. We focused on the role of apatite in forming these textures. The methods employed in our study were scanning electron microscopy (SEM, JEOL electron microscope), electron microprobe (EMP, CAMECA SX100) and polarised-light microscopy.

The first observed stone consisted approximately from 50% apatite, 50% whewellite, and traces of weddellite. The apatite fills up the pores and caverns or it is arranged in continuous layers. There is no sharp boundary between the oxalates and the apatite at some contact of those phases. Apatite infiltrates into oxalates locally. There are also the relics of oxalates in apatite.

The other stone consisted from 90% whewellite, and 10% weddellite, with traces of apatite. In this case, we have also observed similar dissolution texture of oxalates, but without apatite infiltration.

Dissolution textures in oxalates are caused by dehydration and transformation of weddellite into whewellite. The layers of apatite correspond to the change in the crystallization conditions, probably with a higher activity of phosphate. Apatite fills hollows in the aggregates of the oxalates.

Metal sorption on coal mine drainage sludge

Lee, H.E.[1], Choi, S.Y.[1], Doan, D.H.[1], Oh, S.G.[2,3], Lee, J.Y.[3], Sung, Y.H.[2] & Lee, Y.J.[1*]
[1]Dept. of Earth and Environmental Sciences, Korea University, Seoul, Korea (*youngjlee@korea.ac.kr)
[2]Development and Environment Team, Korea Resources Corporation, Seoul, Korea
[3]Dept. of Environmental Engineering, University of Seoul, Seoul, Korea

Coal mine drainage sludge (CMDS), with special interest as recycling products with rich mineral resources, has been tested as an effective sorbent for sorption of different metals. Development and understanding of mechanism(s) of metal uptake by effective sorbents like CMDS is essential for predicting the fate and transport of toxic metals in environments.

Zn sorption on CMDS have been investigated systematically to determine the mechanism(s) of Zn uptake by CMDS collected from Ham-Baek mine site and Ham-Tae mine site, South Korea over a wide range of pH and Zn concentration. These mine sludges were characterized by various techniques, and schwertmannite was also synthesized to compare with these sludges. XRF results show that both Ham-Baek (HB) and Ham-Tae (HT) sludges have an iron oxide as one of the major components. However, XRD indicates that HT sludge is mainly composed of iron (oxy)hydroxides such as goethite whereas HB sludge is composed of an iron sulfate mineral like schwertmannite.

Sorption of Zn on the HB and HT sludges, and the synthesized schwertmannite increases with increasing concentration of zinc at pH 4.0. At pH 7.0, however, the sorption rapidly increases, levels off, and then followed by little changes showing Langmuir sorption behavior. Results also show that Zn sorption on the two sludges and the synthesized schwertmannite increases with increasing concentration of the background electrolyte, suggesting that physicochemical properties of these minerals are likely changed by increasing the ionic strength at the mineral-water interface.

Forming mechanism and geological significance of glauconite in the Cretaceous Xiala section from Zanda, southwestern Tibet of China

Li, X.*, Cai, Y., Hu, X. & Huang, Z.
State Key Laboratory of Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, China (*lixiang_503@163.com)

Glaucony as a typical facies mineral formed at the water-sediment interface with a low sedimentation rate. Glaucony, especially evolved potassium-rich, is the only mineral facies that can give the age of a stratum without volcanic intrusion or well-preserved fossils. Up to date, previous researches were mainly focused on the origin and geological significance extracted from its host rock. None or less attention was brought to its forming mechanism.

A suite of glauconitic sandstone and limestone was outcropped in Xiala section from Zanda, southwestern Tibet of China. Three glauconitic samples, XL33, 34 and 35 were collected at this section. To determine the habit, mineralogy and chemistry of this glauconitic mineral, we carried out the observation under both petrographical microscope and Scanning Electron Microscope (SEM), and the analysis by X-ray diffractometry (XRD) and electron microprobe (EMP) on glauconite in the thin section and hand-picked sample, respectively. Furthermore, we also investigated the samples from the underlying strata which contain no or a few glauconite grains.

XRD pattern of purified glauconitic mineral shows that the basal lattice spacing (d_{001}, ~1nm) is sharp and symmetrical, indicating low content of swelling layer (<10%). The present of other peaks at 0.435($11\bar{1}$), 0.364 ($11\bar{2}$), 0.310 (112) shows that this glauconite has an ordered 1*M* mica-like structure. The EPMA result demonstrates that the content of K_2O is in the range of 6.93-8.30 %, with an average 7.86%. This suggests that the glauconite is highly evolved. Furthermore, there is no correlation between K_2O and Fe_2O_3 in three samples but both XL34 and XL35 show a negative correlation between Al and Fe^{3+} in octahedron.

According to the observation carried under both petrographical and SEM, the glauconite grains were constructed by microslabs of glauconite with the size of several microns. The occurrence of sparry calcite as rims on the periphery of glauconite grains and irregular contour of glauconite grains in glauconitic sandstone suggest their autogenic origin. Petrographical observation shows that glauconite gains closely coexist with detrital quartz in sample XL35. Furthermore, the chemical variation of sample XL35 is similar to XL34 with respect to the correlation between Al and Fe^{3+} in glaunocite grains. These suggest that the glauconite grains in limestone may come from the underlying glauconic sandstone.

As it illustrated in the SEM images, the glauconite grains in the sandstone were well-preserved the shape of debris and plenty of pore among the microslabs. These may suggest that the forming of glauconite was in an open but very quiet environment, and controlled by the dissolution-coprecipitation mechanism. The iron incorporated in the structure of glauconitic mineral come from the iron-bearing minerals while the potassium is supplied by the dissolution of potassium-bearing mineral. The open and quiet environment may be associated with transgression. This may relate to the last break-up of the Indian continent from the Australian-Antarctic continent during the Early Cretaceous.

Utilization of electrochemical methods for monitoring pyrite oxidation by *Thiobacillus ferrooxidans*

Liu Yun[1*], Dang Zhi[1,2] & Shu Xiaohua[1]
[1]School of Environmental Science and Engineering, South China University of Technology, Higher Education Mega Center, Guangzhou, China (*liuyunscut@163.com)
[2]The Key Lab of Pollution Control and Ecosystem Restoration in Industry Clusters, Ministry of Education, Guangzhou, China

In this work, the monitoring of the bacterial and chemical dissolution of pyrite was evaluated using Tafel polarization curves and electrochemical impedance spectroscopy (EIS). A pyrite-carbon paste electrode was utilized in an electrochemical cell in 9K culture medium with a 1% w/v pyrite concentrate as the sole energy source by replacing Fe^{2+} ions for different immersion times in the presence or absence of bacterium. The concentrations of Fe^{2+}, Fe^{3+} and total Fe had also been measured in the different systems during the leaching process. The results of Tafel polarization curves and the concentration of Fe^{3+} in leaching solutions indicated that the presence of bacteria enhances the corrosion process due to their ability to maintain an oxidizing environment rich in Fe^{3+} ion which increases the dissolution rate of pyrite comparing to the chemical attack. The total impedance of pyrite electrode measured in the presence of bacteria was much lower than in their absence, due to the acceleration of the mineral dissolution, because an oxidizing environment was maintained. The results also showed that the corrosion current density and impedance had been changed with leaching time, and these changes were in correspondence with the change of the concentration of Fe^{3+} in leaching solution. This proved that electrochemical methods could be used in a kinetic study of pyrite oxidation.

"Bacterioform" gold in placers and oxidation zones of Northern Uralian deposits (Russia)

Mayorova, T.P.*, Arteeva, T.A. & Filippov, V.N.
Institute of Geology, Komi Scientific Center, Uralian Branch, Russian Academy of Sciences, Syktyvkar, Russia
(*mayorova@geo.komisc.ru)

The problem of participation of microorganisms in dissolving, fining, reprecipitation and mineralization of primary gold and formation of secondary gold has been being discussed so far. However recent works [1] and others showed that "bacteriomorphous" structures on the grains of secondary gold from placers really resulted from the vital activity of bacteria; the attributes of such "bacteriomorphous" structures have been revealed. The direct evidences of biogenic nature of "bacteriomorphous" structures favored revision of previously obtained material on placer gold of the Northern Urals and drew special attention to determination of such structures in other gold-bearing objects of the territory.

In the Northern Urals the "bacteriomorphous" structures of various types were determined on detrital grains of gold from modern alluvial placers, detrital and secondary gold grains of Devonian paleoplacers, in oxidation zones of gold-quartz-sulphide deposits.

The placer gold of modern alluvial placers is characterized by the development of reniform bacteriomorphous structures, which were previously considered as a result of electrochemical dissolution of silver. In the oxidation zone of the gold-quartz-sulphide (arseno-pyrite) deposits the aggregates of filiform crystals were determined for the first time, in the intergranular space the bacterium-like pseudomorphs were found (Fig.1a). On the surface of crystalline grains the areas with reniform bacteriomorphous structures are often observed, where gold is purer (96–98 wt %), than in the bulk volume (58–76 wt %). Bacteriomorphous structures of various types – reniform, bacterium-like pseudomorphous (Fig.1b) and others – are determined both in detrital, and in authigenic sponge gold from Devonian paleoplacers widespread in the north of the Urals and in Timan.

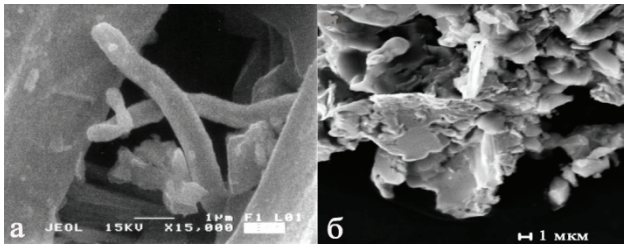

Fig. 1: Bacterium-like pseudomorphs of gold on filiform aggregates from oxidation zone (a) and on authigenic gold from paleoplacer (b).

The wide development of "bacteriomorphous" structures of gold, determined only by morphological characters, is just an indirect evidence of participation of bacteria in the transformation of primary gold in genetically different gold deposits of the Northern Urals; it requires direct evidences [1] and further investigations.

A study of cave sediments as a potential source of radon in Pál-völgyi show cave (Budapest, Hungary)

Nagy, H.É.[1,2*], Szabó, Cs.[1] & Horváth, Á.[2]
[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (*jadzsa@gmail.com)
[2]Dept. of Atomic Physics, Eötvös University, Budapest, Hungary

Several radon measurements in the Pál-völgyi show cave (Budapest, Hungary) indicate high annual average radon concentration (1800 Bq/m^3) [1]. However, the source of this remarkable radon concentration is not understood, therefore the cave sediments as a potential radon source were studied.

Pál-völgy cave is situated in the Buda Hills, which is the NE part of the Transdanubian Central Range. The wall rock of the cave is Eocene Szépvölgy Limestone Formation. Above the limestone, the Eocene Buda marl and Oligocene Tard clay were deposited. A huge multiphase hydrothermal cave system developed in the Szépvölgy limestone resulted in a long-term composite palaeokarstic evolution lasting from the Late Eocene to the Quaternary [2].

The radon concentration in the cave air has been measured continuously by AlphaGUARD radon monitor and meteorological parameters (i.e., temperature, relative humidity, air pressure, wind speed and wind direction) are being measured simultaneously since November 2009 inside and outside the cave. The data show that the radon concentration in the cave air varies in a wide range and depends on the temperature difference between the indoor and outdoor air.

Clayish cave sediments were collected and their radon exhalation rate and radium content was defined in laboratory. Four clay samples derive from section the cave located in the Szépvölgy Limestone, and one sample derives from the cave developed in the Buda Marl.

Based on the results, the radon exhalation rate of the sediment from the Buda Marl is higher (12 Bq/kg) than the sediments located in the Szépvölgy Limestone (1.5-5 Bq/kg). This result is supported by simultaneous in situ radon measurement in three chambers of the cave performed by RAD 7 radon detector in the Buda Marl and in the Szépvölgy Limestone. Average radon concentration during the same period in the Buda Marl is 1096 Bq/m^3, and in the Szépvölgy Limestone in two different chambers 478 and 546, respectively.

However, thoron concentration of the soil gas is close to 0 in the clay sediments on the Buda Marl, and the radon/thoron exhalation rate in this sample is the highest one (E_{Rn-222}/E_{Rn-220}=7). Thus, it is possible that the clay sediment which covers the Buda Marl contains higher amount of uranium and less thorium than the cave clay sediment deposited on the Szépvölgy Limestone.

The occurrence and speciation of arsenic in serpentinites in northern Vermont, USA

Niu, L.[1], Hattori, K.[1*], Takahashi, Y.[2] & Ryan, P.C.[3]
[1]Dept. of Earth Sciences, University of Ottawa, Ottawa, Ontario, Canada ([*]khattori@uottawa.ca)
[2]Dept. of Earth and Planetary Systems Science, Hiroshima University, Higashi-Hiroshima, Japan
[3]Geology Dept., Middlebury College, Middlebury, Vermont, USA

High concentrations of As are reported in ground waters and bedrocks in many parts of New England [1]. Ryan et al. [2] reported that hydrated ultramafic rocks contain high concentrations of As (up to 449 ppm in serpentinites and 1,100 ppm in talc-magnesite rocks) in northern Vermont. Altered ultramafic rocks are common in the Appalachians in New England. We investigated the occurrence of As in representative serpentinites from northern Vermont (103-450 ppm As in bulk rocks). The study includes the examination of polished-thin sections, electron microprobe analysis of minerals, mechanical separation of mineral fractions (ferrihydrite films, antigorite-rich fraction, magnetite-rich fraction), acid leaching and digestion of these fractions, and X-ray absorption spectroscopic study of As. Magnetite-rich fractions yielded high concentrations of As in hot HNO_3 digestion at 90 ºC. Brown films of ferrihydrite along cracks and on surfaces contain very low concentrations of As. Antigorite-rich fractions contain minor As (<50 ppm). X-ray absorption spectra of these fractions show that the As is predominantly +3 in magnetite- and antigorite- fractions.

Magnetite commonly forms a fine dusting in serpentine since the hydration of olivine releases Fe(II). Magnetite also forms rims of chromite grains during serpentinization. Our data suggest that As(III) in water was fixed in magnetite and minor amounts in serpentine during the hydration of ultramafic rocks. Our earlier study of serpentinites in northwestern Himalayas show that As (V) is fixed in serpentinites by replacing Si(IV) in antigorite [3]. The results of these studies suggest that hydrating ultramafic rocks are capable of fixing both As (III) and As(V) and that the speciation of As in serpentinites is controlled by the oxidation state of As in the hydrating fluids.

Mineralogy and genesis of Mn carbonate ores of the Úrkút deposit, Hungary

Polgári, M.[1*], Hein, J.R.[2], Gutzmer, J.[3], Németh, T.[1], Hahn, T.[3], Müller, A.[1] & Vigh, T.[4]
[1]Inst. for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary ([*]rodokrozit@gmail.com)
[2]USGS, Menlo Park, USA
[3]Dept. of Mineralogy, TU Bergakademie Freiberg, Germany
[4]Mangan Ltd, Úrkút, Hungary

An almost continuous stratigraphic section of the Jurassic (Lias) Úrkút black shale-hosted manganese ore body was subjected to careful mineralogical (X-ray powder diffractometry) and petrographic (light microscopy and SEM) studies, with the aim to determine the abundance and distribution of minerals in the microcrystalline ore and to document micro-textural evidence that may hold clues as to the origin of the finely laminated carbonate-rich manganese ore. A total of 112 oriented samples were collected through the extent of the ore-bearing succession for this purpose. These samples represent all macroscopically different ore types, distinguished mainly by their coloration in black, brown and green laminated carbonate-rich ore types. Light cream to pink coloured laminae composed mainly of rhodochrosite occur in all ore types; carbonate concretions up to dm in size, are formed of very similar carbonate-rich material.

Bulk ore samples and subsamples representing individual laminae can be categorized not only by colour, but by their mesoscopic appearance, including attributes such as lamina thickness and abundance of detrital grains.

Black, brown and green laminae are very dense, microcrystalline and rather uniform in mineralogical composition. The most abundant mineral is Ca-rhodochrosite in all ore types. Slight variations in abundance of celadonite (10Å phyllosilicate, green ore), goethite (brown ore), and manganite (black ore) cause the obvious color variations.

Light coloured carbonate-rich laminae are more compact and appear coarser grained than the enclosing darker (including green) laminae. The mineralogical composition of these carbonate-rich laminae is rather variable, with 5 distinct compositional groups, including (i) almost monomineralic Ca-rhodochrosite layers (ii) apatite-rich laminae (mainly fish remnants, and rarely secondary accumulations), (iii) Mn-bearing calcite-rich laminae (often coarse grained, biodetritus accumulation), (iv) barite-bearing laminae (often associated with Mn-bearing calcite, quartz, or apatite), (v) laminae rich in siliciclastic detritus, mainly quartz and K-feldspar.

Mineralogical and petrographic observations are used to suggest that the different laminated ore types owe their origin to a single genetic process. All the formations took place under neutrophylic, mildly alkaline pH. Obvious variations in color are thought to reflect slight changes in Eh during deposition and/or early diagenesis.

Interaction of mineral dust with pollution and clouds: an individual-particle study of atmospheric aerosol from Saudi Arabia

Pósfai, M.[1*], Axisa, D.[2], Tompa, É.[1], Freney, E.[3], Bruintjes, R.[2] & Buseck, P.R.[3]
[1]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary ([*]mihaly.posfai@gmail.com)
[2]National Center for Atmospheric Research, Boulder, CO, USA
[3]School of Earth and Space Exploration, Arizona State University, AZ, USA

Aerosol particles from desert dust interact with cloud drops and influence climate on both regional and global scales. The Riyadh aerosol campaign was initiated to study the effects of dust particles on cloud-droplet nucleation and cloud properties. Here, we report the results of individual-particle studies of samples that were collected from an aircraft in April 2007. We used analytical transmission electron microscopy, including energy-dispersive X-ray spectrometry, electron diffraction, and imaging techniques for the morphological, chemical, and structural characterization of the particles.

During five days of sampling both dust storms and polluted background conditions were encountered. Under dusty conditions, the coarse (supermicrometer) fraction resembles freshly crushed rock. The particles consist almost exclusively of mineral dust and include common rock-forming minerals, among which clay minerals, particularly smectites are most abundant. Unaltered calcite grains also occur, indicating no significant atmospheric processing. The particles have no visible coatings and may contain only traces of sulfur. The fine (submicrometer) fraction is dominated by particles of anthropogenic origin, primarily ammonium sulfate (with variable organic coatings and with or without soot inclusions) and combustion-derived particles (mostly soot). In addition, submicrometer, iron-bearing clay particles also occur, many of which are internally mixed with ammonium sulfate, soot, or both.

Concerning the cloud nucleating ability of the observed particles, almost any type is likely to be effective as cloud condensation nuclei (CCN). Giant mineral aggregates, particularly those that include clay minerals, are wettable and large enough to be CCN. In the fine fraction, minerals partly reacted and coagulated with ammonium sulfate and pollution particles, forming mixtures that are hygroscopic in nature. We studied the relationships between the properties of the aerosol particles and the microphysics of cumulus clouds that formed above the aerosol layer. Under dusty conditions, when a large concentration of coarse-fraction mineral particles was present in the aerosol, cloud drop concentrations were lower and droplet diameters larger than under background conditions, when the aerosol was dominated by submicrometer sulfate particles.

Prevention of the oxidation of mining tailings by etraethylenepentamine

Shu Xiao-Hua[*], Dang Zhi, Yi Xiao-Yun & Yang Chen
Dept. of Environmental Sciences and Engineering, South China University of Technology, Guang Zhou, China
(sxh-9911@163.com)

The ability of etraethylenepentamine (TEPA) to inhibit the oxidation of metal-sulfide tailings was investigated. Samples uncoated and coated by TEPA were both exposed to hydrogen peroxide for one day. This study demonstrates that the extent of tailings oxidation can be reduced by as much as 97% by treating the wastes with TEPA. A passivating layer forms on the tailings surface after exposure to the TEPA as shown by SEM images. This layer presumably suppresses mining tailing oxidation by limiting the advection of aqueous oxidants between oxidants and the tailings because of its nucleophilic functional group. The results presented here show that TEPA is an effective coating agent which can prevent surface oxidation of mine wastes.

A study of wind-polished rock surfaces in the Transdanubian Range (Hungary)

Thamó-Bozsó, E.*, Csillag, G., Kákay-Szabó, O., Kónya, P. & Müller, P.
Geological Institute of Hungary, Budapest, Hungary
(*bozso@mafi.hu)

Wind-polished gravel and rock surfaces are relatively abundant in the hilly area of Transdanubia. They were recognised more than a century ago and mapped later [1-2]. Their polished shiny surfaces are sometimes mentioned as desert varnish which formed under arid climate of Pleistocene [3]. Rock varnish or desert varnish is about 1-600 micrometers thick smooth, high sheen, dark brown to black coating usually with a high clay, iron and manganese oxide content. It is a microlayered mixture of clays and metal oxides [4]. Formation of varnish is not clear yet; beside the chemical processes (weathering, precipitation), microbial action plays probably also an important role [5]. Varnish microlamination can be also used as a correlative dating method [6].

To study the wind-polished rock surfaces, we collected samples from the forelands of the Vértes and Gerecse Hills and from the Keszthely Mountains. The samples are quartzite, metasediments, chert, and dolomite, and were all studied in the Geological Institute of Hungary by optical microscopy, scanning electron microscopy (JEOL JSM-35), electron dispersive spectroscopy (Kevex), and X-ray diffraction (Philips PW 1730).

The studied shiny wind-polished surfaces show different micro-forms under scanning electron microscope according to the composition and texture of the rocks (Fig. 1). On the surfaces of the different rocks, we detected high Si and Mg, and sometimes Fe concentration. They contain illite, kaolinite, chlorite, and goethite.

Acknowledgments: The research was supported by the Hungarian National Research Fund (OTKA K-62478).

Radiological and chemical investigation of coal slag and fly ash bearing building materials in the central part of Hungary

Völgyesi, P.*, Nagy, H.É. & Szabó, Cs.
Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (*petervolgyesi11@gmail.com)

By-products of industrial production processes are often used in national and international construction technologies as building materials on their own or as additives to building materials. In Hungary, from a radiological point of view, one of the most important issues is the utilization of the different types of coal slags and fly ashes. However, such building materials can contain relatively high levels of natural radionuclides [1,2]. Therefore, the main aim of this study is to analyze gas silicate, containing fly ash, and coal slag concrete samples from ten different locations from the central part of Hungary, using a wide range of radiometric and chemical methods. Gamma dose rate in all rooms of the studied houses at the ground floor and at one meter height was measured. To determine the radon concentration, short-term measurements by use of RAD7 and AlphaGUARD radon detectors were carried out. In the course of laboratory analysis, the ^{226}Ra-, ^{232}Th- and ^{40}K content of the samples was determined by HPGe Gamma-spectrometry. These results were use to classify the building materials studied. The radon exhalation of the building materials was measured by Rad7 continuous radon monitor. On the thin sections, made from the coal slag and gas silicate samples, microscopic description and observation, mineralogical/phase estimation ratios were carried out. To identify the chemical composition of phases in the building materials, scanning electron microscope measurement was performed, and they indicate that there are several 2-3 µm uranium-bearing grains in the coal slag sample (Fig. 1), which occur separately in the grain size fraction of the smallest fraction. Around the uranium bearing phases there are phases which contain Mg-Al-Ca-Ti-Fe silicates (Fig. 1).

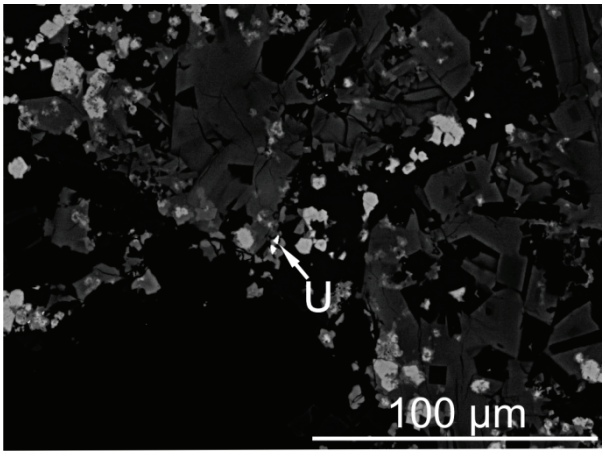

Fig. 1: BSE image of two 2.5-3 µm sized uranium bearing phases (marked with U) in a coal slag sample.

Our study draws the attention to the need of complex radiometric survey which should include the determination of gamma dose rates beside the commonly used radon measurements in case of building materials. The results show that we are facing the radiation-exposure problems not only in geologically exposed sites but also in the fifth floor apartments of a block of flats.

Experiment and a mechanism of utilization of apatite in phosphorus removal under alkaline condition

Xu Hong*, Zhang Jing & Deng Yanxi
State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China (*hongxu88@126.com)

At room temperature, we analyzed the phosphate concentration of K_2HPO_4 solution when apatite, $CaCl_2$ and NaF are added into the different solution respectively with an identical initial phosphate concentration.

The results showed that the phosphate concentration declined significantly when apatite and calcite were added. When apatite along with fluorite was added, phosphate concentration dropped considerably, from the initial 5 mg/L to 0.02 mg/L, indicating that increasing F and Ca with apatite is helpful to P removal. Comparative experiments suggested that a Ca:P:F ratio of 11:3:2.2 is the ideal one for the removal of phosphate. The pH value influenced the efficiency of phosphate removal. At pH=10, apatite can reduce the phosphate concentration to the level below the eutrophic critical line (Fig. 1) and there is no significant pH value change in the solution after P removal.

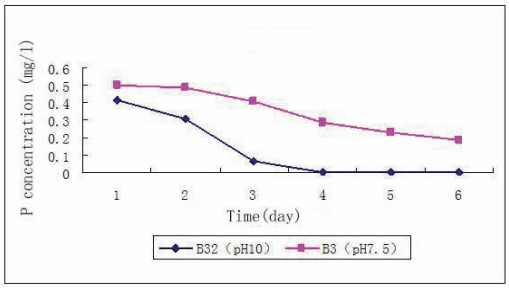

Fig. 1: The results of dephosphorization by apatite under different pH.

Infrared and FT-Raman spectroscopy and electron microscopy (SEM and TEM) analysis of the dried precipitate at room temperature suggests that the precipitate is compositionally and structurally similar to poorly crystalline apatite. Apatite can remove more phosphate from the solution at higher pH condition, and phosphate in the solution might precipitate as apatite-like compound. Other experiments were carried out with sewage and at pH=9 or above, the phosphate concentration of 0.02 mg/L to the level below the eutrophic critical line after P removal. Ca and phosphate crystallize under alkaline condition [1]. In previous P removal experiments with sewage, the product was thought to be calcium phosphate [2]. We carried out the dephosphorization experiments with calcite, and the concentration of the residual phosphate in the solution was higher than that with apatite after P removal. Therefore, apatite likely acts as the seed for P-Ca crystal growth while calcite does not play such a role.

Mineralogical, magnetic and geochemical investigation of the seasonal PM 10 dust fraction from Miskolc, Hungary

Zajzon, N.[1*], Márton, E.[2], Pethe, M.[2,3], Sipos, P.[4], Németh, T.[4], Kovács Kis, V.[5] & Uram, J.[6]
[1]Institute of Mineralogy and Geology, University of Miskolc, Hungary (*nzajzon@uni-miskolc.hu)
[2]Palaeomagnetic Laboratory, Eötvös Loránd Geophysical Institute of Hungary, Budapest, Hungary
[3]Geophysics Dept., Eötvös Loránd University, Budapest, Hungary
[4]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary
[5]Research Institute of Technical Physics and Materials Sciences, Hungarian Academy of Sciences, Budapest, Hungary
[6]North Hungarian Environmental, Nature Conservancy and Water Policy Inspectorate, Miskolc, Hungary

Air monitoring station was installed for collecting PM 10 at a point where vehicular traffic is heavy in the centre of Miskolc. Four times a year the station is ran for two weeks to collect PM 10 fractions. The filters were collected between the period of February of 2009 and February of 2010.

PM 10 from Feb. and Aug. of '09 were investigated with analytical TEM. In the winter sample, shapeless or angular K-Ca sulfates dominate. Large number of black carbon and clay minerals are also present. Only one amorphous Fe-oxide particle was found in this sample with Co content. In the summer sample, the sulfate salts are low, while black carbon and clay particles dominate. There were large amount of Fe-rich particles occasionally with high Zn content. According to the magnetic information and previous studies of the authors on dust fractions from steel factories and coal using power plants (SEM-XRD-ATEM) this phase is magnetite–franklinite.

The PM 10 collecting instrument has a pre-trap for the larger particles of the dust. The XRD mineral composition of the crystalline part of the trapped dust is: quartz > calcite > albite > muscovite >> dolomite > magnetite > amphibole.

Magnetic data, toxic metals (Pb, Ni, As, Cd) and organic compounds were measured on the PM 10 daily filters. The observed minimum values of the mass specific susceptibilities on Sundays suggested that, the magnetic pollutants originate from vehicles. At the same time, no correlation was found between mass specific susceptibilities and the concentrations of the toxic metals. The latter seem to originate from distant industrial sources and although their concentrations is far from constant, the weekend days are by no means less polluted than the work days. The Pb and Cd are in good correlation; they can have the same source. Their amounts increase with the N–NW–W wind, and decrease if the wind direction is opposite (Fig. 1).

The total amount of PM 10 fraction is usually decrease with increasing wind. The lighter samples have higher mass specific susceptibilities, till the absolute values are similar. It means that the magnetic component of the sample, which is coming from the vehicular traffic, is in the same range, but in windy days is less diluted on the filter with non-magnetic components.

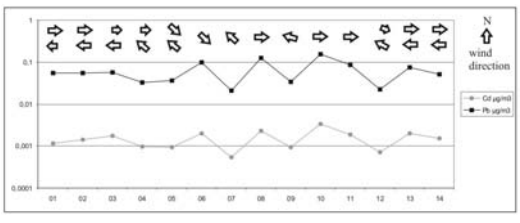

Fig. 1: Pb, Cd and wind data from November of 2009. The Pb and Cd are good correlation with the wind direction.

Mine waste: the good, the bad and the mineralogy

Hudson-Edwards, K.A.
Dept. of Earth and Planetary Sciences, Birkbeck, University of London, UK (k.hudson-edwards@bbk.ac.uk)

Since the dawn of civilization, humankind has been extracting metals and minerals for the production of goods, energy and buildings. These activities have created great wealth, but they have also produced huge quantities of solid and liquid waste, known collectively as 'mine waste'. Mine waste may be considered 'good' in that it contains potentially valuable metal and thus may be a future resource, and because it hosts unique metallophyte communities. However, the often high amounts of metals and metalloids in mine wastes are potentially toxic to other ecosystems and humans if ingested or inhaled, and weathering of mine wastes can lead to problems such as acid mine drainage. As the retention and release of potentially toxic metals and metalloids is controlled by the behavior of their mineral hosts, a full understanding of the ways that these minerals form and incorporate and release these elements in mine waste can help to predict and mitigate related potential risks. Mine waste minerals are characterised using standard (e.g., X-ray diffraction, electron microprobe micro-analysis) and advanced techniques (e.g., XANES, EXAFS), and their behavior is determine using field, laboratory (e.g., column experiments, microcosms) and computer simulation methods. These techniques, which are often used in combination with one another, give insights into the molecular-scale processes affecting metal and metalloid cycling from mine waste. This presentation will describe the complex world of mine waste mineralogy, using case studies to give an overview of the techniques of characterisation, processes of formation and transformation and avenues for future research.

Weathering products in mine wastes at several abandoned ore deposits in Slovakia

Lalinská, B.[1*], Majzlan, J.[2], Chovan, M.[1], Klimko, T.[1], Göttlicher, J.[3] & Steininger, R.[3]
[1]Dept. of Mineralogy & Petrology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
([*]lalinska@fns.uniba.sk)
[2]Institute of Geosciences, Friedrich-Schiller University, Jena, Germany
[3]Institute for Synchrotron Radiation, Karlsruhe Institute of Technology, Karlsruhe, Germany

Mineralogical composition of weathering products in mine wastes is an important factor that controls migration of pollutants. Results from 6 abandoned Sb-Au deposits show differences in As and Sb behavior in the mine wastes. The average content of Fe, Sb, and As present in the studied tailing impoundments is high; Fe average content is in the range from 15.3 g/kg (Dúbrava deposit) to 106.7 g/kg (Medzibrod deposit); Sb from 1.2 g/kg (Dúbrava) to 6.6 g/kg (Pezinok deposit) and As from 0.4 g/kg (Čučma deposit) to 6.0 g/kg (Pezinok). In most of studied localities, pH values of the tailing material are near-neutral, because the acidity produced by sulfides decomposition is neutralized by abundant carbonates. Carbonates are scarce only at the Poproč deposit and the tailings here are acidic.

The most common sulfides in flotation wastes are pyrite and arsenopyrite, stibnite is rare probably due to its rapid oxidation.

At all studied mine sites, oxidation rims on pyrite and arsenopyrite grains are developed and act as effective scavengers of As and Sb. Oxidation rims on pyrite contain up to 10.12 wt.% of As (Pezinok) and up to 7.5 wt. % of Sb (Pezinok); As content in rims on arsenopyrite is generally lower compared to the unaltered arsenopyrite grains, conversely Sb content is up to 14.3 wt.% (Čučma) and in one extreme case even 50 wt.% (Pezinok). The most rapid decomposition of pyrite and arsenopyrite was observed under acidic conditions (Poproč).

In general, As is sorbed onto Fe oxides. According to our μ-XRD data, Fe oxides with the low As content are made of goethite and poorly crystalline As-rich phases are probably made of ferrihydrite. When Pb is present in the pore solutions, Pb/As oxides with chemical composition close to paulmooreite, $Pb_2As_2O_5$, are formed (Medzibrod).

Sb is most often present in form of Sb, Sb/Fe and Fe/Sb oxides (valentinite, stibiconite) and these may be the products of complete replacement of Sb ores or they may have precipitated from solutions which circulate through the impoundments. Sb/Fe oxides were identified as tripuhyite, $FeSbO_4$. Sb oxides with various content of Ca similar to romeite, $Ca_2Sb_2O_6(O,OH)$, are also common (Čučma) and if Pb is present in the tailings, a mineral chemically close to bindheimite, $Pb_2Sb_2O_7$, is formed (Medzibrod).

Fe ochres associated with tailing impoundments and adit discharges are composed mainly of ferrihydrite which transforms slowly into the more stable goethite. Concentration of As in the ochres is high and varies from hundreds mg/kg (Pernek) up to 205.9 g/kg (Medzibrod). Comparison of As and Sb concentrations in the ochres and coexisting waste waters indicates lower sorption affinity of Sb to Fe oxyhydroxides as compared to As.

Preferential oxidation of euhedral pyrite containing relict framboidal morphologies

Weisener, C.G.[1*], Gagnon, J.[1] & Weber, P.A.[2]
[1]Great Lakes Institute for Environmental Science, University of Windsor, Windsor, Canada ([*]weisener@uwindsor.ca)
[2]Environmental Division, Solid Energy New Zealand Ltd, Christchurch, New Zealand

Environmental damage produced from acid generating mines currently represents one of the largest problems facing the mining industry. The aim of this research is to investigate possible mineralogical controls on acid rock drainage (ARD) and metal release associated with pyritic mudstone collected from, the Brunner Coal Measures (BCM), Stockton Mine NZ. Laboratory-based kinetic tests were performed on the potentially-acid forming material by measuring, over time, the changes in mineralogical compositions and acid generating potential along with changing effluent chemistries from the columns. The rate of pyrite oxidation in the BCM is strongly dependent on the reactivity of two morphological types (euhedral and framboids) of pyrite in this region.

After a 4 month period between 70 to 100% of all framboidal pyrite had undergone complete oxidation, despite this acid generation (1730 (mgL-1 CaCO3) after 390 days) continued during the column experiments. SEM micrographs show the persistence of larger euhedral pyrite grains as a contributing factor with evidence of preferential oxidation associated with relict framboidal morphology (figure 1).

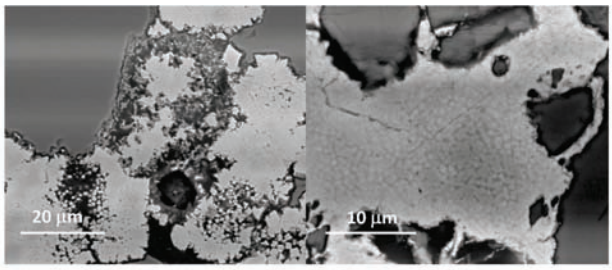

Fig. 1: After 13 months within a humidity cell euhedral pyrite shows preferential oxidation confined to pyritic overgrowth textures.

Samples collected from laboratory humidity cells after 13, 16 and 24 months show preferential dissolution features associated with large pyritic overgrowth textures. From a kinetic perspective the oxidation of pyrite in these samples tend to target the more recent crystallographic overgrowths. Results of the 24 month study will be presented detailing the mineralogical alteration, acidity generation and their controls on trace metals specifically thallium deportment.

Characterization of arsenical compounds and minerals in refractory gold processing residues: implications for arsenic control

Paktunc, D.
CANMET, Mining and Mineral Sciences Laboratories, Ottawa, Canada (dpaktunc@nrcan.gc.ca)

A range of ferric arsenate-sulphate minerals and synthetic compounds representing residues from the processing of refractory gold ores were characterized by XRD, XAFS and microanalysis techniques. Compounds synthesized under hydrothermal conditions in the temperature range of 150 to 225ºC include $Fe(AsO_4)_{0.8\text{-}1}(SO_4)_{0\text{-}0.2}\cdot 2H_2O$ (scorodite), $FeAsO_4(OH)_{0.2\text{-}0.6}$ (phase 4), $Fe(AsO_4)_{0.3\text{-}0.5}(SO_4)_{0.7\text{-}0.5}(OH)_{0.5\text{-}1.5}$ (phase 3) and $Fe(SO_4)_{0.9\text{-}1}(AsO_4)_{0\text{-}0.1}(OH)$ (phase 5), all of which are characterized by a 1:1 molar $Fe/(AsO_4+SO_4)$ ratio (Fig.1). Synthetic scorodite accommodates up to 20 mole % SO_4. Substitution of AsO_4 is limited to between 30 and 50 mole % in phase 3 and 10 mole % in phase 5. In comparison, synthetic jarosite can incorporate up to 17 mole % $AsO_4/(AsO_4+SO_4)$. These compounds represent those formed in the autoclaves during pressure oxidation of refractory gold ores where gold is locked in arsenopyrite and pyrite.

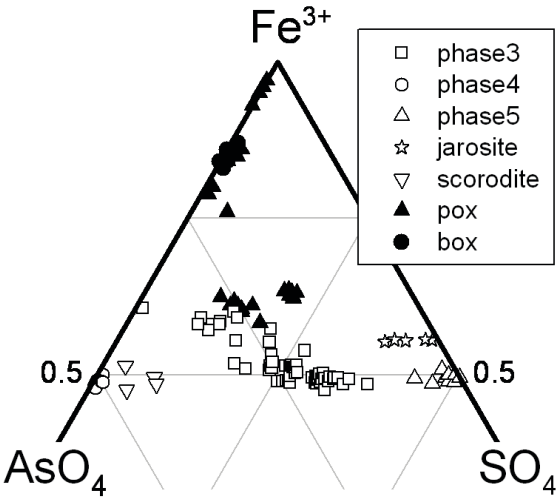

Fig. 1: Compositions of synthetic compounds and residues (pox: pressure oxidation; box: bacterial oxidation) resulted from processing of refractory gold ores.

Natural analogs in this system include hydrated ferric arsenate and sulphate minerals such as bukovskyite, sarmientite, zykaite, scorodite, parascorodite, kankite, ferric arsenate, kaatialaite and ferrisymplesite. Such occurrences, along with arsenate-adsorbed goethite, ferrihydrite, schwertmannite and hematite, were reported in mine tailings, oxidized portions of gold and base metal mineral deposits and acid mine drainage settings. Long- and short-range structures of these compounds and their hydrated natural analogs will be presented along with the experimental data, and their implications on arsenic control practices at mine sites will be discussed.

Crystal-chemistry of Ni and Cr within phyllosilicates and Fe/Mn oxyhydroxydes along a lateritic regolith in New Caledonia

Ultramafic rocks cover about 1% of the continental surfaces and are related to ophiolitic bodies formed near convergent plate boundaries [1]. The most typical ultramafic rocks are dunite and harzburgite, which are composed of easily weatherable ferromagnesian mineral species (olivines and pyroxenes), but also of more resistant spinels (chromite and magnetite). Oceanic serpentinization of these ultramafic rocks usually leads to partial transformation of these initial mineral assemblages by forming hydrous layer silicates such as serpentine (lizardite, chrysotile and antigorite) talc, chlorite and actinolite [2]. However, these ultramafic rocks can lead to different mineral assemblages when they are exposed to meteoritic weathering. Such a situation is encountered in New Caledonia, where tropical meteoritic weathering of ultramafic rocks (peridotites) obducted about 35 millions years ago [3] has lead to the development of very thick regoliths, which contain large amounts of trace elements (Ni, Co, Mn, Cr). Although interesting from an economical point of view, such an occurrence of large amounts of potentially toxic elements can be hazardous for the environment. Characterizing the crystal-chemistry of these elements is then very important to identify the processes driving their transport and/or immobilization upon weathering of ultramafic rocks.

Results of a study performed along a 64 m depth lateritic regolith in the Mt Koniambo (West Coast of New Caledonia) emphasize the major control of phyllosilicates (talc and serpentine) and Fe and Mn oxyhydroxides on the crystal-chemistry of Ni and Cr. When going from the bedrock to the lateritic part of the regolith, Ni moves from Ni/Mg-phyllosilicates to secondary Fe oxyhydroxides, whereas Cr moves from primary silicates and chromite to Cr(III) bearing Fe oxyhydroxides [4,5]. In addition, the occurrences of Ni/Co asbolane and of Cr(VI) after oxidation of Cr(III) by Mn oxyhydroxides emphasize the importance of this mineral species in the intermediate part of the regolith [4,5].

These results bring interesting insights on the importance of phyllosilicates and Fe/Mn-oxyhydroxides on the crystal-chemistry of trace elements upon weathering of ultramafic rocks under tropical conditions.

Jarosites as indicator minerals for acidic conditions in Bányabérc waste dump (Mátra Mts., Hungary)

Farkas, I.M.[*] & Weiszburg, T.G.
Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary ([*]farkasizabella@yahoo.com)

Weathering of Fe-sulphides in mine wastes produces acidity and elevated levels of heavy metals. Common secondary minerals formed on these sites are hydrated metal oxides and sulphates. One of these secondary sulphate phases is jarosite. The presence of jarosites in mining wastes refers to a low pH, high sulphate content and highly oxidative media. In our work natural jarosite samples from the Bányabérc sulphidic waste dump (Mátra Mts., Hungary) were characterized mineralogically and chemically. X-ray powder diffraction, chemical analyses (SEM-EDX, ICP-AES), Mössbauer and Raman spectroscopy were used to characterize the jarosites. Analyses suggest a solid solution series between jarosite and hydroniumjarosite. The c_0 unit-cell dimension in our samples has lower values (17.082(1), 17.087(2), 17.104(3), 17.124(4), 17.136(1), 17.125(4), 17.091(1) Å) than pure jarosite (17.2043 Å; [1]), supporting H_3O^+ substitution. Beside X-ray powder diffraction, chemical data also reveal deficiency in the alkali site. In some of the jarosites, As, P and Al were measured. In the SO_4 anion position in the structure, substitution of AsO_4 and PO_4 is possible.. The lattice constant a_0, which is sensitive to substitution in the Fe site, is very close to that reported for pure end-member K-jarosite (7.3346(4), 7.3325(5), 7.3238(5), 7.3117(4), 7.3241(4), 7.3143(7), 7.3317(5) Å). Although Al was measured in some of the samples, it is not ubiquitous and may reflect other included minerals. In some cases, the Raman measurements demonstrated also a mixing between jarosite and goethite, especially around weathered pyrite, increasing the Fe/S atomic ratio from 1.5, characteristic for ideal jarosite, to higher values. The Mössbauer spectrum of jarosite is characterized by a doublet, revealing six-coordinated Fe^{3+} (*IS* = 0.31–0.38 mm/s; *QS* = 1.00–1.23 mm/s).

Well-crystalline plumbojarosite forms an outer ring around anglesite, the latter enclosing an unaltered core of galena. These textural relationships suggest that galena was the Pb source for the two secondary minerals. Anglesite, Pb-bearing jarosite and plumbojarosite are stable phases under acidic conditions, but as pH increases above 6, their dissolution is favoured. In the pH window between jarosite breakdown and iron oxide/oxyhydroxide uptake, Pb may remain in solution and fully bioavailable. The Raman spectra of jarosite-group minerals slightly differ from each other. Plumbojarosite shows some special spectral features. The 451 and 472 cm^{-1} doublet (splitting) are believed to originate from the doubly degenerate ν_2 bending mode of the sulphate ion that appears at 450 cm^{-1} in aqueous solution. There are three broad bands at 990–1030 cm^{-1} $\nu_1(SO_4)$, around 1180–1120 cm^{-1} $\nu_3(SO_4)$ and around 1160–1180 cm^{-1} $\nu_3(SO_4)$ which are due to overlapping of multiple peaks.

As an oxidation product of pyrite, jarosite is ubiquitous in the Bányabérc waste dump, indicating an acidic environment. Hydronium-bearing jarosite is thought to contribute to acid generation in mine wastes because the H_3O^+ ion accelerates jarosite dissolution. This means that the As in the jarosite is stored only temporary because of the limited pH and redox conditions of jarosite stability.

Mineralogical evolution in arsenic and lead contaminated soils-water systems. Portuguese mine soils laboratory assays

Magalhães, M.C.F.[1*], Anjos, C.[1] & Abreu, M.M.[2]
[1]Dept. of Chemistry & CICECO, University of Aveiro, Portugal ([*]mclara@ua.pt)
[2]UIQA, Instituto Superior de Agronomia, Universidade Técnica de Lisboa (TULisbon), Lisboa, Portugal

Hazardous elements mobilization from mine tailings is a potential contamination process of the surrounding soils and waters. The environmental impact from those elements is not quite related to their presence in anomalous amounts in soils and sediments but is related to their availability (several media available fraction and chemical speciation) to the biota.

The presence of: i) high concentrations of total lead (1.48 – 13.4 g/kg) in the soils of the abandoned Braçal lead mine area together with high percentage of the lead available fraction (12 – 68 % of total Pb) determined by the calcium nitrate method [1]; ii) high concentrations of total arsenic (0.15 - 34 g/kg) in the soils of the abandoned Penedono arsenic and gold mine area also with moderately high percentage of the arsenic available fraction (dl – 6 % of total As) determined by the dtpa method [2]; and iii) high concentrations of total arsenic (0.5 – 3.0 g/kg) and lead (1.9 – 9.2 g/kg) in the soils of the abandoned São Domingos copper mine area where very low concentrations of the arsenic (0.001 – 0.02 % of total As) and lead (0.001 – 0.9 % of total Pb) available fractions were determined as above, induced a search for the identification of possible secondary solid phases that could control arsenic and lead availability. The X-ray diffraction analyses of the soil samples show the presence of langite ($Cu_4(SO_4)(OH)_6 \bullet 2H_2O$), cerussite ($PbCO_3$), and cotunnite ($PbCl_2$) in Braçal, scorodite ($FeAsO_4 \bullet 2H_2O$) in Penedono, and beudantite ($Fe_3Pb(AsO_4)(SO_4)(OH)_6$), carminite ($Fe_2Pb(AsO_4)_2(OH)_2$), kankite ($FeAsO_4 \bullet 3.5H_2O$), mimetite ($Pb_5(AsO_4)_3Cl$), and segnitite ($Fe_3PbH(AsO_4)_2(OH)_6$) in São Domingos [3].

Laboratory experiments were conducted with soils of the above referred mine sites to study the secondary minerals possible changes, mainly, containing arsenic and lead, when in contact with water with characteristics of normal rainwater. Soils were left in contact with distilled water, at room pressure and temperature, for periods ranging from 2 to 393 days in closed vessels shaken and aerated frequently. Aqueous solutions were analysed for elemental composition, and soils were analysed by X-ray diffraction for mineral composition.

The X-ray diffraction analyses of the samples, resulting from the soil-water experiments, evidence different behaviours. The soils from Braçal didn't appear to have noticeable changes with water contact time. In the samples from Penedono the amount of scorodite decreased with water contact time, but intermingled changes evolving with time were perceived in the São Domingos soils.

This study shows that, in the soils, can be found mineral phases considered metastable under those conditions of pressure and temperature, *e.g.* kankite and langite. Once all the aqueous solutions had similar values for the pH and Eh, the diverse behaviour of the studied soils seems to lie in their chemical elemental composition. The São Domingos mine soils are richer than those from the other two mines. Under the experimental conditions the Braçal cerussite and cotunnite only undergo congruent dissolution, but several reactions can occur in São Domingos soils where many chemical elements are in presence of heterogeneous nucleating agents and organic precursors.

Mineralogical and geochemical survey of Lisbon (Portugal) urban soils

Rocha, F.[*], Reis, A.P., Terroso, D., Patinha, C., Dias, A.C. & Ferreira da Silva, E.F.
Geosciences Dept., Geobiotec Unit, University of Aveiro, Portugal ([*]tavares.rocha@ua.pt)

This study is a part of the working program of a research project titled "PTDC/CTE-GEX/68523/2006: URBSOIL-LISBON_ Geochemical survey of Lisbon urban soils: a baseline for future human health studies". The aim of this research is to assess the contribution of soil mineralogy to the geochemistry of the urban soils of Lisbon city. A total of 51 soil samples were collected over Lisbon city. According to the location and land-use, the samples were classified as air side: airport (AE), public garden (GD), public park (PA), road-side (RS: small flower beds along the road-side), playground (PG) and schoolyard (SC). Among the 51 soil samples, 3 were collected in AA land, 7 in GD land, 11 in PA land, 2 in RS land, 22 in PG land and 6 in SC land. Figure 1 shows the sample locations and land-use. Each sample site is labelled from 1 to 51.

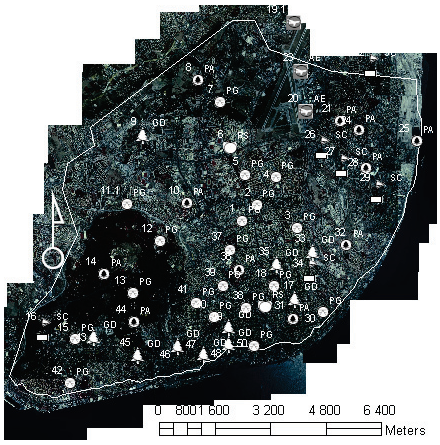

Fig. 1: Soil sampling sites and local land-use.

Of the 51 samples, 11 were selected for the mineralogical study. Table 1 shows the major geochemical outliers in the urban soil at each of those 11 sites.

Table 1: Anomalous elements in the selected soil sampling sites

urban site	land-use	geochemical outliers in the urban soil
11.1	PG	Be, Nb, B, **Y**, Co, **Sc**, **Zr**, Sr, **Ga**, Ni, Fe, Mn, Ti, Cr, V, K, Al, Mg, Na, **HREE**, LREE
15	PG	**Li**, **Y**, Be, **Co**, Ba, Sc, Zr, **Sr**, **Ga**, Ni, **Fe**, **Mn**, **Ti**, Cr, **V**, **Al**, **Mg**, Na, **REE**
20	AE	**Nb**, S, Bi, Pb, Ba, Sb, Cd, Mo, Zn, Cu, Ca
29	SC	very low concentration in all elements
31	PA	**Au**, P, Ag
33	GD	**Pb**, Ba, **Sb**, **Sn**, **Cd**, **Zn**, **Cu**
37	PG	very low concentration in all elements
39	PG	**Au**, **P**, B, **Bi**, **Pb**, Sb, **Sn**, **Cd**, **Ag**, Cu, Ca
43	GD	**Y**, Au, Co, Ba, Sn, **Sc**, Sr, **Ga**, **Ni**, **Fe**, **Mn**, **Ti**, **Cr**, V, Al, Mg, Na, REE
47	GD	S, **P**, B, Bi, **Pb**, Ba, Sb, Sn, Cd, **Ag**, **Sr**, Zn, **Cu**, **Ca**, **Mg**
48	GD	**Bi**, **Pb**, Ba, **Sb**, Sn, **Cd**, **Ag**, **Mo**, **As**, Zn, **Cu**, Na

In general, the samples are siliceous (quartz, feldspars and phyllosilicates) but some show relevant presence of carbonates; iron oxides/hydroxides, sulphates and sulphides are common accessory minerals. Illite is the predominant mineral of the clay fractions, smectite and kaolinite showing dicothomic behaviour.

Characterization and mitigation of the Sn-Ag San Jose mining district, Oruro, Bolivia

Walder, I.F.[1*], Victoria, J.[2], Boon, R.G.J.[2] & Walder, P.[1]
[1]Kjeøy Research & Education Center, Kjeøy, Vestbygd, Norway ([*]ifwalder@kjeoy.no)
[2]Environmental Dept., COMIBOL, La Paz, Bolivia

The San Jose mining district is a typical Bolivian tin-silver province with numerous mines producing silver and tin from a volcanic hosted poly-metallic epithermal, alunite-kaolinite breccia deposit. Silver production started back in the mid sixteen hundreds by the Spaniards. Mining continued, via private companies and was nationalized in 1954. The state mining company COMIBOL, which operated the mines, closed the mines in 1992. Small cooperatives were allowed to continue mining, however, in very small scale by primitive methods.

Mine adits, mine excavations, mine tunnels, tailings and waste rocks are scattered throughout the Oruro Mountains, where these mines are located. The largest operations were San Jose and Itos mines, with smaller, but environmentally important, San Miguel, Del Norte, and Jallpha operations. Most of the tailings and waste rocks have been characterized: the smaller ones primarily with paste pH and on-site mineralogical identification, the larger waste material with ABA, microscopy, leach tests, whole rock chemistry, and kinetic testing.

The upper part of the mineralization has gone through strong weathering. The tailings and waste rocks from the deeper part (below the weathering zone) are very acidic with soil pH 1-3. The pyrite-pyrrhotite content, however, is not very high in most of the analyzed samples. Some of the tailings material has arsenic content of 1-2 wt.%. The leach tests indicate very high TDS loaded with metals. The strong alteration during the ore forming process left little or no neutralizing capacity in the wall rocks and gangue minerals.

Mitigation is complicated due to families living on top of the waste material and interest groups wanting access to the waste material for reprocessing. COMIBOL has suggested several different mitigation options depending upon the location of the waste material and the severity of the contaminant loading on the receiving environment.

Study of hydrodynamic behaviour, fluid conductivity and composition analysis in granite fines

Falcon, I.[1], Rammlmair, D.[2*], Delgado, J.[1] & Juncosa, R.[1]
[1]Civil Engineering School, University of A Coruña, Spain
[2]Federal Institute for Geosciences and Natural Resources (BGR), Hannover, Germany ([*]rammlmair@bgr.de)

'Granite fines' is the silty-clay material generated by the granite dimension stone industry during rock sawing and polishing operations. Such materials have been physico-chemically, mineralogically and geotechnically characterized during the last decade in order to recognize their suitability for various applications of civil engineering such as landfill sealing and waterproofing. This material consists of fine mineral and granite particles of the primary rock and some components added during the process such as a fraction of lime and variable steel grit introduced into the system during the sawing process mixed with water (~38 wt.%).

This study is focused on fluid conductivity and composition analysis, and the hydrodynamic behaviour of a column of granite fines under wetting and drying cycles. Non-destructive methods were used to not disturb the free dynamics of the fluid along the capillary fringes. To achieve it, the material was filled homogeneously into PVC (polyvinyl chloride pipe 7 cm x 50 cm) equipped with a foil having embedded wires for conductivity measurement at 20 different levels of four electrodes each fixed at the inner wall of the tube. Electrical conductivity of the fines was measured at each level for each step of saturation Simultaneously X-ray radiography measurements were carried out through opposing windows with 50 μm thin PVC-foils for the whole length of tube, in order to recognize the kinetics of water movement in the column. It was progressively saturated by adding water from the bottom of the pipe in different steps, while the evolution of the system was monitored.

Once the saturation was completely achieved, the extraction of the interstitial solution was carried out by inserting metal free Rhizon until the suction of the soil was in absolute terms higher than the Rhizon limit, representing around 30% of the total water allocated in the soil. The water was extracted in different steps distinguishing different types of water in relation to the rising difficulty in the extraction: fast water to slow water. In addition, dissolved ions measured by ICP-MS and ICP-OES from the extracted water show different trends in relation to the soil saturation degree and the position in the column where Rhizons are located. Results show a normal fast kinetic behaviour during saturation steps that can be explained by the strong effect of capillary fringes. On the other hand, an exponential increment from the bottom to the top of the column was measured in the conductivity of soil water, which also decreases from the first extraction (fast water) to the last one (slow water). The strong increase in electrical as well as fluid conductivity from bottom to top shows a fast rising capillary head fluid enriched in ions, but with reduced vertical equilibration. The high amount of dissolved ions in the rising head is eventually responsible for cementation processes taking place during the alteration of the fines. The characterization of secondary mineral phases such as green rust helps to understand the alteration processes.

The spatial and temporal evolution of conductivity, fluid composition during saturation and drainage and the amount of water extracted from the granite saw dust, allows understanding the influence of wetting-drying cycles in the granite fines.

Thermal activity of the coal waste dump in Katowice-Wełnowiec, Poland

Ciesielczuk, J.[1*], Bzowska, G.[2] & Cebulak, S.[2]
[1]Dept. of Fundamental Geology, University of Silesia, Sosnowiec, Poland ([*]justyna.ciesielczuk@us.edu.pl)
[2]Dept. of Mineralogy, Geochemistry & Petrology, University of Silesia, Sosnowiec, Poland

The coal waste dump in Katowice-Wełnowiec, Upper Silesia Coal Basin, Poland, which superstructures the former rubbish dump is located in the center of the capital town of Silesian voyewodship. The processes of selfheating of the organic matter still present within the waste rocks, as dispersed or as tiny laminas, has caused the selfignition of the dump on its northern, eastern and south-eastern slopes. As effects of burning, bad smell and toxic fumes emanate from the overburned places. The aim of our study is to recognize the main factors which influence the acceleration or delaying of the selfignition process in the coal waste rocks deposited on the dump, as it has been observed only in some selected places.

The following methods were used: mineral phases were determined by XRD, chemical composition and mineral habits and association by SEM-EDS, and the kind of coal and its percentage in the waste rock as well as temperatures of OH and H_2O loses from clay minerals by DTA.

All the samples were collected from different parts of the dump which have been thermally affected. The measured temperatures in sampling places range from 12^o to 460°C. They were collected from the surface, and up to a depth of 4 m. We have separately investigated samples of: (1) different mass, (2) with high and low oxygen access, (3) fine and semi-grinded, (4) with high amounts of coal (e.g. 53% of C)) and up to almost no coal (0.6% of C), (5) samples were heated up to 600-700°C and 1000°C, (6) different sorts of coal, (7) different degrees of weathering, (8) different locations of coal laminas inside the waste rock piece or on its surface, (9) presence of iron minerals, (10) mineral composition of the waste rock (the amount of quartz and feldspars, kinds of clay minerals and micas, presence and amount of carbonates), and (11) geographical and climatological factors: the location of the slopes, wind direction, intensity of the rainfall and snowfall. The only factor which is important, but impossible to be taken into consideration, was the time of the processes duration.

The best example exemplifying the difficulty of the investigated problem is the sample collected from the place where measured temperature was 350°C. Mineralogically mullite was the main phase present there. According to literature data, mullite can form as a result of kaolinite heating at 1150-1250°C. The ceramic experiments show that the presence of iron minerals and feldspars can lower the temperature of mullite formation to 850°C, suggesting that in hydrothermal environment mullite can crystallize at 500-575°C, but not at 350°C as it has been measured so far!

As the results show, all factors which have been taken into account are important and have the effects on the sample behaviour. This is why the problem of selfheating and selfignition of the coal dumps requires a precise and detailed research.

CO_2 binding by alkaline waste materials: reduction of greenhouse gas emissions and benefit for waste deposition?

Bauer, M.[*], Gassen, N. & Peiffer, S.
Dept. of Hydrology, University of Bayreuth, Germany
([*]markus.bauer1@uni-bayreuth.de)

Alkaline waste materials were shown to be capable of CO_2 binding through fast carbonation reactions [1]. While natural minerals feasible for such a process normally have to be mined, transported or pretreated before use, alkaline wastes (such as combustion fly ashes) are often already available on site at CO_2 sources, like power plants, and readily react on short time scales [2]. During carbonation the mineralogy of the material changes [3]. The ALCATRAP project therefore determines the CO_2 binding potential of different alkaline wastes in laboratory and pilot scale experiments and estimates the effect of carbonation on leaching of metals or anions.

Alkaline wastes, such as fly/bed ashes from lignite, coal, biomass, wood and municipal solid waste incinerators and steel slags, were therefore tested in CO_2 uptake experiments under different conditions (temperature, mixing, pCO_2, CO_2 flow). Two different mixing systems, one for aqueous (Solid/Liquid ratio < 0,2 w/w) and one for semidry (Solid/Liquid ratio > 2 w/w) conditions, were compared. Furthermore, these laboratory findings were used for construction and experimental design of an ALCATRAP pilot plant, operating since September 2009, which enables us to elucidate the applicability of the method on a larger scale.

All waste materials from the sources listed above were able to sequester considerable amounts of CO_2. CO_2 gas phase concentrations decreased while the dissolved inorganic carbon concentration of the aqueous phase and the carbonate content of the solid phase increased. The process was controlled by the initially fast dissolution of CaO/MgO minerals, providing alkaline earth metal cations and increasing the pH. Dissolution of CO_2 induces the $CaCO_3$ precipitation.

The CO_2 uptake varied for different alkaline waste samples, with highest binding capacities (up to 0,1 g kg^{-1}) with lignite fly ashes and steel slags. Increasing temperature accelerated the reaction rate but also increased the overall CO_2 binding capacity (up to between 0,15 and 0,23 g kg^{-1}). This suggests that at high temperatures other mineral phases, e.g. Ca/Mg silicates or sulfates, become involved in the process. Currently source materials and reaction products are tested for the changes in the material properties due to carbonation. This includes grain size, pH as well as the leaching of heavy metals, sulphate and chloride.

Heavy metal speciation on iron oxides precipitates in south Portugal abandoned mines

Antunes, R.[1], Candeias, A.E.[1], Goettlicher, J.[2], Steininger, R.[2] & Mirao, J.[3*]
[1]University of Évora, Chemistry Center of Evora and HERCULES Laboratory, Evora, Portugal
[2]Karlsruhe Institute of Technology, Institut für Synchrotronstrahlung, Eggenstein-Leopoldshafen, Germany
[3]University of Évora, Geophysics Center of Evora and HERCULES Laboratory, Evora, Portugal ([*]jmirao@uevora.pt)

In south Portugal, ores are composed mainly of pyrite with Cu, Zn, Pb and As sulphides and sulfosalts. Furthermore, ores include several minor elements like Mn, Co, Ni, Cd, Sb, Hg and Bi. Sulphides are quickly weathered, leading to water acidification and release of heavy metals. Some of these are hazardous and the drainage basins of the pollutant source areas often induce health concerns in resident populations. Consequently, mining and mineral-processing activities in south Portugal contribute with high amounts of metals to the environment and affect surrounding land and water quality, due to their cytotoxic, carcinogenic and mutagenic potential.

The geochemistry of pollutant elements is controlled by iron that precipitates by chemical bonding with oxygen. The stability of these iron oxides is controlled by climatic factors, imposing a parageneses that is geographically dependent and seasonal. It was hypothesised that these phases could uptake pollutant metals from contaminated waters either by coprecipitation, surface precipitation or a combination of the two.

The iron oxides were collected as chemical sediments in streams and ponds. Selected samples were mounted in epoxy resins preserving the original stratigraphy. The spatial characterization by micro-XRF mapping and XAFS spectroscopy was conducted at the SUL beamline, ANKA synchrotron.

The X-ray fluorescence mapping shows that the chemical elements associations are complex. For example, a large cross-section roughly at the base of the sequence is very enriched in iron and copper and depleted in zinc whereas, at the top of the sequence, the three elements coexist in a same enriched cross-section. This means that the cooper is associated with iron but the zinc has a more complex behaviour. Furthermore arsenic and lead are both associated to sulphate compounds.

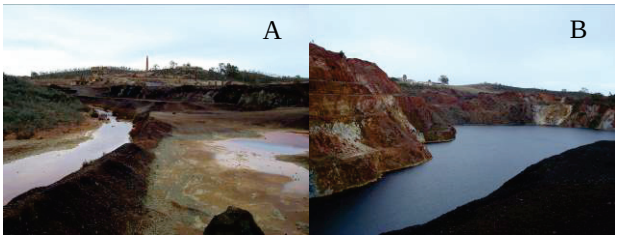

Fig. 1: St. Domingos abandoned mine, south Portugal, image from the open pit (A) and from drainage basin (B).

Preliminary XANES and EXAFS data show that iron is in several different phases. This kind of behaviour is well known from pH/Eh stability diagrams applied to iron compounds in these environments. In addition, copper, arsenic and zinc change their speciation when the iron phases change.

It is expected that the experiments can enlighten the electronic state of each metal and crystalline state of iron oxides. We hope to contribute to a better understanding of the general processes of heavy metal dispersive phenomena in sulphides from abandoned mines.

In this work, the 2.5 ha Hop waste-rock dump from the Roşia Montană gold mine (Romania) was investigated using mineralogical, geochemical, and geostatistical analyses.

The Roşia Montană hydrothermal ore deposit is hosted in andesites and dacites of Neogene age piercing the prevolcanic sedimentary basement as breccia pipes [1]. The volcanic and subvolcanic rocks show pervasive adularia alteration with a phyllic overprint, as well as local silicification and argillic alteration. They host polymetallic sulphides and Au-Ag-Te mineralisations; they are present in epithermal veins, mineralized phreatomagmatic breccias, and stockworks [2]. The ore deposit was mined both underground and in open pit for more than 2000 years. Intensive supergenic alteration due to AMD processes is testified by acid sulphate waters and by the precipitation of large amounts of secondary minerals.

The waste dump shows heterogeneities even at the field scale mainly evidenced by differences in colour. Twenty-two samples were collected following a square cells grid. The particle size distribution was obtained by dry sieving. The mineralogy, petrography and geochemistry were studied by means of optical microscopy, SEM-EDS, XRPD, XRF and ICP-AES analyses.

Samples were poorly sorted and could be classified as sandy gravel sediments. Their paste pH values show a wide variability (3-8) strictly related to sulphur and carbonate contents. Lithology is heterogeneous, comprising the following lithotypes: metasomatized porphyritic dacites, andesites, s flyschoid rocks and polygenic breccias. According to Acid Mine Drainage (AMD) potential these lithotypes contains the following mineral species: 1) AMD-producing sulphides (pyrite ± sphalerite ± chalcopyrite ± marcasite) varying from << 1% up to 5%; 2) AMD-neutral silicates (quartz, alkaline feldspar and micas with variable amounts of cryptocrystalline aphanitic groundmass of the volcanic rocks; 3) AMD-reducing carbonates (calcite + dolomite ± siderite ± rodochrosite) that are generally trace to minor constituents, with the exception of few samples where they represent about 5% of the total constituents. Amphiboles, apatite, rutile and zircon are the main accessory minerals. Secondary minerals that formed as a consequence of AMD processes vary from 5 to 15 %; they are mainly represented by Fe-oxyhydroxides and -oxides and occur as pseudomorphic replacement after primary sulphides, or as voids and fractures filling. They are also present as oxidation halos within the groundmass and as tiny coatings that rim sulphide and silicate grains. Ephemeral sulphates recognized on field were not preserved in the samples. Metallic paragenesis is rich comprising both heavy metals derived from the mineralisation (Cu, Zn, Ag, Pb) and metals from host rock (Rb, Sr, Zr). Further investigation on heavy metal geochemistry and mineral chemistry is ongoing to define the relationships between metals distribution and AMD processes also in order to evaluate the pollution potential of the dump.

The effect of Sb(V) on the transformation of ferrihydrite to goethite

Bolanz, R.M.[1*], Majzlan, J.[1], Ackermann, S.[2], Reich, T.Y.[3] & Kersten, M.[3]
[1]Inst. of Geoscience, Friedrich-Schiller-University, Jena, Germany ([*]ralph.bolanz@uni-jena.de)
[2]SGS INSTITUT FRESENIUS GmbH, Kölliken, Switzerland
[3]Inst. of Geoscience, Johannes-Gutenberg-University, Mainz, Germany

Many aspects of the environmental chemistry of antimony, from its global cycling to its local speciation, are still poorly understood [1]. Antimony can become a pollutant of soils and sediments, especially in acid mine drainage systems and shooting ranges, where it can become adsorbed by iron oxides. The most common Fe oxide in these settings is the poorly crystalline 2-line ferrihydrite, which can be transformed upon ageing to goethite or hematite [2]. The rate and products of the transformation depend on temperature, pH, and the presence of adsorbing ions or molecules [3]. The focus of this study was the formation rate of goethite from synthetic ferrihydrite in the presence of Sb(V).

To verify the association of Sb(V) with ferrihydrite, EXAFS spectra were collected at the Super-XAS beamline at the Swiss Light Source (SLS). In addition to the first coordination sphere (6 O atoms at 1.98 Å), two Fe atoms at the distance ~3.11 Å and four Fe atoms at the distance ~3.57 Å were detected. This result can be interpreted as a strong inner-sphere edge- and corner-sharing complexation on the ferrihydrite surface and agrees well with the conclusions of related studies of antimony adsorption onto Fe oxides [4,5].

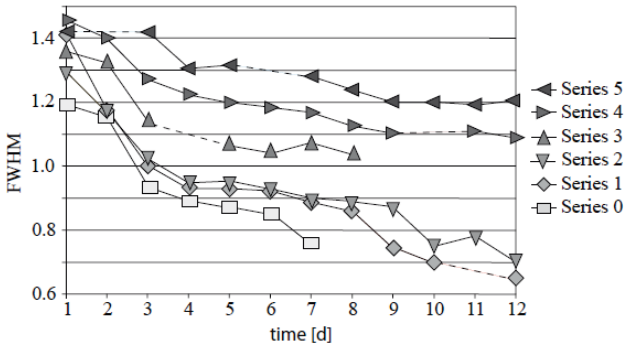

Fig. 1: Full width at half maximum (FWHM) of the (101) peak of goethite (Pnma setting) as a function of ageing time. Series 0 shows the formation of goethite without Sb(V), whereby the Sb(V) concentration increases from series 1 to series 5.

Two-line ferrihydrite was doped with different concentrations of Sb(V) by $KSb(OH)_6$. During aging of the doped ferrihydrite at 60 °C, twelve samples were taken, washed, dried and measured by X-ray diffraction (XRD). An increase of the FWHM with increasing Sb(V) indicates retardation of the transformation of ferrihydrite to well-crystalline goethite, similarly as already known for silicate [3].

Mineralogy and geochemistry of ferruginous AMD precipitates in the Łęknica region (the Muskau Arch, western Poland)

Bożęcki, P.[*] & Rzepa, G.
Dept. of Mineralogy, Petrography and Geochemistry, Faculty of Geology, Geophysics and Environmental Protection, AGH - University of Science and Technology, Krakow, Poland
([*]pbozecki@geol.agh.edu.pl)

The Muskau Arc is a large horseshoe-shaped glaciotectonic belt formed mainly during the Mid Polish Glaciation. Intense disturbances caused uplifting of the Neogene lignite beds (as well as co-occurring sands and clays). These deposits were excavated in numerous quarries and mines, from the late 18th to the late 20th century. The last active lignite mine pit “Babina” (located on the south east of Łęknica) was closed during the early seventies. The abandoned mining areas were filled with water, forming so-called "anthropogenic lakeland". Oxidation of sulphide minerals caused the formation of highly acidic waters. Released iron and sulphates precipitated by forming ochreous Fe-rich accumulations. The aim of this study was to determine the mineralogical and geochemical characteristics of these sediments. For this purpose, over 65 water and precipitate samples were collected.

The waters in the studied area are highly mineralised (electrolytic conductivity ranges from 600 up to 2900 μS/cm), acidic (pH 2,3-7,4) and characterised by very high Fe and sulphate concentrations, reaching ca. 525 and 3000 mg/dm^3, respectively. Ca^{2+} and Mg^{2+} contents are also high and reach about 380 mg/dm^3 and 58 mg/dm^3, respectively, while concentrations of Na^+, K^+ and Cl^- are relatively low (usually few mg/dm^3).

The precipitates are reddish-brown and orange, highly porous and contain numerous organic remnants. In many cases, especially during dry periods, white, yellowish or transparent crystals of gypsum (up to 2 mm in size) cover the sediment’s surface.

Apart from gypsum, the main constituents of the precipitates are goethite α-FeOOH, schwertmannite $Fe_{16}O_{16}(OH)_{12}(SO_4)_2 \cdot nH_2O$ and jarosite $KFe_3(OH)_6(SO_4)_2$. Goethite can be either well or poorly crystalline, depending probably on the formation conditions and water chemistry. Schwertmannite is always poorly ordered and usually forms, typical for this hydroxysulphate, hedgehog-like aggregates of small needle-shaped crystallites (< 2 μm long). Jarosite, on the other hand is much better crystalline, forming a few micrometers in size, pyramidal or platy crystals. Such mineral associations are typical of the AMD environments, although; the concentrations of trace elements in the sediment are lower than these of the other AMD areas. This is probably due to relatively simple composition of the weathering sulphides.

Oxidation of Fe^{2+} is relatively slow, while the rate of sediment formation in the Łęknica region is more rapid. This implies that formation of the precipitates is catalyzed by microorganisms. Seasonal variability in the rate of sediments formation and in the number of specific groups of microorganisms supports this conclusion.

Mineralogy of silicoclastic rocks deposited on an overburned coal waste dump in Wojkowice, Upper Silesia, Poland

Ciesielczuk, J.[1*] & Bzowska, G.[2]
[1]Dept of Fundamental Geology, University of Silesia, Sosnowiec, Poland ([*]justyna.ciesielczuk@us.edu.pl)
[2]Dept. of Mineralogy, Geochemistry & Petrology, University of Silesia, Sosnowiec, Poland

For the purpose of investigating the mineral transformations which have occurred on coal waste dumps due to self-heating and self-ignition, the dump at the Coal Mine Jowisz in Wojkowice, Upper Silesia, Poland, was chosen as an example. The Jowisz Coal Mine was active from November 1912 to April 2000. Coal wastes were deposited there from the sixties to the eighties of the XX century. The coal dump in Wojkowice covers an area of approximately 7 ha, reaching to 21.5 m at its highest point and containing about 1,200,000 tons of waste. The dump had been affected by self-ignition. High temperatures have caused changes to the mineral compositions of the waste rocks. For the last few years, the dump has been cool and the wastes have been exploited.

Areas of dumps affected by fire are divided into three zones: (1) the central fire core, where strongly overburned rocks are welded together by slag, (2) the external aureole where rocks have the colour of hematite, but no slag is present, and (3) the part unaffected by fire in which the rocks are black in colour with small laminae of coal. Three types of rock with different grain sizes were collected from each zone: sandstones, mudstones and siltstones. In addition, slag from the core of fire was studied. For precise identification of the mineral phases present, and for chemical identification, the following methods were used: XRD, SEM-EDS and microprobe analysis.

The intensity of the thermal influence on the waste rocks deposited on the dump can be estimated based on the presence of amorphous material of silica- or feldspathic composition, and of mullite and indialite – the products of high temperature transformation of clay minerals. The presence of spinels or hematite is also indicative.

Among the silicoclastic samples from within the first zone, the most highly thermally altered is a siltstone joined to slag. It consists of amorphous material (~30%), indialite and mullite (~55%), hercynite and hematite (~10%), quartz (~5%) and traces of anorthite and pyroxene. Mudstone also contains amorphous material (~48%) but no indialite and only ~6% of mullite. This rock also contains mica, the structure of which is thermally changed, quartz (~20%) and K-feldspar (~12%). Very fine-grained sandstone is mainly composed of kaolinite and chlorite (clinochlore) (~30%), thermally-affected dioctahedral mica (~20%), quartz (~30%), K-feldspar (~12%), hematite (~3%) and an amorphous substance. The least thermally affected is feldspathic sandstone which consists of quartz (~50%), the clay minerals kaolinite and chlorite (~16%), illite or thermally affected mica (~8%), K-feldspar (~18%) and hematite (~5%). Neither of the last two rocks contains mullite or indialite. The mineralogical composition of the slag differs significantly from the other rocks. It is composed of cristobalite and tridymite (~40%), magnetite, hercynite and hematite (~25%), anorthite (~20%), augite (~8%), indialite (~6 %), and traces of quartz. There is no mullite.

The mineral transformations in the silicoclastic rocks depend on not only the temperature, but also rock type, grain size, and the local conditions generated by the penetration of heat and the lack of oxygen. Minerals crystallized from the melt that formed the slag represent the mineral assemblage of a magmatic rock.

Seasonal variations of Zn, Cu, As and Mo in an As-rich stream at the Mokrsko, Czech Republic

Drahota, P.[1,2*], Mihaljevič, M.[1], Grygar, T.[3] & Filippi, M.[2]
[1]Inst. of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University, Prague, Czech Republic ([*]drahota@natur.cuni.cz)
[2]Inst. of Geology, Academy of Science, v.v.i., Prague, Czech Republic
[3]Inst. of Inorganic Chemistry, Academy of Science, v.v.i., Prague, Czech Republic

The Mokrsko gold deposit (Czech Republic) is probably the largest gold deposit in Central Europe unaffected by mining. Monthly sampling of slightly alkaline stream draining the natural As geochemical anomaly of the gold deposit revealed seasonal variations in dissolved Zn (maximum concentration 7.2 μg/l), Cu (≤2.7 μg/l), As (≤316.1 μg/l) and Mo (≤1.9 μg/l). The contents of dissolved trace metal cations increased by 330% (Zn) and 178% (Cu), with minimum and maximum mean concentrations in the autumn and spring, respectively. The lowest concentrations were associated with the highest pH values (Zn: $r=-0.51$, $p<0.01$; Cu: $r=-0.41$, $p<0.05$) during the autumn. The seasonal variations of the oxyanions were slightly smaller (As: 189%; Mo: 123%) and displayed almost opposite patterns to those of the metal cations. Inconsistent timing of seasonal streamflow and trace element cycling suggested that one or more in-stream biogeochemical processes rather than mere hydrologic changes are the primary control mechanism for seasonal trace element cycles in the stream.

The seasonal Zn and Cu cycles are believed to be caused by cyclic sorption and desorption onto oxyhydroxide substrates in response to the seasonal cycle of the stream pH. In contrast, the As and Mo seasonal variations are more consistent with Mn redox reactions. This hypothesis is supported by the very significant correlation of these oxyanions with Mn (As: $r=0.72$, $p<0.001$; Mo: $r=0.69$, $p<0.001$). The opposite concentration effect for trace metal cations relative to trace element oxyanions and Mn could be attributed to consistent timing among seasonal changes in the pH and oxic/anoxic conditions within the stream sediment. Both processes are controlled by the balance between photosynthesis and respiration.

Some part of the As in the stream sediment is bonded in crystalline arsenates (pharmacosiderite and arseniosiderite), jarosite and coprecipitated Ca-As arsenate in Fe oxyhydroxides, indicating a relevant thermodynamic and/or kinetic barrier in their dissolution after their erosion from the soil and saprolite [1]. Under fluvial conditions, As as well as other trace elements were mainly scavenged by low crystalline Mn oxides and ferrihydrite. The results of mineralogical study and single extractions indicated the abundance and reactivity of oxyhydroxide substrates that could undoubtedly play an important role in the assumed sorption and redox processes.

Arsenic mineralogy and mobility in a medieval mine dump

Filippi, M.[1*], Drahota, P.[1,2], Machovič, V.[3,4] & Böhmová, V.[1]
[1]Inst. of Geology, Academy of Science, v.v.i., Prague, Czech Republic ([*]filippi@gli.cas.cz)
[2]Inst. of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University, Prague, Czech Republic
[3]Inst. of Chemical Technology, Prague, Czech Republic
[4]Inst. of Rock Structure and Mechanics, Academy of Science, v.v.i., Prague, Czech Republic

Environmental samples collected from an arsenic-rich medieval waste dump and the surrounding soils near the arsenopyrite Giftkies mine (Jachymov ore district, Czech Republic) have been studied to understand the fate of arsenic (As) in such an environment.

Successive application of XRD, SEM, EMPA, Raman micro-spectroscopy and a set of chemical extractions and solubility measurements helped to distinguish and characterize the As-bearing minerals and evaluate their environmental stability. Abundant ferric arsenate minerals kaňkite, scorodite and pitticite, locally associated with arsenian jarosite, sulphur and ferric oxyhydroxides (goethite, hematite and lepidocrocite), were determined as the major oxidation products of arsenopyrite. Field observations together with an SEM investigation pointed toward the following succession of arsenates: scorodite – pitticite – kaňkite. Scorodite originated directly on the weathered arsenopyrite; kaňkite and especially pitticite (often present in the form of stalactites) precipitated from As-rich solutions migrating downwards for a very short distance. Chemical analyses of the whole samples showed very high As contents in the dump material (up to 13 wt. %) but relatively low contents in the underlying and surrounding soils (up to 0.6 and 0.4 wt. %, respectively). Goethite and hematite are the only detected As-bearing minerals in the soils.

Selective chemical extractions (sulphate and phosphate sorbed fractions and oxalate reducible fraction [1]) were performed (i) on the dump and soil bulk samples as well as (ii) on the pure ferric arsenates to interpret the chemical extractions in the bulk samples. According to these observations, As was mainly released during reducible extraction in the dump (up to 85% of the total As content - TAC) which corresponded to the total dissolution of pitticite and kaňkite and traces of scorodite (~5%). The reducible fraction of As is lower in the soil (up to 62% TAC) and is especially related to the dissolution of goethite. In contrast, the content of phosphate-exchangeable As is much higher in the soil (up to 28% TAC) compared to the dump samples (< 8% TAC). This points towards a significant amount of specifically-sorbed As that may be potentially mobilized due to changes in the pH or addition of P.

The dissolved arsenic concentrations in the dump (1.4-2.8 mg/l at pH 3.3-4.1) are controlled by the scorodite solubility, which is approximately an order of magnitude lower than the kaňkite solubility and at least two orders of magnitudes lower than the pitticite solubility. The content of pore-water As in the surrounding and underlying soil is very low (<20 µg/l As at pH 4.5-6.1), suggesting efficient As adsorption by Fe oxyhydroxides.

Bukovskýite from medieval dumps at Kutná Hora, Czech Republic; An example of crystallization from Si-Al gel-like medium

Loun, J.[1*], Novák, M.[2] & Kocourková, E.[3]
[1]Dept. of Mineralogy and Petrology, National Museum, Praha, Czech Republic ([*]loun.jan@seznam.cz)
[2]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic
[3]Dept. of Mineralogy and Petrography, Moravian Museum, Brno, Czech Republic

Bukovskýite (Fe^{3+}_2 $(AsO_4)(SO_4)(OH)$. $7H_2O$) was described as a new mineral from this locality [1,2]. It occurs in medieval dumps at Kaňk village near Kutná Hora along with common Fe^{3+}-arsenates and sulphoarsenates (scorodite, parascorodite, kaňkite, zýkaite) and less common sulphates (gypsum, melanterite, jarosite, aluminite, alunogen, rozenite) as pale yellowish-white to grayish-yellow microcrystalline aggregates forming nodules commonly several cm across but locally up to ~1 m in size.

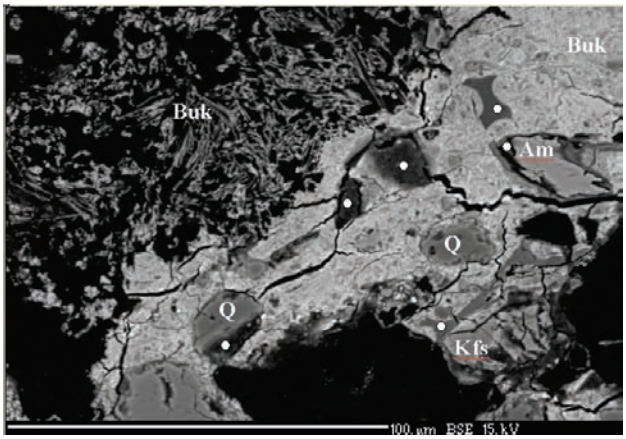

Fig. 1: BSE image showing dissolution of various minerals and crystallization of bukovskýite from Si-Al gel-like medium. The light substance consists of partly crystallized bukovskýite (Buk), relics of various minerals: Q = quartz, Kfs = K-feldspar, Am = Amphibole, and Si-Al gel-like medium (white dots).

Bukovskýite is a product of recent weathering of common sulphides arsenopyrite and pyrite. Field survey revealed two distinct As-rich mineral assemblages on the dumps: 1) scorodite+kaňkite+zýkaite aggregates (with no bukovskýite) in clastic gangue waste material, and 2) abundant bukovskýite with small nodules of parascorodite in clayish parts of the dumps. The almost monomineralic bukovskýite-rich zone commonly occurs ~ 1-2 m under the dump surface. The nodules studied primarily by EMPA revealed the crystallization of bukovskýite needle-like crystals from Fe,As,S-bearing Si-Al gel-like medium (10-82 wt.% SiO_2; 0.7-7 wt.% Al_2O_3; 1.7-24 wt.% Fe_2O_3; 2.2-19 wt.% As_2O_3, 1.2-4.6 wt.% SO_3; ∑oxides 37-89 wt.%; Fig. 1). It is a product of dissolution of various minerals of the dump (Fig. 1) at strongly acidic conditions (pH = 2.4-3.9). This process may be related to the clays used during processing in medieval times.

Significance of bacterial adhesion in the microbiologically mediated dissolution of metal sulfides: an experimental approach

Lu Xiancai[1*], Lu Jianjun[1], Tu Bowen[2], Zhao Xingqing[1], Li Juan[1], Zhou Yuefei[1] & Han Xiaodong[2]
[1]State Key Lab for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Jiangsu, China ([*]xcljun@nju.edu.cn)
[2]Medical school, Nanjing University, Jiangsu, China

The dissolution of the metal sulfides in polymetallic mines not only produces acid mine drainage (AMD), but also releases abundant heavy metals into the surroundings, which generally results in serious environmental contamination. Extensive studies indicate that various microorganisms play important roles in the dissolution of minerals. In recent years, the adhesion of bacteria on mineral surfaces has attracted a lot of attention [1]. In general, the contact between the bacterial external structure and the mineral surface can ehance the dissolution of minerals. This study experimentally investigated the effects of adhesion of *Acidithiobacillus ferrooxidans* on the dissolution of pryite, chalcopyrite and arsenopyrite. Furthermore, key proteins of this bacterium closely related to adhesion behaviors were studied by using two-dimensional electrophoresis, MALDI-TOF MS and checkage of amino acid sequence and peptide mass fingerprint between local and NCBI database. *Acidithiobacillus ferrooxidans* was separated and purified from acid mine drainage (AMD) in eastern China and identified by 16S rDNA. In order to disclose the contribution of adhesion of bacteria, comparative experiments with/without direct contact between cells and minerals were carried out by the employment of dialysis bags.

Remarkable differences were observed between the experimental minerals with and without dialysis bags. The dissolution rates of the sulfides with bacterial adhesion are clearly higher than those in comparative cases. The mineral surface with bacterial adhesion displays many erosion pits, whereas the encased mineral particles are covered by secondary sulfate precipitation and no pit was found. The shape and size of the pits are similar to that of bacteria cells despite of the mineral types. It is deduced that adhered bacteria and their metabolites can promote the dissolution of sulfides via surface corrosion.

In proteomic analysis, more than 30 types of proteins up-regulated had been identified in the two-dimensional electrophoresis of the total protein fraction from different phases of the experimental bacteria cells. Several proteins possibly control bacterial adhesion and quorum sensing during the dissolution of sulfides. Based on the correlation between their functions and expression levels of these proteins in different experimental stages, it is concluded that some of these proteins can help bacteria adhere to mineral surfaces, and that overtop density of cells will result in expression levels of the other proteins down-regulated, and then it greatly influences the bacterial adhesion and even to the formation of biofilms on mineral surfaces. However, more detailed studies about the roles of specific proteins related to oxidation of sulfides are still not resolved for the high complexity of the interfacial components and interactions.

EXAFS analysis of As speciation in poorly ordered Iron(III) (oxyhydr)oxides and oxyhydroxysulfates from Acid Mine Drainage deposits

Maillot, F.[1*], Morin, G.[1], Wang, Y.[2], Juillot, F.[1], Cassiot, C.[3], Bruneel, O.[3], Egal, M.[3] & Calas, G.[1]
[1]Institut de Minéralogie et de Physique des Milieux Condensés, Universités Paris 6 et 7, et IPGP, Paris, France ([*]fabien.maillot@impmc.upmc.fr)
[2]Laboratoire de Chimie de la Matière Condensée de Paris, Université Paris 6, Paris, France
[3]Laboratoire Hydrosciences Montpellier, Université Montpellier 2, Montpellier, France

Acid Mine Drainage (AMD) is generated by the microbially catalyzed oxidization of sulfide minerals (usually pyrite and arsenopyrite) exposed to the atmosphere and meteoric waters in metal sulfide mines and associated mine wastes. The resulting waters are highly acidic and enriched in sulfates and in ferrous iron. The concentrations of arsenic in AMD can reach hundreds of mg/l, as a result of the oxidation of As-rich sulfides [1]. Such As concentrations are potentially harmful for the aquatic ecosystem located downstream from mining sites and compromise a significant part of freshwater resources. In AMD, aqueous arsenic occurs either as As(III) or As(V) [1], with As(III) being more toxic for humans and animals and more mobile than As(V)

The investigation of acid mine drainages, using synchrotron-based techniques, has shown the importance of As adsorption on, or coprecipitation with, hydrous ferric oxides in delaying the long-term impact of As on the biosphere. Although in rare cases the precipitation of tooeleite, an As(III)–Fe(III) mineral, has been observed [2], the As(III) form is rather stable in solution, especially at low pH. On the contrary, As(V) presents a strong affinity for Fe(III). In AMD from the former Carnoule`s mine (France), the formation of an amorphous As(V)–Fe(III)-oxyhydroxysulfate precipitate has been reported [2] [3]. More frequently, As(V) forms scorodite or adsorbs on schwertmannite and ferrihydrite as a function of pH [4] [5]

In the present communication, we will present further EXAFS results on the speciation of arsenic in biogenic various iron(III) oxyhydroxide and oxyhydroxysulfate sampled in Acid Mine Drainage systems. Spectroscopic data indicate arsenic can be adsorbed or coprecipitated with Fe(III) depending on the As/Fe ratio and As oxidation state. This work bring further information on the mechanism of the As scavenging by iron minerals at the atomic scale, in impacted natural context.

Effect of mineralogy and chemistry of metal polluted soils on biodiversity and metal bioaccumulation (Libiola Mine, Italy)

Marescotti, P.*, Carbone, C., Azzali, E., Roccotiello, E., Zotti, M. & Mariotti, M.G.
DIP.TE.RIS., University of Genova, Genoa, Italy
(*marescot@dipteris.unige.it)

The research was carried out in the contaminated soils of the abandoned Libiola sulphide mine (NW Italy) in order to study the relationships between soil composition and biodiversity and to assess the possible accumulation of specific ecotoxic metals in plants and fungi. Nowadays, the entire mining site is characterized by active Acid Mine Drainage process, which determines acidification and heavy metals pollution of soils and waters. As a consequence, the soil related to the waste-rocks deposits and the open pit excavations exceeds residential and industrial limits for a number ecotoxic metals, such as Cr, Co, Ni, Cu, Zn, and Cd.

Ten sampling sites have been chosen in the mining area; seven of these sites (V-sites) correspond to an area of open pit mining, whereas the remaining three sites (F-sites) are located at the base of a 2 ha sulphide-rich waste-rock dump. The V-sites are composed by minor amount (5%) of pyrite showing various degree of oxidation. Clasts of serpentinite, basalts, and ophiolitic breccias are the main components ranging from 50 to 80 wt%. As a consequence the mineralogy of the V-sites is dominated by serpentine-group minerals, chlorite, plagioclase, magnetite and other spinels. Secondary minerals (5-10 wt%) are mainly represented by Fe-rich smectites with very minor amount of goethite and hematite. Serpentinite and basalts mineral assemblages are the main constituents (40-60 wt%) also of the F-sites. Nevertheless, with respect to V-sites, they are significantly enriched (10-30 wt%) in sulphide minerals (pyrite ± chalcopyrite ± sphalerite). The remaining fraction (10-30 wt%) is mainly represented by goethite and hematite with minor Fe-smectites. V-site and F-site samples are significantly different also in their chemical composition: V-sites are enriched in Ca, Mg, Mn, Ni and Cr. Conversely, the F-sites samples are enriched in Fe, Cu, Zn, S, Ag and Au due to the high amounts of Fe-Cu sulphides and Fe-bearing secondary minerals. Specifically for the F-sites, it is worth noting that most of the heavy metals released during sulphide oxidations are efficiently scavenged by the new forming Fe-oxides and oxyhydroxides.

As regards fungi, the study has considered both the micro and macro fungal flora. Most isolated microfungi species are tolerant to a wide range of pH and the biodiversity is remarkable in spite of heavy metals concentrations in native soils (F-sites) as high as 2400 mg kg^{-1} Cu and 1500 mg kg^{-1} Cr.

As concerns macrofungi, *Scleroderma polyrrhizum* (J.F. Gmel.) Pers. and *Thelephora terrestris* Ehrh. sporomata from F-sites have highlighted the capability to accumulate Ag (>50000 µg kg^{-1}) and Cu (>1000 mg kg^{-1}), respectively.

The V- and F-sites are characterised by different successional plant communities ranging from herbaceous to arboreal stages. Among several species *Alyssoides utriculata* has showed more than 1000 mg kg^{-1} Ni in leaves, suggesting a preferential metal allocation. The plant grows on V-sites and is almost absent on F-sites where-Cu sulphides and Fe-bearing secondary minerals are abundant.

The contaminated environment largely affected the biodiversity of the area and exerted a strong selective pressure on the local flora and mycoflora. The study has revealed peculiar plants, which could be fruitfully employed for future phytoremediation, while fungi could help the natural recolonisation of the surrounding vegetation.

Mineralogical and chemical evolution of ochreous precipitates from the Libiola Fe-Cu-sulphides mine (Eastern Liguria, Italy)

Marescotti, P.[1*], Carbone, C.[1], Comodi, P.[2], Frondini F.[2] & Lucchetti, G.[1]
[1]DIP.TE.RIS., University of Genova, Genoa, Italy
(*marescot@dipteris.unige.it)
[2]Dip. Scienze della Terra, University of Perugia, Italy

The Libiola mining area is characterized by active and intense AMD processes involving both the sulphide-rich waste rock deposits and the remaining outcropping and underground ore bodies. Due to these processes, most of the circulating surface and underground waters are strongly acidic (pH ≤ 3) and contain very high levels of ecotoxic elements derived from not only the sulphide mineralizations (such as Cu, Zn, As) but also the host rocks and gangue minerals (such as Cr, V, Ni). At the confluence of the mine-water discharge and unpolluted streams or runoff channels, extensive precipitation of Fe-rich authigenic minerals takes place. Significant mineralogical and chemical differences of the authigenic precipitates occur as a function of pH-Eh variations.

To better quantify the processes as well to monitor the changes in mineralogy and toxic elements distribution, we sampled water and ochreous precipitates (OP) at four mine adits (that continuously discharge acid mine waters) and downstreams from the emergence points where mixing with uncontaminated streams and runoff channels took place during raining periods. Electrical conductivity, pH, Eh, and T of the streaming waters were measured *in situ*, whereas the chemistry of waters and precipitates was determined by ICP-AES and -MS analyses. The mineralogy of the samples was analysed by means of XRPD and TEM.

Two groups of waters were distinguished on the basis of pH, Eh, SO_4, and dissolved metals contents. The first group corresponds to unmixed mine water and it is characterized by the lowest pH (2.37-2.72) and the highest Eh (562-624mV), SO_4 (4903-9450 mg/kg), and metal contents. The second group, sampled after the mixing with unpolluted waters, is characterized by a general reduction of metal load as well as by significant variations of pH (3.67- 4.40), Eh (336-496 mV), and SO_4 (492-1049 mg/kg).

The mineralogy of the OP were controlled by the pH, Eh, and SO_4 content of the corresponding waters; five groups have been distinguished on the basis of main mineral species (for each water, in parenthesis are reported pH, Eh (mV), and SO_4 (mg/kg), respectively): 1) jarosite-rich OP (2.37-2.42; 622-624; 7473-9450); 2) schwertmannite-rich OP (2.55-2.72; 562-588; 4903-5224); 3) goethite-rich OP (3.66-3.67; 465-497; 769-1049); 4) amorphous Fe-oxides rich OP (4.08; 356; 668); 5) ferrihydrite-rich OP (4.4; 490; 492). HR-TEM analyses revealed that most of mineral species within OP are nanominerals (ferrihydrite) or mineral nanoparticles (schwertmannite) that rapidly evolve toward more stable species (mostly goethite) as a consequence of ageing and/or variations of physico-chemical parameters of the circulating waters, as indicated by aqueous speciation and mineral stability calculations.

The bulk chemistry of the OP varies significantly among the different 5 groups. In particular, schwertmannite- and ferryhydrite- and amorphous-OP efficiently scavenge many metals of environmental concern (Cu, Pb, Zn, Ni, As, Cd, and Ag) due to their high surface area and adsorption capacity. Nevertheless, these elements are mainly scavenged through absorption and co-precipitation mechanisms and can be easily released during seasonal transformation and dissolution processes. Therefore, these ephemeral secondary minerals not only represent a short-lasting storage of contaminants but can also act as instantaneous sources of contaminants and/or acidity.

Kinetic testing and mineralogical characterization of sulphide mine wastes from the Oruro deposit (Bolivia)

Móricz, F.[1], Mádai, F.[1*] & Walder, I.F.[2]
[1]Institute of Mineralogy and Geology, University of Miskolc, Hungary ([*]askmf@uni-miskolc.hu)
[2]Kjeøy Research & Education Centre, Kjeøy, Vestbygd Norway

The Itos mine is located in the San Jose Mining District, Oruro, Bolivia. It is a worldwide-known polymetallic vein deposit that had been mined in the 20th century for silver in the early decades and later for tin. The deposit was formed by the superposition of two hydrothermal phases: a high-temperature one defined by cassiterite, pyrite and quartz; and a later one which deposited mostly silver-bearing sulfosalts such as jamesonite, freibergite, andorite, boulangerite, zinckenite and franckeite, accompanied by galena, chalcopyrite and pyrite.

Recently enormous heaps of mining wastes with strong ARD activity surround the town Oruro. Paste pH of the seepage water ranges between 1 and 2. The remediation strategy needed the detailed investigation of kinetics of mine waste minerals decomposition.

Three set of samples were collected from different mining wastes of the Itos mine: reprocessed flotation tailings, oxidized jig processing tailings (Itos jig tailing 01 and 02) and waste rocks (Itos Granza 01 and 02). The samples have been analysed using the column test as a kinetic test method, sequential extraction, EPMA and XRPD. The column test results were interpreted in terms of mineralogical data.

The kinetic test on waste rock samples were run for 101 days at the Kjeøy Research and Education Center (KREC) in Norway. The sequential extraction was made in a specialized Canadian geochemical laboratory and the mineralogical analyses were performed at the University of Miskolc.

The results from the kinetic tests (column test) show that these mine wastes have already been intensively oxidized; furthermore, the pyrite is partly replaced by different sulphates. The kinetic parameters and their change in time depend on average grain size, pyrite content and soluble sulphate content.

The analysis of the sequential extraction indicated that most of sulphur-bearing phases have been decomposed at step 5, that points to the secondary sulphate release potential of the wastes. Sequential extraction proved that there are also easily soluble heavy metal ions in the samples with high or toxic concentration.

The mineralogical analyses show that there are still large amount of those minerals which can oxidise and catalyse the ARD impact. The acid production have two sources: the main is the pyrite and the second one is the soluble secondary sulphate minerals, as jarosite, coquimbite, römerite, copiapite and melanterite.

Table 1: Calculated time for total pyrite degradation

Sample	Pyrite content (1)	Pyrite oxidation rate (2)	Estimated time (3)
Itos jig tailing-01	60	1.56	38
Itos jig tailing-02	50	5.95	8
Itos Granza-01	20	1.35	15
Itos Granza-02	20	5.72	4

(1) [g pyrite/kg sample] , (2) [g pyrite/kg sample/year], (3) years, if the speed of oxidation will not decrease in the future.

The geochemical model calculated from the kinetic test results and mineralogical analyses shows that the waste dumps need several decades to increase the pH to a normal level and decrease the concentration of the dissolved heavy metal ions.

Geological and biological characteristics of the environmental pollution in the Nistru-Băiţa mining area (Eastern Carpathians, Romania)

Nagy-Korodi, I.[1*], Fodorpataki, L.[1], Forray, F.L.[1], Ionescu, C.[1] & Tippelt, G.[2]
[1]Babeş-Bolyai University, Cluj-Napoca, Romania
([*]nagy-korodi.istvan@ubbcluj.ro)
[2]Paris Lodron University, Salzburg, Austria

The Nistru-Băiţa base metal and gold deposit is located in the Oaş-Gutâi Mountains. and belongs to the north-western part of the Neogene volcanic chain in the Eastern Carpathians. In the area the volcanic activity took place in Badenian-Pannonian, 15.4–7.0 M.a. ago [1] and produced calco-alkaline rocks ranging from basalts and basaltic andesites to dacites and rhyolites. The deposit was exploited mostly for Au, Pb, Zn and Cu, by underground and surface mining for a long period of time. Nowadays, the only active open pit still contaminates the Nistru-Băiţa river catchments system.

The samples taken from the Nistru-Băiţa waste dumps and alluvial sediments were investigated by X-Ray Diffraction (XRD) and Electron Microprobe (EMP) in order to outline the speciation of the main cations (Fe^{2+}, Fe^{3+}) and anions (SO_4^{2-}) and to identify the secondary minerals. The biological studies focused on experiments regarding the response of some terrestrial and aquatic plants to the Nistru-Băiţa waters.

The results show a significant pollution with high amounts of Fe, Al, Zn, Cu, Pb, as well as SO_4^{2-} in the mining effluents, and Nistru-Băiţa waters.

The Nistru waste dump material consists mostly of quartz, hydronium- and K-jarosites, goethite and gypsum. Kaolinite and akaganéite [β-$Fe^{3+}_8(OH,O,Cl)_{17}$] are subordinate.

The presence of light yellow to dark yellowish-reddish-brown precipitate forming rhythmic thin layers in the alluvia of the Băiţa creek indicates the mine influence. These deposits consist of Fe-SO_4-O-OH minerals, with metal scavenger properties. The light yellow layers are composed of K-jarosite, goethite, ferrihydrite, akaganéite and gypsum. The dark yellowish-brown and reddish-brown layers consist mainly of poorly crystallised akaganéite and schwertmannite [$Fe^{3+}_{16}(OH)_{12}(SO_4)_2$] mixed with goethite and quartz. In overall, the relative element concentration as revealed by EMP is the following: Fe >> S > Si > Al > P > Zn > As > Ca > Cu > Na > Mg >K > Mn. The presence of Zn, As and Cu is due to the alteration of sphalerite, arsenopyrite and chalcopyrite mineralization.

The experiments of growing various terrestrial and aquatic plants using the Nistru-Băiţa waters show reduced germination energy for seeds and inhibition of growth and reproduction. The ubiquitous presence of *Euglena mutabilis* Schmitz, a good microalgal indicator for acidic waters, demonstrates the intensity of the pollution in the area. The specific parameters of *Euglena mutabilis*, *i.e.* low pH, high concentration of total dissolved solids, and specific conductivity, reduce the biodiversity of periphyton in the environment area.

Removal of lead from wastewater by modified Venezuelian Red Mud

Omana Sanz, B., Gauthier, A.* & Dubois, M.
Laboratoire Génie Civil et géoEnvironnement, Université Lille, Villeneuve d'Ascq, France (*arnaud.gauthier@univ-lille1.fr)

Venezuela produces more than two millions tons of alumina per year. This production generates wastes (such as red mud) which are dumped in old lagoons near the Orinoco river. Actually, the quantity of stored mud is more than 15 million cubic meters [1]. Due to a high alkalinity (pH between 10 and 13) and its mineralogical and chemical composition, this waste becomes a real environmental problem. In order to reduce environmental impact, studies were performed on the adsorption capacity of this kind of wastes. In fact, textural and mineralogical properties of mud provide an important reactive surface with potential adsorption capacity for elements such as cadmium, lead or zinc [2,3]. The aim of this work is to evaluate the remediation potential of Venezuelan red muds. With this aim, we have studied the sorption capacity using lead (Pb) artificially contaminated solutions with varying pH and the lead concentration. The results are interpreted using the Langmuir's Isotherm (Fig. 1). The results show that the simple adsorption is not the only responsible for the lead retention in the system. Other mechanisms like absorption and precipitation can take place.

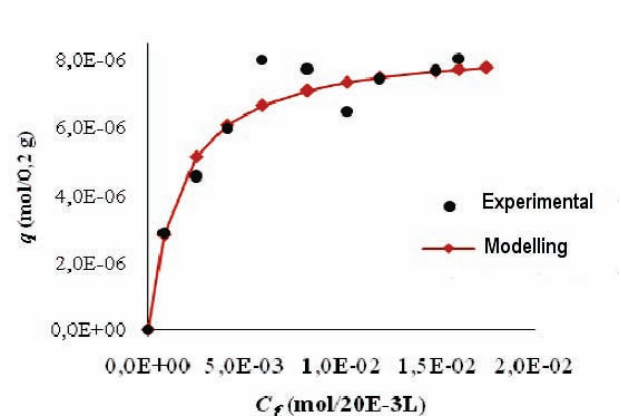

Fig. 1: Lead adsoption isotherm on red muds (pH 4, 25°C).

The Venezuelan red mud has a great potential as a sorbant of pollutant lead and possibly of other heavy metals, which gives it a remediation importance for the treatment of contaminated soils and waters.

Rapid mineralogical transformation of schwertmannite in presence of dissolved Fe^{2+}: mobility and effect of adsorbed arsenic

Paikaray, S* & Peiffer, S.
Dept. of Hydrology, University of Bayreuth, Bayreuth, Germany (*susanta@uni-bayreuth.de)

Poor structural stability of schwertmannite often leads to mineralogical transformation to thermodynamically stable iron oxides, i.e., goethite or hematite through extremely slow processes that completes in months to years [1]. Fe3+ reductive processes widely occur along schwertmannite-rich mine drainage localities catalyzing the reaction kinetics [2] where the phenomena is poorly understood. Excellent sorptive efficiency causes enriched arsenic levels in schwrtmannite, the fate and effect of which on transformation kinetics are unclear.

We investigated schwertmannite (SHM) metastability as a function of varied dissolved Fe^{2+} (0.4, 0.7 and 1.0 mmol L^{-1}) in a glove box for ~ 8 days at pH 7. The pH was maintained using PIPES buffer (pKa=6.8). Schwertmannites sorbed with 0.92 wt % As(III) (SHM-As) was investigated to study the fate and effect of sorbed arsenic. Solid phase was characterized by X-ray diffraction (XRD) and microscopic techniques (SEM), while aqueous phase was analysed for residual Fe^{2+}, As and desorbed SO_4^{2-}.

SO_4^{2-} was released rapidly releasing >45 wt % during 202 h and rate of desorption was relatively higher for SHM and also as dissolved Fe^{2+} concentrations increased. Complete adsorption of Fe^{2+} was observed in case of SHM, whereas minor amounts (~20 umol L^{-1}) was detected in case of SHM-As for initial 1.0 mmol L^{-1} dissolved Fe^{2+}. Schwertmannite was found as the predominant phase together with ferrihydrite (Fh) at lower dissolved Fe^{2+} (≤0.7 mmol L^{-1}), while lepidocrocite (Li) formed after 10 h with traces of goethite (Gt) that eventually transformed to Li and Gt after 202 h in presence of 1 mmol L^{-1} Fe^{2+} (Fig 1). Contrarily, sorbed As inhibits the reaction kinetics resulting Li formation after 34 h at 1 mmol L^{-1} dissolved Fe^{2+}. As was partially mobilized in course of transformation (< 1.0 %) and triggered by increased Fe^{2+} suggesting strong binding of As within SHM and the ageing products.

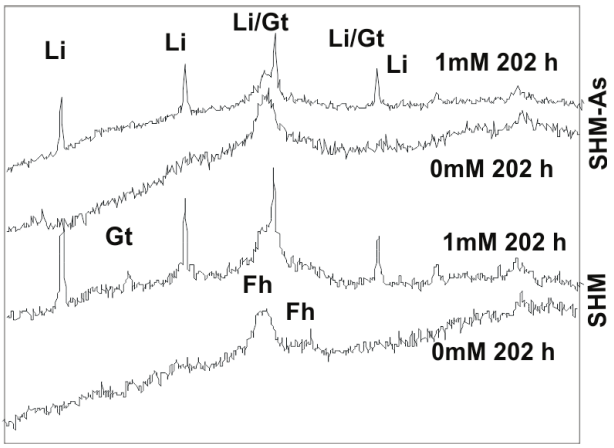

Fig. 1: Diffractograms of transformation products after 202 h.

This study demonstrates that presence of dissolved Fe^{2+} in schwertmannite rich natural streams significantly influence its metastability leading to high SO_4^{2-} loading into the stream. As-rich schwertmannites, which are commonly reported from mine effluents, stabilize the structure towards its sensitivity for Fe^{2+} catalytic transformation and hinders As mobility.

Uranyl sulphate minerals from the vein Červená, Jáchymov (St. Joachimsthal), Czech Republic

Plášil, J.[1*], Čejka, J.[1], Sejkora, J.[1], Novák, M.[2], Škoda, R.[2] & Dušek, M.[3]
[1]Dept. of Mineralogy and Petrology, National Museum, Prague, Czech Republic ([*]jakub_plasil@nm.cz)
[2]Institute of Geological Sciences, Masaryk University, Brno, Czech Republic
[3]Dept. of Structure Analysis, Institute of Physics, Academy of Sciences of the Czech Republic, Prague, Czech Republic

An interesting association of uranyl sulphate minerals was found in an abandoned adit at Červená vein (Rovnost shaft), Jáchymov, Czech Republic. Uranyl minerals are of supergene origin; their formation is related to the precipitation from acid mine drainage in the environment of the open mine-adit. The mineral association includes zippeite, pseudojohannite, Cu–Ca rich marécottite, rabejacite, uranopilite, unnamed Cu^{2+}–$(UO_2)^{2+}$–SO_4^{2-} phase and the new mineral sejkoraite-(Y)[1]. Minerals were studied by X-ray diffraction, EMPA, TG analysis and spectroscopic methods. A short description giving important physico–chemical properties of studied phases follows.

Zippeite occurs often as yellow to yellow-orange crystalline aggregates up to 1 mm. Refined unit-cell (Spgr. *C*2) is a=8.785(1)Å, b=14.025(1)Å, c=17.699(2)Å and β =104.196(7)°. According to EMPA main cation present in studied sample is potassium (0.91 K *apfu*).

Pseudojohannite occurs as yellow-green to green fine crystalline aggregates up to few mm in size. According to single crystal diffraction is triclinic of space group *P*-1, refined unit-cell is a=10.15(1)Å, b=11.52(8)Å, c=13.39(7)Å, α=95.5(5)°, β=108.1(4)°, γ=93.3(5)°. EMPA showed that at least two chemically different types of pseudojohannite exist, differing mainly in their Cu contents.

Cu-Ca rich marécottite forms sulphuric yellow to light green yellow aggregates up to few mm in diameter. Its powder diffraction pattern is similar to that of marécottite [2] even if slightly shifted. EMPA showed the presence of high Cu (up to 0.68 Cu *pfu*) and Ca (up to 0.40 *pfu*) in the cationic site.

Rabejacite occurs as yellow to orange yellow crystalline aggregates consisting of fine bipolar crystals (up to 10 μm in size). X-ray powder diffraction pattern is consistent with the published data [3]. By visual inspection, two types of rabejacite can be distinguished. Aggregates of orange colour represent altered ones with the surface enriched by Fe^{3+} and depleted in $(UO_2)^{2+}$ contents.

Uranopilite forms rich crystalline aggregates consisting of elongated prismatic crystals of sulphuric yellow colour. Its refined unit-cell is (Spgr. *P*-1) a=8.874(1)Å, b=13.985(2)Å, c=14.363(2)Å, α=96.71(1)°, β=98.75(1)°, γ=99.76(1)°.

Sejkoraite-(Y) forms orange to yellow-orange plate crystals up to 0.5 mm. According to single-crystal diffraction sejkoraite-(Y) is triclinic of the space group *P*-1 with the unit-cell of , a=14.0734(4),□b=14.3172(4),□c=15.0446(5)Å,□α=107.289(3) ,□β=95.716(2),□γ=102.826(2)°, V=2777.2(1)Å^3, Z=2. The chemical composition corresponds to the ideal formula $Y_3[(UO_2)_8O_8(SO_4)_4(OH)](H_2O)_{25}$; its crystal structure consists of zippeite-type sheets and yttrium/*REE* based polyhedra and water molecules in the interlayer space. The interlayer spacing 9.28 Å is similar to that found in pseudojohannite [4].

Mineralogy of the wastes from diamond-bearing mines

Posukhova, T.V.[1*], Dorofeev, S.A.[2] & Gao Xiaoying[3]
[1]Dept. of Mineralogy, Moscow State University, Moscow, Russia ([*]tposukhova@mail.ru)
[2]TsNIGRI Institute, Moscow, Russia
[3]Scientific & Technical University of China, Hefei, China

Extraction of diamonds is accompanied by huge amount of wastes. New technological classification of kimberlites, based on features of their mineral composition, will help to develop rational ways of recycling of these waste products. The samples from 18 kimberlitic bodies of Russia (Arkhangelsk & Yakutian provinces) and China (Liaonin & Shandong provinces) were investigated for this purpose. The kimberlites were studied by X-ray diffraction, thermal and electron-beam analysis, IR-spectroscopy and Ca-measurements (fig. 1).

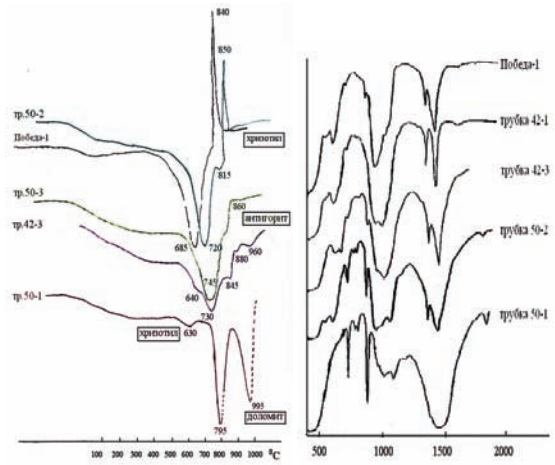

Fig. 1: Results of thermal analyses and IR – spectres of kimberlites from China.

The investigated kimberlites differ by individual ratio of the mineral phases: serpentine, carbonates, phlogopites and saponite where established kimberlites in which dolomite is prevailing (Chernyshevskaya, Botuobinskaya, Morkoka and pipe 50). The prevailing type of serpentine is also different. Basic mineral is close to pure chrysotile in pipes Victory 1 and 50, and in pipe 42 – and to antigorite. Differences in the chemical composition of the minerals were also established. Phlogopites from Liaoning have increased TiO_2. High-Al and low-Ti phlogopites are absent in kimberlites of China, and they are present in the Arkhangelsk provinces. Phlogopites with increased FeO were established in kimberlites of China

Proceedings from the received data, all investigated kimberlites were divided into four mineral-technological types: 1 - with prevalence of saponite (Chidviya and Lomonosov); 2 - with high contents of serpentine (Snegopadnaya, Aikhal, Dalnyaya, Udachnaya); 3 - with increased contents of carbonate and phlogopite (Chernyshevskaya and Botuobinskaya); 4 - with a complex mixed structure (Morkoka, 23 s'ezd KPSS, Nurbinskaya, Mir and pipes of China). The circuit of recycling is offered for each of the allocated types of kimberlites.

Mineralogical speciation of Pb-bearing secondary phases from a former lead-silver district (Pontgibaud, France)

Rakotoarisoa, O.*, Courtin-Nomade, A. & Bril, H.
GRESE, University of Limoges, France
(*ony.rakotoarisoa@etu.unilim.fr)

Because of its abundance and toxicity in mining environments as reported in previous studies (e.g. [1,2]), Pb was studied in the former mine of Roure (Pontgibaud district, France) where Ag and Pb were extracted from the middle to the late 19th century. Lead was present in the primary mineralization as galena (PbS) always associated with silver in quartz veins [3].

Studied residues from these activities are slags or tailings deposited on a 0.25 km^2 area. Tailings show various textures and structures (e.g. with a sandy texture or as hardpan) and Pb concentrations vary from a few mg/kg to 6.6%. Slags show a vesicular texture and Pb concentrations ranging from 850 mg/kg to 2.5%. Whatever the material, primary gangue minerals prevail on the mineralogical assemblages (e.g. quartz or muscovite) but the most important Pb-bearing phase is anglesite ($PbSO_4$). Anglesite results from the oxidative dissolution of galena and is observed in various forms as massive minerals (anhedral to euhedral up to 100 µm), associated to barite or embedded in a silicated matrix. The presence of anglesite as the main Pb-mineral species is in agreement with the oxidizing conditions and the pH values measured for the collected samples (3.5<pH<6.5), which explain that this species is stable according to the Pourbaix diagram. In mine tailings, however, the mineralogical assemblages show numerous other secondary Pb phases, even if more widely distributed in the residues, such as sulphates and phosphates mainly as: plumbojarosite ($PbFe^{3+}{}_6(SO_4)_4(OH)_{12}$), beudantite ($PbFe_3(AsO_4,SO_4)_2(OH)_6$), plumbogummite ($PbAl_3(PO_4)_2(OH)_5(H_2O)$), kintoreite ($PbFe^{3+}{}_3(PO_4)_2(OH,H_2O)_6$) or phosphohedyphane ($Ca_2Pb_3(PO_4)_3Cl$). The identification of these secondary phases is only supported by spatially resolved and more sensitive techniques such as SEM, micro-Raman spectrometry and EPMA.

In slags from smelter residues, galena or Pb metallic droplets are usually reported [4, 5]. In our case, none of these two phases have been observed which may be explained by the specific metallurgical process used at Pontgibaud due to the low Pb ore content (c.a. 12,6 kg/t) [6]. It may also be due to the fact that part of the tailings has been treated during the exploitation by crushing and flotation in order to collect the residual sulphides. Thus, it is expected that no galena and/or very little amounts of Pb should be detected [7,8]. However, even if galena was present in small quantities in the residues from this second treatment, the lack of galena in every residue as observed nowadays could also be explained by the in situ geochemical conditions which may have favoured its complete oxidative dissolution. Therefore, as the secondary Pb-bearing phases in the on-site conditions represent the main source of Pb towards the environment, their stability should be determined and would be achieved by leaching experiments, currently carried out at different pH.

Understanding micro-environment development in mine tailings using MLA and Image Analysis

Redwan, M. & Rammlmair, D.*
[1]BGR - Federal Institute for Geosciences and Natural Resources, Hannover, Germany (*rammlmair@bgr.de)

Discharge of mine tailings by spilling generates vertical and lateral grading in grain size, and subsequently chemical and mineralogical patterns different from the bulk spilled material along the spilling path. After deposition, these finely laminated mine tailings are exposed to alteration. Due to the depositional premises, the level of water saturation and the degree of alteration are variable. But even at the relatively coarse grained dam intercalated fine grained lamina change the hydraulic properties, creating capillary barriers, and lamina with enhanced water retention capacity. Alteration occurs in microenvironments at the interface of lamina contrasting in grain size, porosity, saturation, mineralogy, redox, pH and chemistry. The oxidation/dissolution and hydration of minerals cause a loss and gain of volume, respectively by generating new micro porosity and clogging pores at different positions. The aim of the investigation was to obtain quantitative information on the distribution of primary minerals, porosity as well as secondary crystalline and amorphous phases, for individual layers of the tailings, and for grain size distribution of all primary minerals, related to the mineral processing. This will help to reconstruct the primary porosity and to understand the role of the newly formed phases in clogging pores and in the development of cemented horizons, elucidating processes at individual positions in the heap.

The quantitative mineralogical analysis was carried out by using the MLA (Mineral Liberation Analyzer) software package from JKTech. The MLA method is based on the grey value evaluation of back-scattered electron (BSE) signals in conjunction to the EDX spectra collected from each individual grain in the image by means of SEM. [1,2]. A database was created for all phases based on BSE-images, EDX spectra and identification of phases by optical microscopy (Fig. 1).

The MLA results were further evaluated by using image analysis. Regions of interest (ROI) were chosen to evaluate the mineral distribution, and changes in porosity in individual layers, and to elucidate the progress in alteration due to dissolution and precipitation processes in microenvironments.

Unusual fibrous mimetite from the Rovnost mine, Jáchymov (St. Joachimsthal), Czech Republic

Sejkora, J.[1*], Plášil, J.[1], Císařová, I.[2] & Hloušek, J.[3]
[1]Dept. of Mineralogy and Petrology, National Museum, Prague, Czech Republic (*jiri_sejkora@nm.cz)
[2]Dept. of Inorganic Chemistry, Faculty of Science, Charles University in Prague, Prague, Czech Republic
[3]U Roháčových kasáren 24, Prague, Czech Republic

An interesting mineral association of morphologically anomalous mimetite and other supergene Pb minerals was found in the Rovnost mine, Jáchymov (St. Joachimsthal) ore district, Czech Republic. Mimetite forms greyish white fine-crystalline aggregates (up to 1 cm in the area) growing on the surface of strongly supergene altered gangue. Individual mimetite crystals are represented by colourless transparent flexible fibers of up to 1 mm in lenght and up to 10 μm in diameter. Mimetite was studied by X-ray powder diffraction but obtained pattern is significantly different from the published data of mimetite. According to EPMA (WD mode), its chemical composition is: PbO 75.92, SiO_2 0.45, As_2O_5 20.13, P_2O_5 1.05, SO_3 0.07, Cl 2.19, F 0.10, O=Cl+F -0.53, total 99.38 wt. % and its empical formula is $Pb_{5.15}[(AsO_4)_{2.65}(PO_4)_{0.23}(SiO_4)_{0.11}(SO_3)_{0.01}]_{\Sigma 3.00}(Cl_{0.93}F_{0.08})_{\Sigma 1.01}$ which are consistent with known members of mimetite - pyromorphite series; only contents of (SiO_4) in range 0.08 - 0.16 *apfu* were observed. A possible presence of clinomimetite or other structurally close mineral phase was checked by single crystal diffraction. The crystal structure of studied mineral has been solved by direct method and refined to an R_F index of 3.96 % based on 305 observed reflections (F_o>4sig(F_o)) collected on a four-circle diffractometer with Mo$K\alpha$ X-radiation. The obtained results - hexagonal space group $P6_3/m$, unit-cell parameters a=10.2373(6) Å, c=7.4257(4) Å and V=673.97(7) Å^3 (from 9868 reflections) and atom positions agree very well with published data for mimetite [1]. Differences between the experimental and calculated X-ray powder diffraction patterns of the studied mimetite are probably caused by its fibrous nature. There is a preferred orientation of the sample usual only for minerals with perfect cleavage.

Studied mimetite and associated minerals are of (sub)recent supergene origin; their formation is connected with very specific conditions in the supergene zone of the ore-vein *in-situ*. This type of supergene alteration has not been previously observed in the Jáchymov ore district and the research has not been completed yet.

Mineralogy and bio-weathering of fallen dusts at ferrosilicon production factory. Example from Si-Fe foundries in the Pirapora-Várzea da Palma region, Minas Gerais, Brazil

van Hullebusch, E.[1*], Fuchs, Y.[1], Horn, A.H.[2], Baggio, H.[3], Trindade, W.M.[2], Ribeiro, E.[2] & Rossano, S.[1]
[1]Laboratoire Géomatériaux et Environnement, Université Paris-Est, Marne la Vallée, France (*Eric.vanHullebusch@univ-mlv.fr)
[2]Laboratório de Geoquímica Ambiental Universidade Federal Minas Gerais, Belo Horizonte, MG, Brasil
[3]Laboratório de Ggeologia e Geomorfologia, Universidade Estadual de Montes Claros, Pirapora, MG, Brasil

Industrial activities that use processes of high temperature to produce ferrosilicon alloys (FeSi) and silicon metal (Si-metal), starting from diversified raw materials cause, among other problems, the release of fine dusts in the atmosphere. These particles are quite heterogeneous in term of shape and size features and elemental composition. In addition, they may have adverse impacts on the quality and quantity of agricultural products in the surrounding areas and drastic changes in the aquatic and irrigation systems. This influence can happen following two different ways: (i) deposition on plants, causing a direct chemical interaction, and (ii) through the deposition on soil and entrance into the bio-cycles.

Samples studied in this work come from two foundries located in the Varzéa da Palma region in Central to Northern Minas Gerais State, Brazil that generate air emissions from Fe-Si and Si furnaces. The raw materials used in these processes are barite, crushed quartz from, argillite, charcoal and wood for the Si production together with scrap materials for the Fe-Si alloys production.

Particulate matter in smoke display spherical C- compounds (μ), chromium - spinel balls (μ), irregular amorphous and crystalline SiO_2-agglomerates and rare well formed magnetite and Si crystals. The particle shapes are irregular to spherical. Grain size varies from tenths of a micrometer to one millimetre.

The plumes show transport distances of up to 50 km with changing flux conditions due to temperature and wind direction changes. The preferential transport directions are (NE to SSW 50%, NW - SW 15% and N - S 35%). The depositional factors were studied by field observations, optical microscope, grain-size measurements, XRD, environmental SEM and microprobe. ICP-OES and ICP-MS analyzes of the primary dust composition may show the direct impact over plants and soils in the selected area and the specific problems. Investigation performed in the laboratory about the bio/leaching of the particulate matter in smoke and leaching tests point out direct and chronic dangers by direct plant-dust and dust-soil-plant contacts.

Mineralogical and geochemical characterization of mine tailings from central Mexico, environmental implications

Villasenor-Cabral, M.G.[1*], Romero Martín, F.[1], Luna, L.[2] & Morales, I.[2]
[1]Instituto de Geología, Universidad Nacional Autonoma de México (UNAM), Ciudad de México, México
([*]mgvc@servidor.unam.mx)
[2]Postgrado en Ciencias de la Tierra, UNAM, Ciudad de México, México

Mining activity in Mexico has been very intense since Colonial times up to the present. This fact has been reflected as well in a great quantity of mining-waste. Here we present the mineral and chemical characterization of tailings from two different mines in central Mexico: one in the state of San Luis Potosi and the other one in the state of Guerrero. The purpose of this study is to establish the mobility of arsenic and lead as the main possible contaminants.

Total content of arsenic (140-3627 $mg.kg^{-1}$), lead (148-10900 $mg.kg^{-1}$), zinc (0.021–3.86 %) and iron (2.4–35.7 %) has been done with ICP-AES and mineralogical determinations with optical microscopy, XRD and SEM-EDS. In both sites, oxidized tailings (brown color) and reduced tailings (gray color) were identified. The oxidized samples from Guerrero presented acid pH values from 2.4 to 3.7, indicating the formation of acidic drainage as a consequence of extensive sulfide mineral oxidation. However, the pH values found in the oxidized tailings San Luis Potosi varied between 6.5 and 8.2.

Minerals of the reduced tailings from both areas included quartz (SiO2), calcite ($CaCO_3$), plagioclase, orthoclase, pyrite (FeS_2), and sphalerite (ZnS). Reduced tailings from San Luis Potosi additionally contained wollastonite and more calcite. Relative abundances of the sulfide minerals, determined by point-counting in polished sections, indicate that the unoxidized tailings from the Guerrero contain approximately 10% pyrite, 4% sphalerite and traces of chalcopyrite and galena. However, unoxidized tailings from San Luis Potosi contain approximately 5% pyrite, 7% sphalerite and trace galena. Oxidized samples of both areas have gypsum, Fe-oxyhydroxides, kaolinite, jarosite and anglesite. Oxidized tailings from the Guerrero also contain beudantite.

The results of the mineralogical characterization and acid-base accounting tests allow to predict that unoxidized gray tailings from Guerrero will be acid generating when they oxidize.

The highest concentrations of dissolved Zn (55 $mg.L^{-1}$) and Fe (28 $mg.L^{-1}$) were found in the acidic tailings from Guerrero, while low concentrations of As (0.4 $mg.L^{-1}$) and Pb (0.2 $mg.L^{-1}$) were found in these acidic oxidized tailings showing low mobility of these potentially toxic elements (PTE). Because the reported solubility for beudantite is very low under acidic conditions, this minerals may serve as the most important control in the mobility of As and Pb from the oxidized tailings at Guerrero. In contrast, Fe-oxyhydroxides are relatively soluble under acidic conditions; therefore, they may have a less significant role in PTE on-site immobilization. The dissolved concentrations of PTE in oxidized tailings from San Luis Potosi were below the detection limits. Our results may indicate that the sorption on Fe-precipitates play an important role in the mobilization and attenuation of PTE within the oxidized circum neutral tailings from San Luis Potosi.

The mineralogical determinations are very useful for interpretation of mobility.

Preferential oxidation of euhedral pyrite containing relict framboidal morphologies

Weisener, C.G.[1*], Gagnon, J.[1] & Weber, P.A.[2]
[1]Great Lakes Institute for Environmental Science, University of Windsor, Windsor, Canada ([*]weisener@uwindsor.ca)
[2]Environmental Division, Solid Energy New Zealand Ltd, Christchurch, New Zealand

Environmental damage produced from acid generating mines currently represents one of the largest problems facing the mining industry. The aim of this research is to investigate possible mineralogical controls on acid rock drainage (ARD) and metal release associated with pyritic mudstone collected from, the Brunner Coal Measures (BCM), Stockton Mine NZ. Laboratory-based kinetic tests were performed on the potentially-acid forming material by measuring, over time, the changes in mineralogical compositions and acid generating potential along with changing effluent chemistries from the columns. The rate of pyrite oxidation in the BCM is strongly dependent on the reactivity of two morphological types (euhedral and framboids) of pyrite in this region.

After a 4 month period between 70 to 100% of all framboidal pyrite had undergone complete oxidation, despite this acid generation (1730 (mgL-1 CaCO3) after 390 days) continued during the column experiments. SEM micrographs show the persistence of larger euhedral pyrite grains as a contributing factor with evidence of preferential oxidation associated with relict framboidal morphology (figure 1).

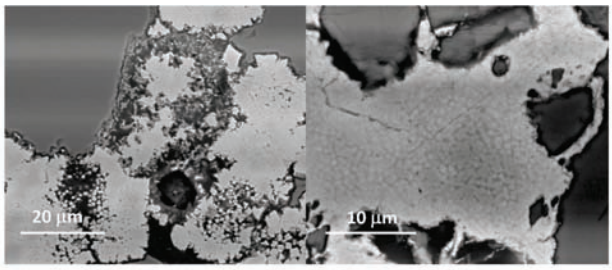

Fig. 1: After 13 months within a humidity cell euhedral pyrite shows preferential oxidation confined to pyritic overgrowth textures.

Samples collected from laboratory humidity cells after 13, 16 and 24 months show preferential dissolution features associated with large pyritic overgrowth textures. From a kinetic perspective the oxidation of pyrite in these samples tend to target the more recent crystallographic overgrowths. Results of the 24 month study will be presented detailing the mineralogical alteration, acidity generation and their controls on trace metals specifically thallium deportment.

Mechanisms of contaminant metal and metalloid sequestration using reactive amendments for soil and sediment remediation

O'Day, P.A.[1*] & Vlassopoulos, D.[2]
[1]School of Natural Sciences, University of California, Merced, California, USA ([*]poday@ucmerced.edu)
[2]S.S. Papadopulos & Associates, Inc., Portland, Oregon, USA

Reactive amendments optimized for specific (bio)geochemical site conditions offer a promising remediation technology for high-priority metal and metalloid contaminants in soils and sediments. The overall aim of *in situ* amendment technologies, whether added directly to geomedia or emplaced within barriers or caps, is to sequester and stabilize contaminants in place in order to reduce their ability to partition to water or biota, their toxicity, and their potential for transport. Metal and metalloid elements are especially problematic because many are considered hazardous at low bulk solid concentrations (i.e., ~1-10's ppm). They are often widespread in the surface and shallow subsurface at these low concentrations, making removal and disposal of a large volume of material impractical or prohibitively expensive. Many soil amendment studies have focused on performance as measured by standardized leaching or bioavailability tests. Less research has been aimed at understanding the basic chemistry, molecular mechanisms, reaction rates, or detailed mineralogy associated with amending contaminated soils or sediments with different types of treatment.

Sequestration mechanisms fall into two broad categories, surface adsorption and structural incorporation, which may each have several molecular-scale variations. In complex mixtures of amendments and soil, both mechanisms may occur and change with time. Adsorption using media such as clays, zeolites, or iron oxides can be an effective immobilization mechanism for metal contaminants, which may change speciation but do not degrade. However, there is an inherent risk that future changes in soil water pH or ionic strength, or in other environmental factors, will shift surface equilibria and lead to desorption. Treatments that react with soil water and minerals, leading to dissolution and precipitation reactions, can structurally incorporate contaminant species into new phases that form as a result of altering the composition and pH of the system. This class of sequestration mechanisms has the potential for more permanent immobilization since mineral dissolution is required to partition the bound contaminant to water, rather than simple desorption or exchange. A variety of mineral-based solids or mixtures of materials are used in reactive amendment treatments, including phosphates, carbonates, sulfates, iron-based solids, silica, lime, and Portland-type cements, as well as industrial residual and by-product materials such as coal fly ash, furnace slags, mining residuals, and scrap iron. In addition to coprecipitation or solid solution formation, amendments may also encapsulate contaminants in nano-to-microscale inclusions, or encapsulate contaminant-bearing nanoparticles within other resistant phases. Once molecular-scale mechanisms have been identified, reactive transport models incorporating thermodynamic and kinetic data can be used effectively to constrain biogeochemical outcomes of sediment-amendment reactions, which can then be tested in laboratory and field experiments. Better understanding of chemical and physical controls on contaminant immobilization, together with a framework for site assessment, would aid in both extending the use of mineral and other amendments for soil and sediment remediation, but also in selecting materials that are compatible with, and optimized for, a specific site.

Iodine uptake by Layered Double Hydroxides

Aimoz, L.[1,5*], Taviot-Guého, C.[2,3], Vespa, M.[4], Dähn, R.[1], Leroux, F.[2,3], Mäder, U.[5] & Curti, E.[1]
[1]Laboratory for Waste Management, Paul Scherrer Institute, Villigen, Switzerland ([*]laure.aimoz@psi.ch)
[2]Clermont Université, Université Blaise Pascal, LMI, Clermont-Ferrand, France
[3]CNRS, UMR 6002, Laboratoire des Matériaux Inorganiques, Aubière, France
[4]Dept. of Chemistry, Division of Molecular and Nanomaterials, Catholic University of Leuven (K.U. Leuven), Heverlee, Belgium & DUBBLE CRG, ESRF, Grenoble, France
[5]Institut für Geologie, University of Bern, Bern, Switzerland

Spent nuclear fuel from nuclear power plants contains ^{129}I which is dose-determining in repository safety analyses due to its long half life, anionic form and weak retention by common minerals. Often, safety analyses do not include the uptake of anionic radionuclides by secondary minerals such as Layered Double Hydroxides (LDHs). The most common naturally occurring LDH phase is hydrotalcite (Mg-Al LDH). LDHs have a brucite-like structure of edge-sharing hydroxide octahedra forming layers of positive charge, balanced with anions in the interlayer space surrounded by water molecules. The retention mechanisms of anions in LDH phases are poorly understood, particularly at the atomic-scale. The structural configuration of iodine-bearing LDH phases was elucidated by the Rietveld refinement of the average structure from powder X-ray diffraction data, together with Extended X-ray Absorption Fine Structure (EXAFS) spectroscopy.

Zn-Al LDHs were selected as an analogue to hydrotalcite since they usually display a higher crystallinity compared to the Mg-Al phases, allowing better access to further structural investigation by means of XRD. LDHs were synthesized by co-precipitation of I (as I^- or IO_3^-) with Zn^{II} and Al^{III} salts at Zn/Al ratios = 2, 3 and 4. XRD analysis confirmed the formation of pure LDHs, with a layered hexagonal structure (R-3m), and I sitting in the interlayer space. A Rietveld structural refinement was attempted on the most crystalline sample (I-LDH, Zn/Al=4). This structural refinement revealed the occurrence of stacking faults, a common feature in LDH phases. Such disorders prevent the resolution of structural features using XRD alone and require methods such as EXAFS which can probe the short-range order.

Fourier transformed EXAFS spectra at the zinc K-edge showed a local order within the octahedral layer for all samples. An oxygen shell was found at ~2.10 Å. Wavelet transforms of the EXAFS spectra confirmed the presence of both Zn and Al in the three subsequent shells found between 3 and 6 Å, as already observed by Funke et al. [1]. In addition, the wavelet transform analysis did not reveal the presence of any heavy backscattering atoms such as iodine, suggesting a lack of short-range ordering between Zn in the octahedral layer and I in the interlayer. This interpretation was further confirmed by data measured at the iodine K-edge on the same samples, which did not reveal any preferred distance for I-Zn pairs.

The results unambiguously show that iodine can be incorporated in the interlayer space of LDH phases via co-precipitation, confirming their potential as a sink for ^{129}I. A short-range ordering within the octahedral layer was confirmed, whereas no local preferential arrangement was found between the interlayer anions and the octahedral sheets.

Mineral formation and anion sorption at naturally-occurring hyperalkaline springs in Oman

Anraku, S.[1*], Morimoto, K.[2], Sato, T.[3] & Yoneda, T.[3]
[1]Graduate School of Engineering, Hokkaido University, Sapporo, Japan ([*]anraku@eng.hokudai.ac.jp)
[2]National Institute for Materials Science, Japan
[3]Facluty of Engineering, Hokkaido University, Sapporo, Japan

In Japanese transuranic (TRU) waste disposal facilities, ^{129}I is the most important key nuclide for the long-term safety assessment. Thus, the distribution coefficients (Kd values) of I to natural minerals are important factor in the safety assessment. However, the degradation of cement materials in the repositories can produce high pH pore fluid which can affect the anion transport behaviour. Therefore, it should be necessary to understand the behaviour of anions such as I- under the hyperalkaline conditions.

This study examined the naturally-occurring hyperalkaline conditions near the springs in Oman as natural analogue for the interaction between cement pore fluid and natural Mg-HCO_3^- river water. The generated natural hyperalkaline spring water (pH>11) from the partly serpentinized peridotite in the Oman ophiolite is characterized as hyperalkaline, reducing, low-Mg, Si and HCO_3^-, and high-Ca while the river water where the alkaline spring , is moderately alkaline, oxidizing, high-Mg and HCO_3^-. The mixing of these spring and river water resulted in the formation of secondary minerals, forming river terrace with height of more than 10 meters. The present aim of this paper is to examine the conditions of secondary mineral formation and the anion uptake capacity of these mineral phases generated. The long-term satiability of this sorption behaviour in this system was also investigated.

Water and precipitate samples were collected at various distances from the spring vent to identify the effect of mixing ratios between spring and river water on mineral composition and water-mineral distribution coefficient of various anions. On-site synthesis was also carried out to support these data quantitatively. Furthermore, samples of deposits were collected from the river terrace at different height which corresponds approximately to the the depositional age in order to find out the alteration of minerals and possible anion desorption.

The results of the mineralogical and chemical characterization of the collected samples confirmed that the formation of secondary mineral was dominated by aragonite at the mixing points of the spring and surface water, due to high Mg content of the latter. Hydrotalcite like compound (Mg-Al hydroxides) was also detected as accessory minerals since the hyperalkaline springs contain relatively rich in Al.

During the formation of the minerals at the mixing points, HCO_3^- in the river water was fixed as carbonate minerals in aragonite and calcite phases while $H_3SiO_4^-$ in the river water was dominantly fixed into the interlayers and surfaces of HTlc. Iodine in spring and river water was mainly fixed in aragonite. XRD quantitative analysis by Rietveld method indicated Kd values of iodine increase proportionally to the aragonite content in the precipitate samples. Consequently, in terms of short-term assessment, particularly for I^-, uptake by secondary minerals can be expected at hyperalkaline conditions as observed at Oman hyperalkaline springs.

Synthesis, characterisation and environmental application of bentonite organoclays

Sarkar, B.[*], Xi, Y., Megharaj, M., Krishnamurti, G.S.R. & Naidu, R.
Centre for Environmental Risk Assessment and Remediation (CERAR) & Cooperative Research Centre for Contamination Assessment and Remediation of the Environment (CRC CARE), University of South Australia, Mawson Lakes, Australia ([*]Binoy.Sarkar@postgrads.unisa.edu.au)

Organoclays are generally synthesised by incorporating alkyl ammonium surfactant cations into clay structure. Such modification imparts hydrophobic properties to the clay products and enhances their affinity towards hydrophobic organic contaminants in the environment [1]. Moreover, some organoclays can also adsorb inorganic anionic contaminants [2]. However, one of the main hindrances that discourages widespread uptake of this remediation technology is the high cost involved with the synthesis of these materials. Therefore, attempts are necessary to synthesise organoclays from comparatively cheaper surfactants to reduce the cost of production to some extent.

In the present study, organoclays were synthesised from natural bentonite in hydrothermal cation exchange reaction using a commercially available cheap surfactant known as Arquad 2HT. Organoclay products having various surfactant loadings were obtained and characterised by XRD and FTIR. As the surfactant loadings increased, the XRD results showed incremental basal spacing (d 001) in the organoclays due to incorporation of the surfactant molecules in the interlayer space of the bentonite (Table 1). The IR peaks generated by symmetric and asymmetric stretching of the $–CH_2$ groups at 3000-2800 cm^{-1} wave number further proved successful organic modification of the natural bentonite.

Table 1: Basal spacing of the natural bentonite and its organoclays

Clay/organoclays	Clay-surfactant ratio (w/w)	d (Å)
QB	Natural bentonite	15.03
QB-Aq1	0.60:1	15.15
QB-Aq2	1.19:1	15.36
QB-Aq3	1.79:1	27.93
QB-Aq4	2.38:1	30.00
QB-Aq5	3.57:1	34.73

The synthesised organoclays were tested for their environmental application in batch adsorption experiments using phenol and *p*-nitrophenol as the model contaminants in water. The adsorption data fitted reasonably well into Langmuir isothermal models and the adsorption maxima for these two contaminants were calculated (Table 2). Results showed that removal efficiency of phenol and *p*-nitrophenol improved with incremental surfactant loadings in the organoclays.

Table 2: Langmuir maxima (mg g^{-1}) for adsorption of phenol and *p*-nitrophenol by natural bentonite and its organoclays

Clay/organoclays	Langmuir adsorption maxima (mg g^{-1})	
	Phenol	*p*-nitrophenol
QB	No adsorption	23.1
QB-Aq1	13.7	45.2
QB-Aq2	34.8	59.1
QB-Aq3	47.6	63.3
QB-Aq4	61.0	79.4
QB-Aq5	82.6	87.7

This study demonstrates the potential of Arquad 2HT modified bentonite in remediation of polar organic contaminants similar to phenol and *p*-nitrophenol from contaminated waters and soils.

[1] Xi, Y. et al. (2005) *Langmuir*, **21**, 8675-8680. [2] Krishna, B.S. et al. (2001) *Appl. Clay Sci.*, **20**, 65-71.

Groundwater chemistry of Kandal province, Cambodia and arsenic removal from tube well water

Pich, B.[1*], Yoneda, T.[1], & Sato, T.[1]
Laboratory of Environmental Geology, Hokkaido University, Sapporo, Japan ([*]pichoeun@eng.hokudai.ac.jp)

A comparative study of arsenic-rich groundwater in alluvial aquifer of the Cambodian Mekong delta between rainy and dry season was conducted in Prek Tameng and Prek Thom villages of Kandal province, Cambodia. As a result, Kandal groundwater was characterized by low to high concentration of dissolved As, moderate to high concentrations of dissolved Fe, Mn, HCO_3^-, NH_4^+ and DOC, and low concentrations of SO_4^{2-} and NO_3^-, circum-neutral pH and slightly reducing condition. Comparatively, the groundwater chemistry of Prek Tameng slightly varies due to chemical dilution caused by surface water infiltration during rainy season, while that of Prek Thom remain almost the same throughout the year.

Positively stronger correlations of high As with DOC, NH_4^+, and SO_4^{2-} but negative correlation with low Fe and PO_4^{3-}, in Prek Thom in dry and rain season, indicated that arsenic mobilization was more probably in association with microbial activities and organic matter degradation. This process could be mostly found in less reducing condition of the near-surface wetland site of the Kandal province in the Cambodian Mekong delta. However, dissolved Fe(II) was thought to be still retained in the sediment to form Fe(II) or mixed Fe minerals.

On the contrary, low As in Prek Tameng was well-correlated with high Fe, Mn, HCO_3^-, and low PO_4^{3-} and inversely-related with low SO_4^{2-} and NO_3^-. This suggests that arsenic in Prek Tameng is mobilized to the groundwater due to reductive dissolution of Fe and/or Mn(hydr)oxide minerals rather than oxidative desorption/decomposition of organic matter. This mechanism was mostly found in more reducing condition of deeper aquifer of the Cambodian Mekong delta. Last but not least, competitive adsorption to the same surface site between As and PO_4^{3-} due to their similar affinities may also contribute to arsenic release.

This research provided some significant information on how to deal with the arsenic problem in Kandal province, Cambodia since nearly 1 million residents in this province have been threaten and at risk by the presence of arsenic in groundwater. Therefore, it is definitely necessary to remove arsenic from tube well water by utilizing locally available low-cost adsorbents. In the presentation, applicability on usage of the laterite from Kampong Cham province, Cambodia as arsenic adsorbent will be also discussed based on the groundwater chemistry.

Utilization of schwertmannite for sustainable remediation of contaminated land and water

Sato, T.[1*], Fukushi, K.[2], Ito, K.[3], Takada, M.[4] & Yoneda, T.[1]
[1]Faculty of Engineering, Hokkaido University, Sapporo, Japan ([*]tomsato@eng.hokudai.ac.jp)
[2]Institutes of Nature and Environmental Technology, Kanazawa University, Kanazawa, Japan
[3]Cooperative Research Center, Miyazaki University, Miyazaki, Japan
[4]Graduate school of Engineering, Hokkaido University, Sapporo, Japan

Schwertmannite, poorly crystalline Fe (III)-oxyhydroxysulfate with the composition $Fe_8O_8(OH)_{8-2x}(SO_4)_x$ (where ideally x=1), is more commonly reported as an orange or ocherous precipitate in streams and lakes affected by acid mine drainage. Schwertmannite has a large reactive surface and is capable of scavenging significant quantities of trace elements. Therefore, there are many reports describing sorption properties and mechanisms of hazardous element. According to the high affinity with arsenate, phosphate and chromate anions, schwertmannite has been expected as geochemical sink and candidate material of adsorbents for hazardous oxyanions. However, there is hardly able to find reports on practical utilization of schwertmannite for remediation of contaminated land and water.

In Japan, we intensively introduced schwertmannite for practical utilization to prevent an arsenic release from contaminated soils and to remediate contaminated water such as acid mine drainage in passive treatment systems. In remediation of contaminated land, the stabilized schwertmannite has directly been mixed with the contaminated soils and used with fibrous materials in adsorptive bed installed between contaminated soils and aquifer. In passive treatment facility of acid mine drainage including arsenic, schwertmannite was successfully synthesized from acid mine drainage by pH adjustment to pH 3.5 and almost completely removed arsenic from the drainage. From the synthesis, it has been achieved economical use of the reagent for the neutralization process, reduction of the sludge produced from the neutralization, and safety encapsulation of arsenic into the solid material.

For performance and safety assessments in utilization of schwertmannite for sustainable remediation of contaminated land and water, sorption capacity of arsenic, kinetics of schwertmannite transformation to goethite and solid-solution relationship between sulphate and arsenate schwertmannite have been investigated by our research group. Therefore, performance and long-term safety assessment for the utilization of schwertmannite are available in reactive transport modelling for sustainable remediation of contaminated land and water. In the presentation, the authors would like to introduce some of examples in utilization of schwertmannite for sustainable remediation of contaminated land and water, and their performance and long-term safety assessment.

Clustering of impurities in natural calcite: theoretical and spectroscopic study of As-As and As-Eu relationships

Bardelli, F.[1], Benvenuti, M.[2], Charlet, L.[3], Costagliola, P.[2], Di Benedetto, F.[4*], Fernandez Martinez, A.[5], Valenzano L.[1], Lattanzi, P.F.[6], Meneghini, C.[7] & Romanelli, M.[4]

[5]Lawrence Berkeley National Laboratory, Berkeley, USA
[6]Dipto. di Scienze della Terra, Università di Cagliari, Cagliari, Italy
[7]Dipto. di Fisica, Università di Roma Tre, Rome, Italy

An experimental and theoretical study was undertaken on crystal chemical features of the $CO_3^{2-} \leftrightarrow AsO_3^{3-}$ substitution in calcite lattice, which is suggested to occur in As-bearing travertine rocks from Tuscany (Italy). This study has been carried out by means of As K-edge XAFS (X-ray Absorption Fine Structure), Electron Paramagnetic Resonance, Electron Spin Echo spectroscopy and Density Functional Theory (DFT) calculation.

In particular, the possible self-clustering of As impurities or the hetero-clustering of As with other trace elements were investigated. The former was studied by means of XAS and DFT in natural As-bearing travertines, whereas the latter was pursued through EPR and ESE on opportunely synthesized As-, Eu- co-doped calcites, chosen on the basis of ionic radius of Eu (>Ca).

The experimental confirmation of the As clustering was provided by the presence of strong signal (i.e. with coordination number close to the maximum allowed for the calcite cell) from an As-As coordination shell to the EXAFS signal of a travertine sample.

Although involved in a relatively rare replacement process, the uptake of As(III) by calcite feasibly occurs via self-clustering in local domains of calcite.

Conversely, scarce evidence of As-Eu clustering in calcite was observed in the EPR-ESE characterisation of synthetic calcite samples, suggesting that general clustering of impurities (independent of their nature) can occur only under specific boundary physico-chemical conditions, and that the steric effect in this case can be imputed to prevent the clustering of impurities in calcite.

A new approach for remediation of polluted soils: interaction between vitreous matrix and metallophyte plants

Gauthier, A.[*] & Dubois, M.
Laboratoire Génie Civil et géoEnvironnement EA 4515, Université Lille 1, Villeneuve d'Ascq, France
([*]arnaud.gauthier@univ-lille1.fr)

The contamination of soils by heavy metals has become a really important problem, especially in some highly industrialized areas such as North of France. One solution is to treat soils by remediation using metallophyte plants able to trap pollutants from soils. The aim of this work is to follow the evolution of a plot of polluted land in the presence of metallophyte plants (*Arabidopsis halleri*) and of a phosphated amendment. This amendment consists of a glassy matrix (Ca-Si-P) in order to increase the phosphorus concentration into the soil. In addition the alteration of this glass results in the formation of crystallized secondary phases (hydroxyapatite) which can trap heavy metals.

The metal content in metals after culture is about 2 % for cadmium and 4 % for lead. Moreover, the metal content of the superior parts is much more important than in the absence of amendment (5 and 8 % respectively for Cd and Pb). Samplings of ground were besides realized and prepared in order to observe root / soils contacts by ESEM. To investigate the impact of amendment on the behaviour of metals contained in the sediment, element mappings were made on polished sections (Fig 1).

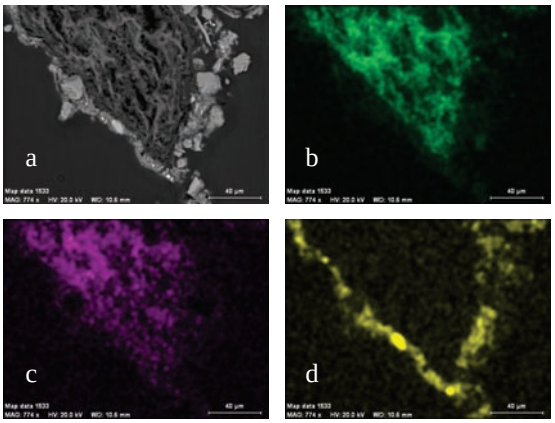

Fig. 1: SEM-BSE observation (a) and elementary mapping (b: Ca, c: Zn, d: Pb) of an A. halleri root

Observations tend to prove that the zinc diffuses and was preferencially integrated within the root. When using a stake in absence of amendment, we observe a gradient of rather weak concentration with only the presence of a zone more concentrated in periphery (pas compris). In presence of amendment, the mapping brings to light a more important concentration, with a gradual increase towards the heart of the root. A very clear enrichment in lead is set up in the outer border, whereas this element is absent in the heart of the root. Besides, the lead distribution on the edge of the root seems to be correlated to the type of substratum of culture. So in presence of amendment this border appears more continuous and thicker.

This study has permitted to show a great capacity of *A. halleri* to mobilize specifically zinc from solid phases of soil. A complementary approach will be performed in order to quantify the distribution of metal in the plant and in the neo-formed minerals.

Formation of ettringite in steel slag recycled as roadbed materials

Mikami, M.[1*], Oota, S.[1], Sato, T.[2] & Yoneda, T.[2]

Steel slag is a by-product of the steel manufacturing process and is currently reused as roadbed materials in Japan. From the results of previous experimental researches, some of steel slag could be altered and form secondary minerals such as hydrotalcite, hydrocalumite, and ettringite ($[Ca_6Al_2(OH)_{12}](SO_4)_3 \cdot 26H_2O$) by interaction with water. Among the secondary mineral phases, hydrotalcite and hydrocalumite have a much amount of anion exchangeable capacity due to the isomorphic substitution of Mg for Al and Ca for Al, respectively. However, the selectivity of anion sorption depends on the chemistry of solution, especially the concentration of competitive anions. On the other hand, ettringite can incorporate some oxyanions such as sulphate anion into the structure, even though ettringite also have anion sorption capacity on the surface. Once some oxyanions incorporated into the structure, the oxyanions can stably retain in the structure until the dissolution. Thus, ettringite is important phase determining chemistry of the pore water in the roadbed steel slag.

In this context, this study investigated the formation of secondary minerals in the mixed steel slags with different mixing ratios, especially ettringite. The three different kinds of slag used in this study were air cooled blast furnace slag (ACBFS), granulated blast furnace slag (GBFS) and basic oxygen furnace slag (BOFS). Flow-through experiments were conducted to calculate the dissolution rates of different ions and the formation of various secondary minerals were evaluated.

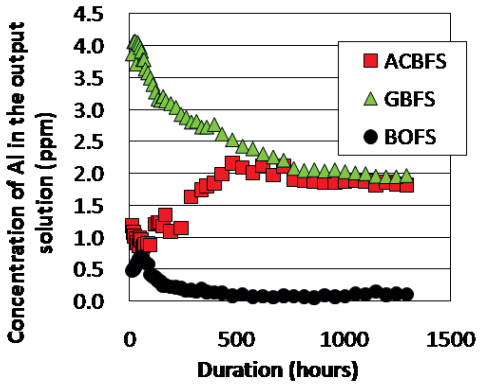

Fig. 1: Al concentration of the output solution obtained from flow-through experiments for the three different kinds of slag.

The results of the flow-through experiments showed that the concentration of Al and SO_4^{2-} at initial state in GBFS and ACBFS were significantly higher compred to other type of slag. Batch experiments were also conducted in relation to particle size, temperature, liquid/solid ratio and blend ratio. The results from batch experiments indicated that ettringite was detected only in coarse samples and large blend ratio of ACBFS samples. Additionally, ettringite was not observed when GBFS blend ratio was 0%. In the case of coarse samples, it is expected that soluble parts (dissolution at initial state) were concentrated on the surface of particle. The overall results of this study confirmed that the formation of ettringite is mainly controlled by the concentration of Al and SO_4^{2-} from GBFS and ACBFS at initial state, respectively. Thus, formation of the secondary minerals can be controlled by mixing ratio of the slag for release control of the anions, although the mixing ratio should be selected with consideration of physical behaviour of the slag used as roadbed materials.

Alteration and hazardous anions behavior of steel slag used as roadbed materials

The steel slag which is a by-product from iron manufacturing processes has been utilized as recycle materials since it has low impact on the environment. In Japan, the fluorine emission standard recently gives rise to regulations at 0.8 mg/L. Therefore, the use of fluorite (CaF_2) as a fusion agent in the refining process causes a great environmental concern. In the previous research, however, the results showed that some of steel slag could easily generate anion absorbents such as hydrotalcite and CSH by interaction with water in the laboratory experiments. Therefore, the fluorine in the steel slag which is currently used as roadbed materials and cement admixture would be expected to retain in the secondary mineral phases.

In this context, the aim of the study is to confirm the alteration and hazardous anions behavior (especially fluorine) of the steel slag which was used as roadbed materials. Moreover, this study aims to propose a construction method of steel slag based on the data obtained from the analyses of field site. To understand alteration and hazardous anions behavior, different combination ratios of Air-cooled blast furnace slag (ACBFS), Granulated blast furnace slag (GBFS), Basic oxygen furnace slag (BOFS) and durations were examined and the samples were analysed by using XRD, XRF, SEM-EDX and X-ray CT analyses. Leaching test of fluorine was also conducted. To evaluate the alteration behavior of each three types slag, flow-through and batch experiments were also carried out with the same types of steel slag used as roadbed materials. The results of flow-through and batch experiment as well as the behavior of hazardous anions were modeled to duplicate the dissolution and alteration process in slag by using REACT program in The Geochemist's Workbench-professional software.

Ten samples of roadbed materials using a combination of three kinds of steel slag (ACBFS, GBFS and BOFS) were collected from six different sites in order to compare the difference of combination ratios and durations. Samples of three types of slag used before as roadbed materials (ACBFS, GBFS, BOFS) were also collected.

The results of XRD analyses showed that the secondary minerals such as ettringite, hydrotalcite and hydrocalumite which have anion adsorption properties were actually generated in the slag samples. The differentiation of these minerals phases could be dependent on the various initial combination ratios of slag. SEM-EDX analyses showed the high concentration of fluorine was observed at the same point where magnesium content was rich. This result suggests that fluorine could be associated with the secondary minerals generated during the alteration of GBFS. The results of the leaching test also revealed that the highest concentration of fluorine was observed in GBFS (100% after construction sample) in which hydrotalcite, hydrocalumite and CSH were observed. Moreover, the results of flow-through experiment showed that the behavior in the dissolution of different elements were dependent on each type of slag. The difference in the generation of secondary minerals in these experiments may be attributed to the different of reactions in each slag.

Lastly, the geochemical modeling was able to simulate generally the result of batch experiment. However, there is a need to consider more several thermodynamic data to improve the fit and further determine the better combination ratio of steel slag to provide better results in fluorine leaching inhibition.

Persistence and bioaccumulation of heavy metals around an ancient mine site at Gromo-Gandellino (Valseriana, Northern Italy)

Porro, S.*, De Capitani, L. & Grieco, G.
Dipto. di Scienze della Terra "Ardito Desio", Milano University, Milan, Italy (*Silvia.Porro@unimi.it)

The land surface is altered by mining activities and mine dumps often become sources of pollution. Near Gromo and Gandellino villages, on both sides of the Valseriana in the Central Orobic Alps (Bergamo, Italy), several signs of historical mining activities are present. Since XIth century these mines, exploited specifically for Fe and Ag, played an important role for the economic development of the valley. The deposits, whose ore mineralogy is dominated by sulphides, sulphosalts and carbonates were intensely exploited in the Middle Ages and abandoned in the early decades of XXth century. The ore mineralization, represented by a complex and polyphase association of sulphides and sulphosalts containing Cu, Fe, Zn, Pb, Co, Ni, Ag, Sb, As with dominant chalcopyrite and tetrahedrite, is hosted in quartz breccia bodies that crop out along contacts between South Alpine basement and Permo-Triassic cover rocks.

Mining activities generated a large amount of waste rock dumps located close to villages. Three dumps (Coren del Cucì, Pradel and Vedriol) were investigated in details: an amount of 75 earth samples were collected from 15 to 40 cm depth and the fraction < 2 cm was separated for subsequent pH and geochemical analyses. Representative quantities of aerial parts and roots of two plant species that grow over the dumps, *Calluna vulgaris* (15 samples) and *Dryopteris filix-mas* (20 samples), were collected in the same soil sampling places. Trace-element concentrations (Pb, Zn, Co, Ni, Ag, Cu, Cd and As) in both earth and plant samples were determined by ICP-AES. Bioaccumulation Factor (BF) and Traslocation Factor (TF) were calculated for plants data set.

In earth materials all elements reach high level concentrations: if only averages are considered, Zn and Pb exceed 3500 and 3000 mg kg^{-1} respectively, while As reaches 860 mg kg^{-1}. The three sites show different element associations. High metal concentration values were founded also in soils far from dumps, upholding the presence of an anomalous area that must be carefully controlled and monitored for its potential geochemical risk. Data set elaboration led to establish that elements are in conditions of geochemical immobility and several accumulations are mainly related to morphological factors.

C. vulgaris shows several BF values >1 displaying an evident tendency to accumulate metals, especially in roots. In aerial parts BF value for Cd reaches 2.90. Ranges of TF values uphold the behaviour of this species as a metal bio-accumulator, when present around mine sites [1]. In *D. filix-mas* metal concentrations are like to baseline values for plants that grow over not contaminated soils and slightly exceed toxic levels [2] only for As and Pb. BF values are low and < 1 for all elements. Evaluation of trace-element concentrations shows that these two species are not hyperaccumulators; however they are interesting for soil stabilization and could be used to re-establish a vegetative cover at sites where natural vegetation is scarce due to high metal concentrations, such as contaminated habitats. Especially *C. vulgaris* is able to grow on acid, ore-characterized and nutrients-poor substrates by employing a metal exclusion-strategy and could be used for contaminated land phytostabilization.

Ab initio investigation of actinide incorporation in Ti, Zr, Hf, and Sn-containing garnet crystals

Rak, Zs.*, Ewing, R.C. & Becker, U.
Dept. of Geological Sciences, University of Michigan, Ann Arbor, MI, USA (*rakzsolt@umich.edu)

Garnets, with general formula $A_3B_2X_3O_{12}$, have recently been investigated as a potential candidate for actinide-bearing host matrices [1-3]. Due to the presence of the three different cation sites (A, B, and X) various elements can be incorporated into the structure. This not only gives rise to a significant range of elemental compositions, but also opens up the possibility of synthesizing artificial actinide-bearing phases with garnet structure. Present efforts are focused on structures that are derivatives of the fluorite structure, e.g., pyrochlore [1-4]. Garnet crystals with high level of Zr and Ti have been found in nature, and their synthetic analogues have been investigated experimentally as nuclear waste form materials [4]. In order to understand the capability of garnet crystals to incorporate actinides, it is crucial to obtain a basic theoretical understanding of the bonding and electronic structure of the materials.

We have investigated the crystal structure, nature of interatomic bonding, and electronic structure of $Ca_3(Ti, Zr, Hf, Sn)_2Fe_2SiO_{12}$ garnet, using first-principles calculations within the density functional theory (DFT). The calculated equilibrium lattice parameters and the interatomic distances are close to the available experimental values, with a slight overestimation of bond lengths due to the generalized gradient approximation (GGA) used in our calculations. The incorporation of actinides has been simulated by substituting different cation sites with uranium. The theoretical total density of states (DOS) and its projections onto the atomic orbitals are presented and analyzed for different values of the on-site Coulomb interaction (Hubbard *U*) within the Fe *d* states. In order to quantify the strength of the interatomic bonds, we have performed Bader analysis of the charge density. The results of this analysis provide insight into the relative radiation resistance of the garnet crystals as a function of composition.
