The potential of palygorskite to synthesise organoclays is less explored as compared to bentonite and montmorillonite. As palygorskite is a 2:1 type clay mineral having moderately high negative structural charge, it can be modified with cationic organic surfactant [1]. Palygorskite has high surface area and it is non-swelling in nature. Also, organopalygorskites supposed to be more permeable than bentonite based organoclays when used to remediate environmental contaminants through a permeable barrier.

We synthesised organoclays from palygorskite using cetylpyridinium chloride. The cation exchange capacity (CEC) of the palygorskite was 17.0 cmol (p+) kg-1. For organic modification, we used surfactant doses equivalent to 100% (CP1) and 200% (CP2) CEC of the palygorskite. We conducted FTIR studies to prove successful organic modification of the palygorskite.

We studied the kinetics of *p*-nitrophenol (PNP) adsorption on to the synthesised organopalygorskites (adsorbent dose 10 g L^{-1}; PNP concentration 3.59 mM L^{-1}; agitation time 2 h; pH = 4.8; temperature 23^0C) and compared various kinetic models by fitting the kinetic data into them. Table 1 shows the goodness of fit of various kinetic models for PNP adsorption onto CP1 and CP2.

Table 1: Kinetic models fitting parameters for PNP adsorption on to the organopalygorskites

Kinetic model	CP1			CP2		
	R^2	F	p	R^2	F	p
Pseudo second	1.0	302049	<0.0001	0.9998	47298	<0.0001
Pseudo first	0.9443	119	<0.0001	0.9246	86	<0.0001
Elovich equation	0.9098	81	<0.0001	0.948	146	<0.0001
Power function	0.9094	80	<0.0001	0.9456	139	<0.0001
Parabolic diffusion	0.7593	25	0.001	0.8185	36	0.0003
Second order	0.5566	10	0.0132	0.6565	15	0.0045
First order	0.5544	10	0.0135	0.6440	14	0.0052
Zero order	0.5521	10	0.0138	0.6309	14	0.0061

We demonstrate in this study that the adsorption of PNP on to the organopalygorskites is best explained by the pseudo second order kinetic model. The best fitness of pseudo second order kinetic model confirms that chemical adsorption, rather than physical adsorption, controls the adsorption rate over the whole range of PNP concentrations [2]. The maximum amounts of PNP adsorption calculated from the pseudo second order model are 0.12 and 0.18 mM g^{-1}, respectively for CP1 and CP2. Therefore, the adsorption process and adsorption rate of PNP on organopalygorskites depend on the surfactant concentration at their surface. This study will be helpful to design palygorskite based organoclay adsorbents for remediating ionisable organic contaminants in the environment.

Use of silico-manganese slag for the production of industrial aggregate

Žigovečki Gobac, Ž.[1*], Oršulić, D.[2], Mladenovič, A.[3], Jadrijević, A.[2], Kampić, Š.[1] & Bermanec, V.[1]
[1]Inst. of Mineralogy and Petrology, Faculty of Science, University of Zagreb, Croatia ([*]zeljkaz@geol.pmf.hr)
[2]CSS d.o.o., Zagreb, Croatia
[3]Slovenian National Building and Civil Engineering Institute, Ljubljana, Slovenia

Silico-manganese slag is an industrial by-product of manganese production in the former TEF factory, Šibenik, Croatia. The crushing and separation facility has been used to produce industrial aggregate fractions. Test samples were taken from stockpiles of the slag and crushed aggregate fractions deposited in the Crnica area, near Šibenik.

Analyses of the mineralogical, chemical, radiological, physical and mechanical properties of the manufactured aggregate were performed in order to determine the composition, possible use in civil engineering, and potentially hazardous effect on the environment.

The samples of silico-manganese slag were investigated using X-ray powder diffraction, scanning electron microscopy (associated with an energy dispersive spectrometer), gamma spectrometry and leaching tests.

Silico-manganese slag contains a silicate glassy phase with various micro- to nano-crystalline phases, which originated in the reaction with the melt or in subsequent crystallization. These crystalline artificial/synthetic phases include akermanite, pyroxene, cristobalite and ramsdellite, which are the equivalents of minerals originating in high-temperature contact metamorphic areas or in basic volcanic rocks. Nodules or grains of silico-manganese alloy are also identified in the glassy matrix (Fig. 1).

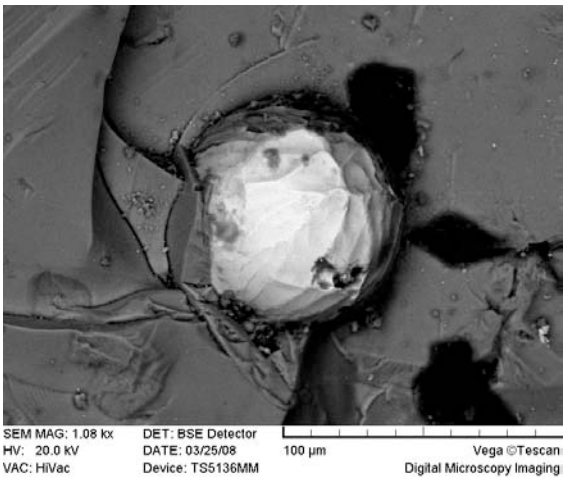

Fig. 1: A ferro-silico-manganese nodule (cca. 60 µm in diameter) in a glassy matrix.

The potentially hazardous properties of slag may be due to radioactivity or from the release of heavy metals. Tests of radioactivity showed that aggregate is not, globally, dangerous, and tests on the leaching of heavy metals gave values lower than the maximum permitted values.

The results of all the tests performed show that the aggregate can be used for the production of asphalt and concrete, according to the EU standards. This provides a good example of converting waste material from the ferroalloy industry into secondary raw material, as has been described earlier [1].

Isotopes and predicting the long-term behaviour of high-level nuclear waste

Fayek, M.
Dept. of Geological Sciences, University of Manitoba, Winnipeg, MB, Canada (fayek@cc.umanitoba.ca)

A main criterion for performance assessment of a potential high-level nuclear waste (HLNW) repository is predicting the fate of HLNW. For example, most geologic disposal concepts require that the spent nuclear fuel (SNF) remain isolated from the accessible environment for more than 100 000 years (i.e., the time required for the fission and actinide products to reach safe levels [1]). Therefore, one of the most challenging aspects of nuclear waste management is the extrapolation of laboratory data, collected over short periods of time (hours to years) to longer periods required in performance assessment calculations [2]. Most studies that attempt to predict the behavior of HLNW under repository conditions are based on models which, when unconstrained by data, often produce ambiguous results. Therefore, researchers have studied natural analogues and characterized the fluid history of potential repository sites to provide data on the long-term performance of radioactive waste forms and assess a potential repository site.

Geochronology and stable isotope geochemistry are techniques well suited for investigating potential sites and the study of natural analogues. Hydrogen and oxygen isotopes can provide information on the origin of water that has interacted with minerals along fractures and analogous material to SNF such as uraninite. Variations in stable isotope contents can be related to palaeohydrological and palaeoclimatic conditions [3]. Carbon isotopic composition of dissolved carbon in pore fluids and carbonates can be used to determine the source of the carbon. Strontium and sulfur isotopes can be used to discriminate between several generations of fracture-filling minerals. Studies have shown that multiple mineralizing events represent migration of fluids ranging from high-temperature hydrothermal systems to present-day groundwater circulation [4].

U-Pb and U-series geochronology can be used to constrain the chronology of minerals that form along fast diffusion pathways (e.g., fractures [5]), and provide a record of geologically significant fluid or thermal events that may have affected the repository site. Geochronology of uraninite from several deposits that are considered natural analogues for SNF (e.g., Cigar L., Nopal I, Oklo) has shown that fluid events related to large-scale tectonic and paleoclimatic events can cause radionuclide migration in near surface environments [6]. *In situ* isotopic micro-analysis of zoned minerals with a spatial resolution on the scale of a few μm can provide information at the forefront of scientific research. For example, U-Th-Pb isotope studies of Quaternary opal occurring in calcite–silica fracture and cavity coatings within Tertiary tuffs at Yucca Mountain preserve a record of paleohydrologic conditions [5].

The age of groundwater is also a key factor for performance assessment of HLNW disposal in deep geological formations. Radiogenic noble gases (He, Ar, Xe) and Cl isotopes can in some circumstances provide age information due to their inertness, their well-known sources and their increase in concentration with time [7]. The age of the water table can be used to assess the rate of recharge and whether the water table may someday engulf the repository.

Potential of radiation-induced defects in clay minerals to trace past uranium transfers in the Athabasca Basin (Canada)

Morichon, E.[1,2], Allard, T.[1*], Beaufort, D.[2] & Quirt, D.[3]
[1]IMPMC, UMR, Paris, France
([*]thierry.allard@impmc.jussieu.fr)
[2]Hydrasa, University of Poitiers, France
[3]AREVA Resources Canada Inc., Saskatoon, Canada

Defects produced by radiations in the structure of clay minerals such as kaolinite have been used to reconstruct past migrations of uranium in the geosphere [1]. They may also be helpful for prospection. This study presents the first unequivocal identification of radiation-induced defects in proterozoic kaolinite, illite and sudoite (di-trioctahedral Al-Mg chlorite) from the alteration halo surrounding the unconformity-type uranium deposits in the Athabasca basin (Canada), using Electron Paramagnetic Resonance spectroscopy. In all samples originating from 25 drill holes, defects of the clay minerals are similar and consist in electron holes on oxygen atoms of the structure. Defects in illite and sudoite are thus new potential tracers of ancient radioactivity. The concentrations of defects can widely vary from the regional background to several orders of magnitude. The maximum of fluctuations of defects concentrations is observed at the level of the unconformity between upper sandstones and underlying basement rocks and associated crosscutting brittle structures, which appears as the main vector of U-bearing fluids transfer in the basin. A somewhat scattered pattern of defect concentrations decreasing from unconfomity levels towards the barren rock is observed without correlation with the present dose rate produced by the radioelements (U, Th decay chains and ^{40}K). More specifically, concentrations of defects can vary significantly for a same dose rate. These observations are strong indications of past migrations of radioelements in the studied system that occurred after the clay mineral formation. Moreover, the proximity of mineralization can be revealed through defects that recorded past presence of radioelements in the altered rocks at significant distance from the mineralized bodies, an interesting perspective for prospection.

Coupled substitution of neptunium (V) and iodate into a uranyl phosphate: implications for mitigating the release of ^{237}Np and ^{129}I in repositories

Wu, Shijun[1,2], Chen, Fanrong[1], Simonetti, A.[2] & Albrecht-Schmitt, T.E.[2*]
[1]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, Guangdong, China
[2]Dept. of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, Indiana, USA ([*]talbrec1@nd.edu)

The simultaneous incorporation of IO_3^- and NpO_2^+ into $Ba_3(UO_2)_2(HPO_4)_2(PO_4)_2$ (BaUP), which serves as a model for uranyl alteration phases, was investigated. LA-ICP-MS data demonstrate that the incorporation of both of these species is significantly enhanced when they are present together. The most probable explanation is that charge balance is obtained by the coupled substitutions of $NpO_2^+ \leftrightarrow UO_2^{2+}$ and $IO_3^- \leftrightarrow HPO_4^{2-}$. In the absence of iodate as much as 2.91±0.14% to 3.44±0.25% of the uranium in BaUP can be replaced by neptunium. When iodate is present in the reaction, the uranium substituted by neptunium was as high as 6.05±0.65% to 7.93±0.83%. The net increase for neptunium is 116±0.30% to 225±0.25%. Similarly, in the absence of NpO_2^+, iodate incorporation into BaUP reaches an I/U level of 0.0021±0.0004 to 0.0038±0.0005; whereas in its presence there is a as much as 100±0.11% increase to 0.0042±0.00100. Some H_2O should be substituted for HPO_4^{2-} to get charge balance because of the high Np level (Fig. 1).

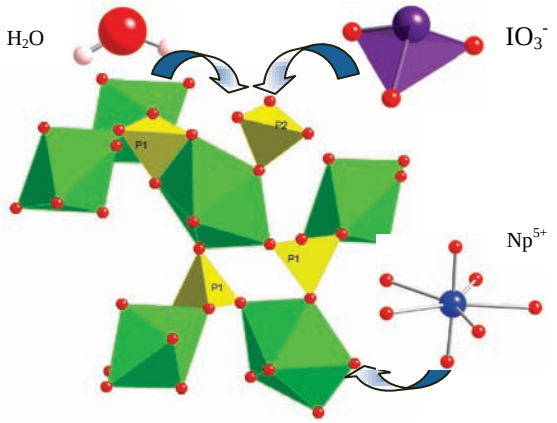

Fig. 1: An illustration of the substitution of IO_3^-, NpO_2^+ and H_2O in BaUP.

The radionuclides within the waste form, such as ^{137}Cs, ^{235}U, ^{237}Np, ^{239}Pu, ^{79}Se, ^{99}Tc, ^{129}I, can be divided into cations and anions. In the previous studies, the retardation of cationic and anionic radionuclides was investigated separately though they exist together in the waste form [1-3]. Since coupled substitution of $NpO_2^+ \leftrightarrow UO_2^{2+}$ and $IO_3^- \leftrightarrow HPO_4^{2-}$ is observed in BaUP, it provides an enhanced mechanism for mitigating the release of ^{129}I and ^{237}Np from a nuclear waste repository. Similar phenomena for coupled substitution are expected to occur in other uranyl phases, such as uranyl silicates and carbonates. Furthermore, coupled substitution of other cationic and anionic radionuclides is also expected.

Structural investigations of minor actinide-bearing fuels

Vespa, M.[*], Rini, M. & Somers, J.
Institute for Transuranium Elements, European Commission, Joint Research Centre, Karlsruhe, Germany
([*]Marika.VESPA@ec.europa.eu)

Fast reactors (e.g. as outlined in the Gen IV initiative and in the Sustainable Nuclear Energy Technology Platform (SNETP)) provide a means by which nuclear energy sustainability is ensured. Furthermore, they make a positive step forward in the destruction of the minor actinide (MA) waste that they produce. Novel nuclear fuels will be needed and, in a likely first step, they should be based on actinides-U mixed oxides. Fuel development is a lengthy process, and little is known about MA-bearing fuels, which needs to be treated through experimental and theoretical approaches at the molecular level.

The Strategic Research Agenda (SRA) of the SNETP (www.snetp.eu) clearly indicates the need to establish fundamental properties and irradiation behaviour of these new and largely untested materials. Nuclear fuel research is facing a paradigm shift from "Observe and Validate" towards "Design and Control" and is being driven by advances in multiscale modelling, and in particular ab initio calculations and molecular dynamics. Though tremendous advances have been made in these areas, there is a clear need for validation by experiments. Local structure investigation, by means of X-ray absorption spectroscopy (EXAFS and XANES), is one method poised to make important contribution towards the validation of such codes. An important fuel parameter, which has to be taken into consideration, is the oxygen potential and the corresponding O/M (oxygen to metal) ratio of the Am containing-mixed oxides. Since the O/M will increase during the irradiation time, an increase in the oxygen potential may limit the fuel burn-up due to possible fuel-cladding interactions. During this process Am is expected to be reduced to its trivalent state, a requirement to limit cladding oxidation. Consequently, the thermal conductivity should decrease due to the defects and distortion in the cubic structure [1-4].

In this study (U, Am)O_2 samples with different O/M, have been prepared and investigated at the beamline for radioactive materials (INE-beamline) at the ANKA-synchrotron light source. EXAFS measurements were performed on the U- and Am-L_{III} edges. These first measurements demonstrated the feasibility of analysing highly radioactive materials (7.93×10^8 Bq/g), and will aid in developing and improving future nuclear fuels.

In the next steps, it is planned to complement the EXAFS investigations with magic angle spinning nuclear magnetic resonance (MAS NMR) measurements. The combination of these spectroscopic methods will lead to an accurate determination of the coordination number and bond length change within the structure, and the evolution thereof as the sample undergoes self irradiation damage.

Mineral matrix material development for immobilization of REE radionuclides and actinoids

Kovalskii, A.M[*], Suvorova, V.A., Kotelnikov, A.R. & Akhmedshanova, G.M.
Institute of Experimental Mineralogy of Russian Academy of Sciences, Chernogolovka, Russia ([*]kovalsky@iem.ac.ru)

For synthesis of ceramics on the basis of titanates, zirconates and complex phosphates with the purpose immobilization of REE radionuclides and actinoids techniques of hot pressing and pirosynthesis [1] are used. These methods allow obtaining high-leaching stability matrix materials, however technology of that maintain are complex enough. In this work the method of synthesis of matrix materials is based on metasomatic replacement reactions under the scheme of "wet process" [2]. The method allows spending process of radionuclides sorption on phosphate-containing mineral compositions at room temperature and atmospheric pressure in wet conditions

Synthesis of phosphates of strontium and cerium were carried out, as well as synthesis of mineral matrixes on the basis of (Sr, Na) - and (Ce, Na) – phosphates. Products of experiments were investigated by an X-ray method; for an estimation of compositions of the synthesized solid phases on the elements maintenance, the method local X-ray microanalysis was applied. The analysis of a filtrate on the strontium maintenance carried out by a method AAS spectroscopy on devices AAS-1N, cerium – by a method photocolorimetry on the device "Spekol 11".

Deficiency of solutions of nitrate Sr or Ce leads to formation in a column of the minerals allied substances to natural minerals olgite $NaSrPO_4$ or vitusite $Na_3Ce(PO_4)_2$. These minerals are met in hydrothermal changed rocks of Lovozero and Khibina alkaline massifs, Kola Peninsula and have shown high stability to leaching as the age of these massif formations exceeds 360 million years. So those minerals can serve as matrix materials in spite of the fact that the maintenance of strontium and cerium in them is essential less, than in simple orthophosphates.

Simple orthophosphates of Sr and Ce were synthesized at use of super quantities of nitrates solutions. For decrease in temperature of sintering of matrixes with the purpose of their density increase, instead of separate grains feldspar and quartz, as initial has been used leucocratic granite of Spokojninskoe deposit. As a result of experiences on metasomatic replacement, the subsequent drying and calcinations, the polymineral ceramic compositions consisting of feldspar, quartz and phosphates of strontium in two experiences and cerium in one experience have been received.

Strontium ortophosphate is analogue of apatite, and phosphate of cerium – of monazite, enough widespread accessory mineral of granites, its high stability to processes leaching is shown in work [1]. The granite matrix serves as an additional barrier to leaching elements processes by hydrothermal solutions.

Local and medium range order around fission products: implication for structural control of the stability of nuclear waste glasses

Galoisy, L.[1*], Calas, G.[1], Cormier, L.[1], Jollivet, P.[2], Delaye, J.-M.[2], Gin, S.[2] & Ghaleb, D.[2]
[1]Institut de Minéralogie et de Physique des Milieux Condensés, Universités de Paris 6&7, IPGP and CNRS, Paris, France ([*]Laurence.galoisy@impmc.upmc.fr)
[2]CEA, Laboratoire du Comportement à Long Terme, Centre de Valrho, Marcoule, France

Vitrification of liquid high-level radioactive waste in borosilicate glasses has received a great attention in several countries. As for other waste forms, their fundamental properties are their chemical and mechanical durability.

In a first part, we will present an overview of the local structure around some elements such as Zn, Mo, Fe or Zr, in a borosilicate glass (SON68) taken as an inactive analogue of the French nuclear glass (R7T7). Due to the complex composition of these glasses (up to 30 oxides), chemically selective methods are required to understand the environment of these elements. Structural information was obtained by a combination of X-ray Absorption Spectroscopy (XAS) and Wide Angle X-ray Scattering (WAXS) to probe local and medium range order, respectively. Eventually, XAS was used to study the interaction between noble metals (Pd and Ru) and the glassy matrix. These elements are at the origin of small precipitates that induce changes in melt viscosity. These structural data were compared with MD calculations on simplified glass compositions.

Assessing the long-term behavior of nuclear glasses implies the prediction of their long-term performance during interaction with water or under irradiation. In the second part, we will present some structural features of the evolution of the glass under these forcing conditions. The protective character of the gel, observed during alteration in near- or under-saturated conditions will be rationalized by its structural properties.

These structural modifications may explain the chemical dependence of the initial alteration rate and the transition to the residual regime. They also illustrate the molecular-scale origin of the processes at the origin of the glass-to-gel transformation. During external irradiation, there is direct evidence of a coordination change of B at the glass surface. In addition, for a better understanding of the modification of glass structure under irradiation by heavy ions, complementary information is provided by molecular dynamics simulations, showing a combination of elastic and inelastic effects. These two processes are suspected to produce a modification of different physical properties of nuclear glasses during irradiation.

Uranium speciation in opals from the Nopal I deposit (Sierra Peña Blanca, Mexico): a SEM, TEM and TRLFS study

Othmane, G.[1*], Allard, T.[1], Menguy, N.[1], Vercouter, T.[2], Morin, G.[1], Galoisy, L.[1], Calas, G.[1] & Fayek, M.[3]
[1]Institut de Minéralogie et de Physique des Milieux Condensés, CNRS UMR 7590, UPMC, Paris, France
([*]Guillaume.Othmane@impmc.upmc.fr)
[2]LSRM, CEA Saclay, Gif-sur-Yvette, France
[3]University of Manitoba, Winnipeg, Manitoba, Canada

The study of uranium migration and trapping in the environment is relevant to estimate the safety of high-level nuclear waste repositories (HLNWR). With this aim in view, the analysis of speciation in natural analogues of HLNWR can be used to determine the conditions of uranium sequestration.

The Nopal I uranium deposit (Sierra Peña Blanca, Mexico) is a natural analogue located in volcanic tuff. The primary uranium mineralisation occurred in a breccia zone and consisted in uraninite, subsequently altered in secondary uranium minerals. During a last episod, opal was formed and coated uranyl silicates such as uranophane and weeksite [1,2].

The aim of this study is to determine the uranium speciation in these opals from the millimeter-micrometer scale of electron microscopies to the atomic or molecular scale provided by spectroscopy. Three samples of green or yellow opals have been analysed by scanning electron microscopy (SEM) on cross-section embedded in resin and by transmission electron microscopy (TEM) on a focused ion beam (FIB) section.

The first results mainly show:

1) uraniferous opal with a Ca:U atomic ratio of 1:1 showing spherical growth-features (Fig.1).

2) the complex association of uranium-bearing species like uranophane and calcium phosphates.

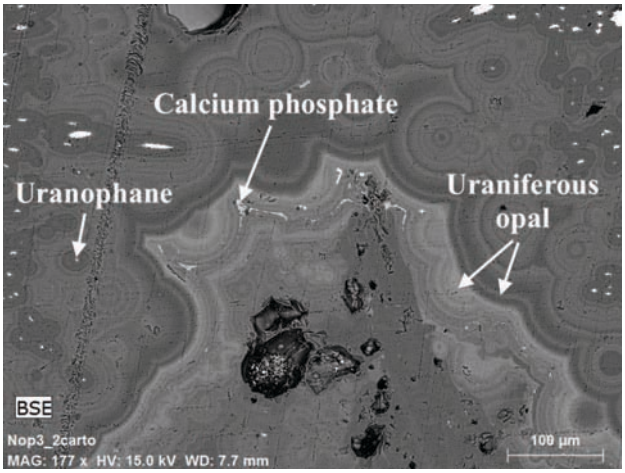

Fig. 1: SEM back-scattered electron picture of a yellow opal cross-section from the Nopal I uranium deposit, Mexico.

In addition, a combination of TEM observations in the uraniferous opal and time-resolved laser fluorescence spectroscopy (TRLFS), a well-suited technique to coordination chemistry of uranyl complexes [3], will be shown. These observations will help revealing the speciation of uranium occurring either as embedded complexes or uranium-bearing nanophases in the opal.

Uranium nanoparticles: synthesis, structures, compositions and aggregation

Burns, P.C.[*], Ling, J., Sigmon, G.E., Unruh, D.K. & Forbes, T.Z.
Dept of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN, USA ([*]pburns@nd.edu)

The structural and compositional details of approximately thirty nano-scale clusters containing uranium will be examined. All of these clusters are built from uranyl peroxide polyhedra and some also include pyrophosphate or oxalate units. Their topologies are highly varied, incorporating combinations of squares, pentagons and hexagons. Many of these clusters are highly soluble in water, and small-angle X-ray scattering (SAXS) data has demonstrated that these clusters persist when dissolved in ultrapure water. Aggregation of such clusters into colloidal materials is readily triggered by addition of cations, as demonstrated by SAXS data. The ramifications of such cluster formation on the performance of nuclear waste forms will be examined.

Selenite reduction by green rust

Nedel, S.*, Skovbjerg, L.L., Christiansen, B.C., Bovet, N. & Stipp, S.L.S
Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Denmark (*sorin@nano.ku.dk)

Relying more on nuclear energy for production of electricity will inevitably result in an increase of spent nuclear fuel that countries need to store. As a consequence, ensuring the safety of radioactive waste repositories and improving performance assessment models of storage facilities is crucial. Se^{79}, a long-lived fission product (half-life~10^6 years), may dominate the radiation dose from high level radioactive waste and is therefore of concern when considering a radionuclide leakage scenario. Se can be rather mobile, if present as the soluble species Se(VI) and Se(IV), but is less mobile as the sparingly soluble Se(0) and Se(–II). The prevalence of one form or another can be related to the interaction with dissolved ions and minerals in the near and far field. Se(VI) and Se(IV) are known to sorb to iron oxides and to be reduced by Fe(II)-bearing minerals. GR, an Fe(II)-Fe(III) layered double hydroxide, is a redox active compound with high surface area that forms where iron concentrations are high such as during Fe(0) corrosion. The purpose of this study was to examine the interaction of Se(IV) with sodium sulphate green rust ($GR_{Na,SO4}$) and propose a mechanism for the observed processes.

$GR_{Na,SO4}$ was synthesised using typical methods such as oxidation of an Fe(II) solution. Selenium was then added to the $GR_{Na,SO4}$ suspension as selenite, $Se(IV)O_3^{2-}$ and its concentration was followed with time. In less than 12 hours, all Se was removed from solution. Transmission electron microscopy (TEM) and X-ray diffraction revealed that Se(IV) was reduced to elemental selenium while iron oxides replaced $GR_{Na,SO4}$ (Fig. 1).

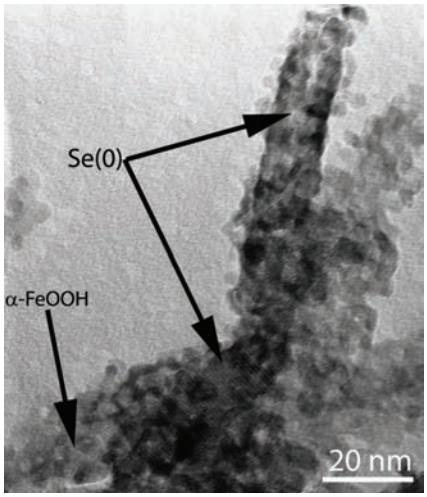

Fig. 1: TEM showing the formation of Se(0) (plates) and α-FeOOH (spheres) after $GR_{Na,SO4}$ interaction with Se(IV).

These results demonstrate that $GR_{Na,SO4}$ can decrease the mobility of Se^{79} by transforming the aqueous species into solids. The iron oxides formed during the reduction process could potentially limit even more Se migration in the soil through sorption of the remaining Se(VI) and Se(IV) .

Preliminary studies of bioreduction and biooxidation of biotite and chlorite and implications for radionuclide mobility

Kountcheva, D.R.*, Lloyd, J.R., Pattrick, R.A.D.P. & Vaughan, D.J.
School of Earth, Atmospheric and Environmental Sciences, University of Manchester, United Kingdom
(*diana.kountcheva@postgrad.manchester.ac.uk)

As part of a larger study of radionuclide mobility in the subsurface, interactions between pure cultures of the model Fe(III) reducing bacterium *Shewanella oneidensis* MR1 and the iron-containing phases biotite and chlorite have been investigated in the presence (and absence) of Cs and Sr as proxies for their radioactive equivalents. Biotite and chlorite are recognised as key mineral phases in subsurface environments [1] with the potential to control the mobility of radionuclides. Biologically promoted redox reactions involving iron are important for the stability of these mineral phases and their interactions with radionuclides.

Time course anaerobic batch experiments have been conducted where both dissolution of the mineral and uptake of either Cs or Sr have been compared in biotic and abiotic experiments Microbial reduction of structural iron was stimulated by the addition of lactate as an electron donor, while microbial oxidation of structural iron was stimulated by addition of nitrate to act as an electron acceptor. The minerals were characterised by XRD, ESEM, Microprobe and Mössbauer spectroscopy before and after the batch experiments. Analysis of dissolved species was carried out by ICP-MS.

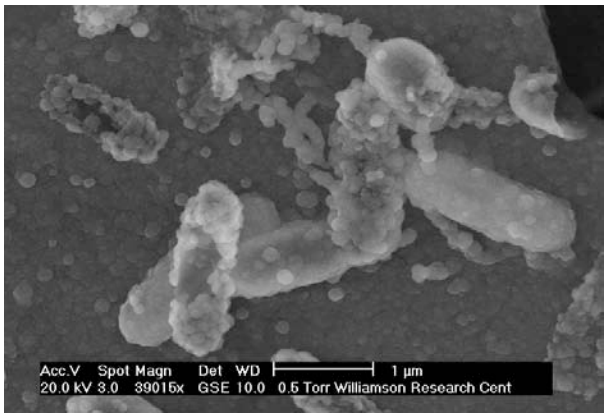

Fig. 1: ESEM image of *S. oneidensis* encrusted with secondary Fe phases formed from released Fe(II).

Bioreduction results show that microbial reduction of structural iron in biotite and chlorite is achieved and promotes mineral dissolution (releasing Si and Fe(II)) resulting in a change of reactive sites. In the presence of trace oxygen, a thin film of secondary Fe(III) oxide minerals formed at the redox interface on the liquid surface and was reduced by bacteria to form Fe-nanophases (Fig 1). The relationship between the microbes and iron minerals suggests that cell surface functional groups may act as nucleating sites. Microbially mediated mineral dissolution was not accompanied by a reduction of Cs sorption despite the likely loss of sorption sites. With the precipitation of secondary phases of iron oxy/hydroxides the sorption capacity of the system increased.

Synthesis and structural characterization of four new U^{6+} germanate compounds

Morrison, J.M., Moore-Shay, L.J. & Burns, P.C.*
Dept of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, United States (*pburns@nd.edu)

As the United States moves into a new era of nuclear energy development, interest is growing in the basic science associated with the nuclear fuel cycle. Uranium, the key element in the nuclear fuel cycle, has a storied history and a host of dynamic properties that must continue to be rigorously explored. Specifically, there is value in the study of U^{6+} crystal chemistry as the nearly linear uranyl ion, (UO_2^{2+}), complexes readily in a variety of inorganic systems within oxidizing environments [1].

Here we present the syntheses and structural characterizations of four new uranium germanate framework compounds. The crystal structure determinations of these isotypic compounds reveal three symmetrically distinct U^{6+} sites—two that are coordinated by five equatorial oxygen atoms each to form pentagonal bipyramids and one that is coordinated by six oxygen atoms to form a distorted octahedron with U-O bond lengths that do not indicate the presence of the uranyl ion.

These complex framework structures also include cation-cation interactions (CCIs), which occur when an oxygen atom of the uranyl ion acts as an equatorial oxygen atom in a neighboring U^{6+} polyhedron. As CCIs are present in fewer than 2% of U^{6+} compounds, and it is uncommon for a U^{6+} compound to occur without the uranyl ion, these compounds exhibit unusual structural connectivities and are expected to have interesting properties, while also providing direction for future studies.

Development of novel bioactive materials based on nucleation and crystal growth concept

Kokubo, T.
Dept. of Biomedical Sciences, Chubu University, Kasugai, Japan (kokubo@isc.chubu.ac.jp)

Various kinds of bone-bonding bioactive calcium phosphate ceramics have been developed and clinically used as important bone substitutes. However, they have poor mechanical strengths, and hence cannot be used under load-bearing conditions.

We attempted to prepare a composite of apatite with wollastonite which occurs in a fibrous form in nature by a process of crystallization of a glass. A glass in the system $3CaO_3{\cdot}P_2O_5$-$CaO{\cdot}SiO_2$-$MgO{\cdot}CaO_2{\cdot}SiO_2$ was crashed into fine powders, pressed into desired form and heat-treated up to 1050°C for sintering and crystallization. A glass-ceramic containing nano-sized apatite and wollastonite in a glassy matrix was obtained. It showed a higher mechanical strength than human cortical bone and high bioactivity. It was named glass-ceramic A-W and clinically used as bone substitutes in various shapes. However, its fracture toughness was lower than that of the human cortical bone [1].

During a study of the bone-bonding mechanism of glass-ceramic A-W, we found that it bonds to living bone through an apatite layer formed on its surface, and that this apatite can be reproduced even in an acellular simulated body fluid (SBF) with ion concentrations nearly equal to those of the human blood plasma. Based on these findings, it was assumed that a material able to form bonelike apatite on its surface, in SBF also forms apatite in the living body and bonds to living bone through this apatite layer.

Later it was found that even a pure titania gel forms apatite on its surface in SBF. This indicated that even Ti metal would induce apatite formation in the living body and bond to living bone through the apatite layer, if a functional group effective for apatite nucleation could be formed on its surface. Actually, Ti metal that formed a sodium titanate surface film by reaction with NaOH and subsequent heat treatments was confirmed to induce apatite formation in the living body and tightly bonded to living bone. Bioactive Ti metal prepared in this way was applied to artificial hip joints and has been clinically used in Japan since 2007. Although this treatment is not effective for inducing apatite formation on new types of Ti-Zr-Nb-Ta alloy free of cytotoxic elements, a slightly modified treatment with $CaCl_2$ solution and water applied before and after the heat treatment, respectively, is suitable for these alloys. The apatite formation on chemically treated Ti metal and its alloys was attributed to electrostatic interaction of the negatively charged metal surface with the positively charged calcium ions in the body fluid.

On the other hand, it was also shown that if acid treatment is applied to Ti metal after the NaOH treatment or without the NaOH treatment, Ti metal forms a titanium oxide film on its surface after subsequent heat treatment, and induces apatite formation on its surface in the living body to bond to bone. This apatite formation was also attributed to electrostatic interaction of the positively charged metal surface with negatively charged phosphate ions in the body fluid. Porous Ti metal with titanium oxide formed on its surface by the present method showed bone formation not only at bone defect sites but also ectopically in muscle tissue. Most recently this bioactive porous Ti metal was successfully subjected to clinical trials as a spinal fusion device [2].

New insights into acid-induced structural changes of enamel apatite the effect of sodium fluoride and artificial saliva

Mihailova, B.[1*], Wang, X.[1], Klocke, A.[2], Fittschen, U.E.A.[3], Broekaert, J.A.C.[3] & Bismayer, U.[1]
[1]Dept. of Earth Sciences, University of Hamburg, Germany ([*]boriana.mihailova@uni-hamburg.de)
[2]Dept. of Orofacial Sciences, University of California San Francisco, San Francisco, USA
[3] Dept. of Chemistry, University of Hamburg, Germany

Changes in the chemistry and structure of tooth enamel due to a non-peroxide-based home bleaching product were studied in vitro using attenuated total reflectance infrared (ATR IR) spectroscopy, Raman spectroscopy, electron probe microanalysis, flame atomic absorption spectroscopy and total reflection X-ray fluorescence [1]. The results revealed that the citric-acid-containing gel-like component of the bleaching system substantially impacts on the dental hard tissue. Within a layer at least several microns thick, the organic component of enamel is removed and remnants of the bleaching gel are embedded in the ensuing voids. Cracks and severe chemical inhomogeneities occur on the enamel surface. Within a submicron layer of enamel, the Ca--O bond strength in apatite decreases, thus enhancing calcium leakage from the bleached enamel hard tissue.

Citric acid-induced changes in the local atomic structure of enamel stored in distilled water and in artificial saliva were further studied by ATR-IR spectroscopy as well as electron-induced X-ray emission spectroscopy and scanning electron microscopy [2,3]. The protective potential of fluorine-containing reagents against citric acid-induced erosion was investigated on enamel and geological apatite treated with aqueous solutions of citric acid and sodium fluoride of different concentrations. The two solutions were applied either simultaneously or consecutively. The application of basic fluoride-containing solutions did not demonstrate a protective effect on the enamel apatite structure per se. However, the addition of NaF to citric-acid solutions leads to formation of surface CaF_2 and considerably reduces the changes in the apatite P-O-Ca framework. The CaF_2 globules deposited on the enamel surface appears to be insufficient to prevent the alteration of the apatite structure upon further exposure to acidic agents. No evidence for fluorine-induced structure recovery of enamel apatite stored in water was found, whereas the application of artificial saliva for several hours leads to partial recovering of the local structure of eroded enamel apatite. However, artificial saliva surrounding cannot stop the process of loosening and breaking of P-O--Ca atomic linkages in enamel subjected to multiple citric acid treatments.

Biocompatibility of inorganic materials utilizable for mimetic bone substitution

Šesták, J.[1*], Strnad, J.[2], Strnad, Z.[2] & Holeček, M.[1]
[1]New Technology-Research Center in the Westbohemian Region, West Bohemian University, Pilsen, Czech Republic ([*]sestak@fzu.cz)
[2]LASAK-Laboratory for Glass and Ceramics, Prague, Czech Republic

Since 1970 two material groups have been identified capable to form a mechanically stable and functional interface with bone. One group consisted of certain soda-lime-silica glasses [1-4], which are exhibiting the bone bonding ability (defined as "*the bioactivity is the characteristics of an implant material which allows it to form a bond with living tissues*"). Another material found to exhibit the bone–bonding ability [5,6] was machined titanium [7,8]. The phenomenon of attachment to bone was named osseointegration (defined as "*osseointegration represents the formation of a direct contact of a material with bone without intermediate fibrous tissue layer, when observed using light microscope*"). Apparently, surface quality [4-6] determines tissue reactions to an oral implant and its assets can be classified regarding (i) mechanical (j) topographic (roughness, porosity, fractality) and (v) chemical properties. Bio-chemical bonding is related to bioactivity, which existence, however, has often been questioned because there is not a clear evidence of separated effects of surface roughness and interfacial chemical reactions. In modern dental and spinal implantology, advanced treatment protocols (e.g. early or immediate loading) are frequently used to enable reduction of the treatment time. A shorter healing period and shorter time of unloading, entails new demands on both the primary and secondary stability of the implant. The bioactivated surface, which is rich in hydroxyl groups, in contrast to machined surface, rapidly induces adsorption of calcium and phosphate ions on contact with the ions of the blood plasma. The calcium phosphate-rich layer promotes adsorption and concentration of proteins and constitutes a suitable substrate for the first apatite structures of the bone matrix, which are synthesized by the osteogenic cells at the beginning of the formation of the new bone tissue. The clinical study on dental implants was designed as a comparative study of two commonly used surfaces: classical machined titanium surface and bioactivated titanium surface (LASAK©). The bio-surface is created by sand-blasting, acid etching and a final treatment in an alkaline solution andexhibits more favorable values of the major surface characteristics compared to the machined surface and other commercially available implant surfaces studied so far studied, such as the resonance frequency analysis method used to measure the implant stability quotient. A more easily wettable hydrophilic bio-surface allowed the contact formation between the body environment (blood) and the complicated rough and porous structure of the implant surface, and thus contributes to cell and bio-molecule migration and adhesion.

Polarized FTIR of B type carbonate in fluorapatite

Tacker, R.C.[1*], Lawver, D.R.[1], Vance, Z.R.[2] & Douglas, N.K.[3]
[1]North Carolina Museum of Natural Sciences, Raleigh, North Carolina, USA ([*]christopher.tacker@ncdenr.gov)
[2]Dept. of Geological Sciences, University of North Carolina, Chapel Hill, North Carolina, USA
[3]Division of Earth and Ocean Sciences, Duke University, Durham, North Carolina, USA

Several substitution mechanisms have been proposed for carbonate in apatite, the details of which have importance for petrology, biomaterials and biomimetic materials. Recent FTIR research documented two B type substitutions within large natural fluorapatite crystals [1] and synthetic carbonate apatites [2]. Three hypotheses can be advanced: (A) The substitutions take place on different faces of the phosphate tetrahedron; (B) The differences in peak positions result from differing charge balance mechanisms; or (C) The differences result from a combination of hypotheses (A) and (B).

Polarized infrared spectra have been taken of oriented sections of fluorapatite with the objective of elucidating the orientation of the carbonate group within the structure. Spectra and polarization are very similar to that of francolite investigated in earlier studies [3], but with additional features resolved (Fig. 1). Hence the earlier francolite spectra likely reflect two substitutional types and not one alone.

Orientation of the two different B type absorbers is very similar, which supports hypothesis (B), that the differences in dipole transition moment are due to differences in local structure and charge balance. These substitutions would be near the O1-O2-O3 face of the substituted phosphate tetrahedron. Polarized spectra rule out the possibility that the carbonate group lies on the mirror plane [4], or near the O1-O3-O3 or O2-O3-O3 faces of the tetrahedron.

In addition, some spectra display a weak OH stretching vibration polarized parallel to the *a*-axis at about 3550 cm^{-1}. First principles calculations predict a Ca(2) vacancy charge balancing a B type substitution, leading to an OH group rotating perpendicular to its usual position [5].

Understanding biological control and environmental influence – unlocking the secrets of biomineralisation

Cusack, M.[1*], Ji, B.[1,2,3], Freer, A.[2], Yin, H.[3], Gadegaard, N.[3], Dobson, P.[3], Pérez-Huerta, A.[1] & Dalbeck, P.[1]
[1]Dept. of Geographical & Earth Sciences, University of Glasgow, UK ([*]Maggie.Cusack@ges.gla.ac.uk)
[2]Dept. of Chemistry, University of Glasgow, UK
[3]Dept. of Electronics & Electrical Engineering, University of Glasgow, UK

In the natural world of biominerals, elegant functional structures are produced from the most basic of resources. Vertebrates have skeletons made from calcium phosphate (apatite) while invertebrates tend to assemble mineral structures from silica or calcium carbonate. Although the ingredients are simple, the control of how these fundamental building blocks are put together is very much under the control of biological processes. Understanding this biological control and its rôle in the formation of biominerals has implications in a number of diverse areas and offers the possibility to exploit this high level of control to produce novel materials of pre-determined material and physical properties. We are currently exploring these processes using lab-on-a-chip (microfluidics) (Fig. 1) to investigate the complexities of the diffusion processes involved in these complex reactions [1].

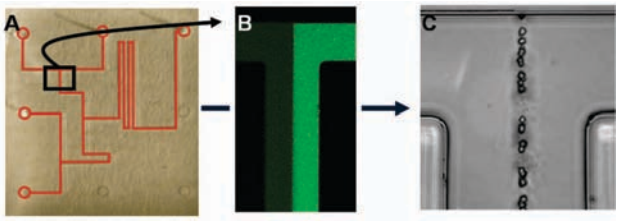

Fig. 1: Lab-on-a-chip microfluidics to screen activity of biomineral proteins. A. Channels in chip highlighted in red. B. Interface between two solutions indicated with fluorescent dye on right side to indicate lack of turbulence. C. Calcite crystals formed at interface between calcium chloride and sodium carbonate solutions. Channel width = 50 µm throughout.

From a climate proxy standpoint, understanding the biomineralisation process [2-4] will also provide a much more accurate interpretation of climate data stored within marine biominerals, e.g. brachiopods [5-7] and corals [8]. Exploring the biological control exerted in biomineral formation across several phyla provides an essential context to unravelling this environmental information.

On the way to understanding surface processes that drive biomineralisation

Bovet, N.[*], Yang, M., Javadi, M.S., Sand, K.K., Pasarín, I.S. & Stipp, S.L.S.
Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Denmark ([*]bovet@nano.ku.dk)

Calcium carbonate minerals account for almost 50% of known biogenic material. Among them is chalk, which hosts oil in reservoirs and water in aquifers. Work in our group is showing that the biogenic nature of chalk plays an important role in the behaviour of both water and oil in chalk. Despite calcite having been widely studied, a better understanding of the processes that control the calcite interface with fluids is still needed to truly understand the mechanisms of biomineralisation.

Surface sensitive techniques such as X-ray photoelectron spectroscopy (XPS), X-ray reflectivity and atomic force microscopy (AFM), together with theoretical simulation, have provided new insight into the interaction between organic molecules (such as alcohols, carboxylic acids, saccharides) and the calcite surface. We used this fundamental information for simple organic compounds to interpret interaction of more complex organic molecules (as polysaccharides and proteins) produced by organisms to control biomineral formation.

It is possible to observe direct interaction between clean surfaces and these organic molecules, as shown in Fig. 1 for ethanol sorbed on calcite, in-situ, in the XPS chamber.

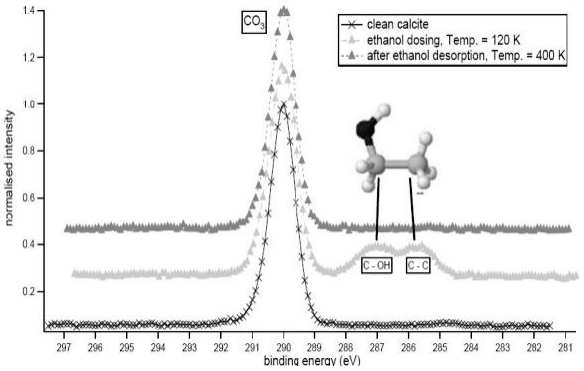

Fig. 1: X-ray photoelectron spectra of the carbon region during ethanol dosing on freshly cleaved calcite. The ethanol is present at low temperature and it desorbs at 270 K, returning the surface to its initial, unreacted state. Ethanol links through the OH end of the molecule and the CH_3 group extends into the solution. T-butanol behaves differently.

The fundamental knowledge we have gained in these studies shows that mineral surfaces structure organic molecules into distinct patterns and through them, the fluids in contact, so dissolution and precipitation are inhibited, except at specific locations.

Self-organized tubular honeycombs near weathered feldspar surfaces: perfect reactors for prebiotic chemistry

Parsons, I.[1*] & Lee, M.[2]
[1]Grant Institute of Earth Science, University of Edinburgh, UK ([*]ian.parsons@ed.ac.uk)
[2]Dept. of Geographical and Earth Sciences, University of Glasgow, UK

Parsons et al. (1998) [1] proposed that orthogonal networks of μm-diameter tunnels near the surface of weathered alkali feldspars would provide ideal protected reactors for the assembly of prebiotic molecules, and Smith et al. (1999) [2] suggested that coatings of zeolite minerals on tunnel walls, particularly organophilic zeolites related to the synthetic molecular sieve silicalite, would have catalytic properties. Branciamore et al. (2009) [3] have carried out cellular automaton simulations of how replicator communities might evolve in such a reactor.

We here review how understanding of both tunnels and of atomic structure close to weathered feldspar surfaces has developed since 1998. Tunnels develop by dissolution of strained structure around misfit dislocations on semicoherent perthite lamellae. Studies of alkali feldspars from a wide range of geological environments and ages show that the potential to develop honeycombs is a near-universal feature of plutonic alkali feldspars, from both igneous and metamorphic rocks, limited only by the relationship between bulk composition and the feldspar solvus. The existence of honeycombs in detrital feldspars in ancient sedimentary rocks has been demonstrated. Large feldspar crystals from surfaces exposed by the last glaciation show much deeper development of weathering features (>10 mm) than predicted by experimental dissolution rates. Tunnels with diameters of a few nm (nanotunnels) have developed in many feldspars by reaction with deuteric fluids during their initial cooling, and have been enlarged by weathering. The tunnels therefore taper from ~1 μm at the crystal surface to <10 nm in the interior, itself a feature favouring the assembly of long-chain organic molecules. Fluids in such tunnels will be buffered by two-feldspar–aqueous fluid phase relationships to have Na:K ratios close to sea-water (and modern extracellular fluids in mammals), suggesting that compatibility of emerging pre-biotic molecules with fluids of such compositions could have been a restriction imposed within the honeycomb without the threat of dispersion in the open ocean.

Understanding of the structure, at atomic level, of weathered feldspar surfaces has been considerably advanced by application of Focussed Ion Beam sample preparation techniques to TEM work, and of X-ray Photoemission Spectroscopy to obtain the composition of near-surface layers. Great care must be taken to avoid amorphization during sample preparation. Neither crystalline 'leached layers', preserving feldspar structure, nor amorphous layers, have been found on feldspars weathered in acid soils, although the latter have been found in material treated at pH 1 in the laboratory. Clay mineral surfaces are common. Zeolitic surface layers have not yet been found.

Attachment of biomolecules to mineral surfaces: surface speciation as a function of environmental conditions

Hazen, R.M.[1], Sverjensky, D.A.[1,2*], Klochko, K.[1], Lee, N.[1,2], Cleaves, H.J.[1], Cody, G.D.[1] & Ohara, S.[1]
[1]Geophysical Laboratory, Carnegie Institution, Washington DC, USA
[2]Dept. of Earth & Planetary Sciences, Johns Hopkins University, Baltimore MD, USA ([*]sver@jhu.edu)

Biomolecule attachment to mineral surfaces is of fundamental importance in a wide range of topics including biomineralization, adhesives, medical implants and the role of mineral-molecule interactions in the origin of life. Our studies have focussed initially on the adsorption of amino acid and nucleic acid fragments on rutile because it is a model colloidal substance that is highly insoluble and well-characterized. We have studied the adsorption of these molecules under wide ranges of environmental conditions including pH, ionic strength, and surface loading using batch adsorption and potentiometric titration methods. Modeling of the data using the extended triple-layer model indicates the importance of different modes of attachment of the molecules to the rutile surface. For example, glutamate and aspartate adsorb at low pH and low surface coverages with four points of attachment, i.e. lying down on the surface. However, at pH values of 5 to 7 they adsorb with only two points of attachment through the oxygens of the carboxylate on the side-chain, i.e. standing up. These different modes of attachment and their dependence on environmental conditions are important for understanding the potential reactivity of the adsorbed molecules in geochemical and industrial processes.

Quantification analysis of mineral content and crystallinity in bone using FTIR spectra deconvolution

Álvarez-Lloret, P.[1*], Yebra-Rodríguez, A.[2] & Rodríguez-Navarro, A.B.[1]
[1]Dept. of Mineralogy and Petrology, Faculty of Sciences, University of Granada, Spain ([*]pedalv@ugr.es)
[2]Dept. Geology, IACT Associated Unit (CSIC-UGR), University of Jaén, Jaén, Spain

Bone tissue is one of the most important biological structures in the field of biomineralization [1]. Bone is composed of an organic matrix (mainly collagen type I) and a mineral component (nanocrystalline carbonate hydroxylapatite) in proportions varying with age and location within the skeleton [2]. Mineral bone features such as crystallinity, phosphate content, carbonate content, and mineral environment may be substantially altered as a function of different remodelling/turnover mechanisms. FTIR is a well suited technique for the quantitative investigation of bone mineral content and composition providing insights into the chemistry of bone mineral deposition and organic matrix components [3].

Bones from different species were analysed (rats, chickens, partridges). The amounts of phosphate, carbonate and collagen in bone tissue were determined from the peak area absorption bands associated with phosphate, carbonate and amide groups in the FTIR spectra. Overlapping peaks were resolved using a second derivative methodology, allowing for a detailed and quantitative analysis of different molecular constituents of bone. This methodology provides the most information about the underlying peak by determining width, area, amplitude and position of each absorption band/peak. Different parameters were used to characterise bone chemical composition and crystallinity from FTIR spectra. Integrated areas of the v_1, v_3 stretching phosphate and amide I regions were calculated to determine the relative quantity of mineral present in bone tissue (degree of mineralization). The quantity of carbonate present in the apatite phase was calculated by taking the integrated areas under v_2 carbonates and v_2, v_3 stretching bands (carbonate/phosphate ratio). Crystallinity Index was also determined as the ratio of the area corresponding to one of the peaks related to highly crystallinity phosphate divided by another peak related to lower crystalline phosphate. Samples were also analyzed by X-ray diffraction to develop FTIR spectra-structure correlations (Crystallinity Index from FTIR vs. FWHM diffraction from different apatite diffraction peaks). Thermogravimetric analyses were also performed to compare the values obtained from different FTIR parameters related to carbonate and mineral content.

This study demonstrates the capabilities of combining second-derivative spectroscopy and curve-fitting of FTIR spectra in the analysis of mineral content and crystallinity in bone. In addition, FTIR spectra allow quantifying the amount of different components (mineral and organic matrix) of such a complex material as is bone.

Crystal growth patterns in foliated aragonite of monoplacophorans (Mollusca)

Checa, A.G.[1], Sanchez-Navas, A.[2] & Rodriguez-Navarro, A.B.[2*]
[1]Dpto. Estratigrafía y Paleontología, Universidad de Granada, Granada, Spain
[2]Dpto. Mineralogía y Petrología, Universidad de Granada, Granada, Spain ([*]anava@ugr.es)

Crystal growth features of the foliated aragonite from two species (Micropilina arntzi and Rokopella euglypta) of the rare monoplacophoran mollusks have been analyzed in detail by SEM and EBSD. These analyses show the occurrence of a discrete number of constant angular relationships between the aragonite crystals which is explained by twin laws and different epitaxial relations. Additionally, the morphology of the crystals of the foliated aragonite is unique and very different to that found in inorganic aragonite, which usually precipitates as prisms or fibres elongated along the ***c*** axis. In contrast, in foliated aragonite, growth along the ***c*** axis is restricted and lath-like crystals elongated along the ***a***-axis form. The occurrence of these unusual morphologies is explained by different structural factors and the action of specific organic matrix components [1].

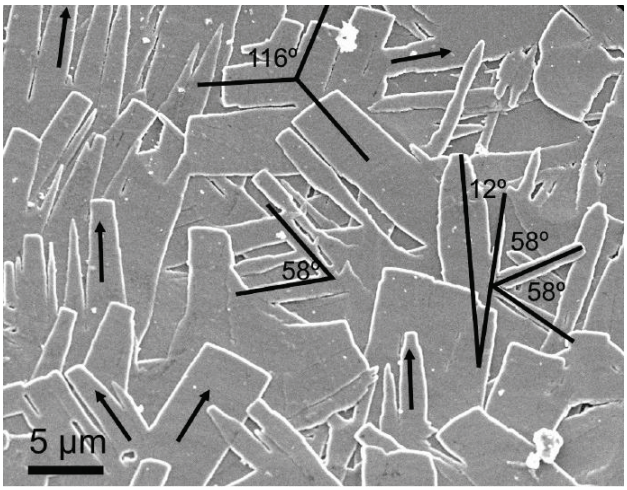

Fig. 1: Secondary electron images of the shell interiors of Micropilina arntzi.

Stone analysis: mineralogy and morphology of pathological biominerals in humans

Giannossi, M.L. & Summa, V.*
Laboratory of Environmental and Medical Geology, IMAA-CNR, Tito Scalo (PZ), Italy (*summa@imaa.cnr.it)

Stone analysis is rarely carried out in clinical centres even if the identification of the components of kidney stones is essential for deciding on future prophylaxis. Furthermore, very few studies on this issue have been published in Italy up to now [1]. All this encouraged a study on a regional scale in order to analyze the type of kidney stones affecting the Basilicata (southern Italy) inhabitants so as to classify them in accordance with new classifications which take into account the relations between the components and the packing arrangements of the stone crystals.

A total of 80 kidney stones of different compositions were collected, photographed, observed under an optical and scanning electron microscope, and analysed by X-ray powder diffraction.

The results show that 65% of the kidney stones studied are composed of calcium oxalates (38% calcium oxalate monohydrate - whewellite; 27% calcium oxalate dihydrate - weddellite). Trace quantities of other organic and inorganic components are still present. Calcium oxalates are absent or negligible in the remaining 35%, these being composed mainly of uric acid (15%), hydroxyapatite (13%), struvite (6%) or cystine (1%). 32% of stones are multi-composed (eg. weddellite plus hydroxyapatite or whewellite plus uric acid).

The internal structure and the relations between the major and minor components provide information to classify the 80 kidney stones in 8 distinctive types and 13 subtypes in accordance with the scheme proposed by Grases et al. [2], but improved considering a new type of kidney stone composed of weddellite mixed-struvite.

Among stones with predominant calcium oxalate, there is also a high percentage of papillary kidney stones consisting of whewellite developed on kidney walls. The core of this stone type can form exclusively on sites with altered (damaged or just slightly injured) epithelium [3]. Cells of damaged epithelium tend to accumulate calcium thus creating favourable conditions for the formation of kidney stones containing crystals which, under urinary conditions suitable for the crystallization, produce an important deposit of material on the damaged epithelium which serves as a substrate for ulterior nucleation of whewellite stones.

The results of the study of some thin petrographic sections, obtained from a representative number of bigger kidney stones, show that there are usually more cores within whewellite kidney stones which are the result of several simultaneous nucleation and growth processes. Cores appear as spherulitic aggregates, the form best adapted to non-equilibrium conditions. Simultaneous crystallization and oscillation between growth and dissolution events contribute to stone formation.

[6]Institute of Nanostructured Materials, Bologna, Italy

Magnetic scaffolds (MagS) can provide an additional advantage to manipulations of magnetic nanoparticles (MNPs) and cells with MNPs in magnetic field and creation of tissue-engineered constructions. The cell development inside MagSs strongly depends on both biocompatibility and microarchitecture of the scaffold material that defines nutrient and oxygen distribution. Therefore it is extremely important to optimize the scaffold size and microarchitecture for optimum growth of cells in static conditions using mathematic modelling. In its turn, the analysis of experimental parameters allows to create an adequate mathematic model for cell proliferation evaluation in different layers of the scaffolds.

Two kinds of porous magnetic scaffold [1] were used for loading with human Bone Marrow Mesenchymal Stem Cells (BMSCs). The first was a hydroxyapatite/collagen (HA/C) scaffold obtained through a biomimetic mineralization process, whereby the apatitic and the magnetic phases were co-precipitated over and inside the collagen fibers. The second was a hydroxyapatite (HA) ceramic scaffold produced by foaming technique and magnetized using vacuum-assisted infiltration with magnetite nanoparticles (diameter <50 nm). Nonmagnetized HA and HA/C scaffolds were used as a control.

Scaffolds were saturated with cells and incubated in osteogenic medium according to a standard protocol [2]. Proliferation and distribution of BMSCs were assessed using standard tests (MTT-test, acridine orange/ethidium bromide, hematoxylin/eosin staining, etc). Mathematic modeling to predict cell proliferation/distribution in the scaffold space was carried out based on the dynamic nutrient distribution model according to Dunn [3] using the Comsol 3.5a.program.

It was found in vitro that MagSs provide suitable microenvironments for supporting BMSCs proliferation. However, no differences in the ability of MagSs to support proliferation of BMSCs were observed in comparison with non-magnetized scaffolds ($p<0,05$; $n=6$). At the same time the distribution of cells in the scaffold space was different in HA and HA/C MagSs. Intensive proliferation was observed basically in superficial layers of HA/C MagS especially during the first 5 days after saturation with cells. In HA-scaffolds we observed much more homogenous cell distribution during all period of incubation (20 days), but the proliferation rate was lower by a factor of two at least. The computerized model of cell proliferation and distribution used agrees reasonably well only with experimental data for periods between 7 and 12 day of cell cultivation in scaffolds and hence should be further developed in future researches. Thus, it can be concluded that MagSs showed similar dynamic of proliferation processes as the non-magnetic scaffolds.

Calcium oxalates in renal stones

Izatulina, A.R.[*], Punin, Yu.O., Shtukenberg, A.G., Frank-Kamenetskaya, O.V. & Gurzhiy, V.V.
Dept. of Crystallography, Saint-Petersburg State University, Saint-Petersburg, Russia ([*]alina.izulina@mail.ru)

Urolithiasis is a rather widespread disease. However till now there are no reliable methods of preventive maintenance of this illness, despite of significant efforts made in the past. Moreover, it is not completely clear, how renal stones are forming.

The majority of renal stones consist of the calcium oxalate hydrates whewellite $CaC_2O_4 \cdot H_2O$ and weddelite $CaC_2O_4 \cdot (2+x)H_2O$. Origin and growth kinetics, area of stability and the phase transitions of calcium oxalate crystals were studied in details for a long time. However, the comparison of experimental data shows strong differences suggesting that some additional factors may influence formation and stability of calcium oxalate phases.

The main purpose of this work is to research the factors that raise the weddellite stability: temperature, pH, proportion of calcium and oxalate ions, organic and inorganic components of physiological solution, amount of micromycets and bacterial-viral associates, and time of crystallization. Special attention has been devoted to study the variability of the water content in the structure of weddellite and its influence on the dehydration and phase transitions in renal stones. Besides, another purpose of the work was to reveal correlations between *x* and weddellite unit cell parameters and to offer on this basis an express way to estimate the amount of zeolitic water present.

The influence of crystallization conditions on the formation of calcium oxalates was investigated by simulation experiments according to a physiological medium. To estimate the variation of the amount of zeolitic water in the structure of weddellite and to reveal the ratio of *x* and unit cell parameters the crystal structures were refined by single crystal x-ray diffraction of nine weddellite crystals from different renal stones.

The results showed that the factors increasing the weddellite stability are supersaturation, pH, concentration of stabilizing impurities (for example CO_3^{2-} or Mg^{2+}), and the amount of protein substance. Since it was found that weddellite transforms into whewellite with time, the stability of the former presumably depends on the amount of structural water.

In the weddellite crystal structure (S.G. *I*4/*m*) [1] Ca atoms are coordinated in slightly distorted square antiprisms linked by a common edge to two adjacent ones to form chains along the *c* axis. These chains are connected to each other by common oxalate groups and hydrogen bonding of water molecules. Ca-polyhedra chains form channels occupied by "zeolitic" water molecules.

Our investigation showed that the amount of "zeolitic" water indeed causes a variation of the unit cell parameters, especially the *a* parameter (12.336 – 12.371 Å) as well as the interatomic spacing. For example, the distance between W1 water molecules, adjacent to the "zeolitic" water of one layer parallel to (001) varies from 3.211 – 3.287 Å.

According to the limiting values of the *a* unit cell parameter our result allows to estimate the variation of the *x* values (0.13 – 0.37 at. u.) in the weddellite crystals of renal stones. Thus in most cases *x* is close to the upper limit.

Quaternary mammalian bones and teeth diagenesis in karst cavities of Middle and Northern Urals, Russia: implications of thermal, elemental and spectroscopy data

Kiseleva, D.V.[1*], Votyakov, S.L.[1], Smirnov, N.G.[2], Shchapova, Yu.V.[1] & Sadykova, N.O.[2]
[1]Institute of Geology and Geochemistry, UB RAS, Ekaterinburg, Russia ([*]kiseleva@igg.uran.ru)
[2]Institute of Plant and Animal Ecology, UB RAS, Ekaterinburg, Russia

Chemical composition and microstructure of Quaternary mammalian bones and teeth remains have been investigated by means of scanning electron and atomic force microscopy, electron probe microanalysis, trace element inductively coupled plasma mass-spectrometry, thermal and thermokinetic analysis, infrared, Raman and electron spin resonance spectroscopy.

Samples of bones and teeth remains represented 11 various sites of Middle and Northern Urals, Russia. They included Holocene and Pleistocene ornithogenic and zoogenic rodent remains from the earth surface, rock-shelters, grottoes and karst cavities [1].

The hydrolytic degradation of the organic component of bone tissue and the conversion of the inorganic constituents of bone have been registered on SEM images, *e.g.* porosity increase, peeling, bacterial attack, rotting, initial structure decomposition and secondary mineral formation [2].

The dynamics of elemental composition of bone have been investigated and geochemical indices were calculated. The rare earth elements (La-Lu) and high field strength elements (Y, Zr, Hf, Ta, Th, U) appear to be promising indicators of relative age estimation by tissue accumulation degree.

After thermal analysis (20-800°C) estimates of organic content determined as mass loss at 200-650°C in bone remains series have been used to reveal different age admixtures and chronological ranging.

Ion-radicals induced by thermo-chemical transformations of organic constituent in the temperature range of 200-650°C have been observed in bone (tooth) tissues. The line shape and width parameters of ion radicals have been analyzed and their age variations examined.

Phase transformation during fossilization has been examined by infrared and Raman spectroscopy in four spectrum ranges attributed to inorganic phase structural fragment vibrations (PO_4^{3-}, H_2O and OH^-, CO_3^{2-} in A and B-positions). From this, bone apatite crystallinity, degree of apatite P-O bond ionicity-covalency, carbonate-ion relative concentration and its inter-positional distribution, and alterations in bone surface micro- and nanostructure were deduced.

Several types of fossilization distinguished by correlations of organic components of bone and trace elements content have been assigned. The results obtained were used to evaluate the relative age of bone. Some questions about the degree of synchronism were discussed for the investigated series of fossil and sub-fossil rodent bone remains representing various sites in the Urals.

Nucleation and growth of hydroxylapatite as proxy for bone apatite

Klasa, J.[*] & Valsami-Jones, E.
Dept. of Mineralogy, Natural History Museum, London, UK
([*]jolk@nhm.ac.uk)

Bone and teeth are biomineralised materials with a unique organic/inorganic composite structure. The main inorganic component is nanocrystalline bioapatite which is embedded in collagen matrix. During the lifetime of the organism bones are continuously remodeled by dissolution/reprecipitation processes although the details of the mechanisms are still poorly understood. For example nanosized crystals in bone have been shown to be insensitive to demineralisation in experiments using constant composition method [1].

Bioapatite is a complex solid solution [2] and understanding its interaction with body fluids requires a fundamental study of the solid solution – aqueous solution system. Furthermore nucleation of nanoapatite from multicomponent solutions is also likely to involve the formation of compositionally inhomogeneous phases. For example a solution supersaturated with respect to hydroxylapatite may also be supersaturated with respect to other apatite solid solutions as well as other calcium phosphate phases.

We have carried out nucleation and growth experiments under constant composition conditions (in which supersaturation is kept constant throughout the experiment) at physiological pH (7.4) and in a solution resembling blood plasma. The aim is to investigate the effect of solution composition and saturation on apatite properties, particularly size and shape and rate of formation. Scanning Electron Microscopy (SEM), Atomic Force Microscopy (AFM) and Fourier Transform Spectroscopy (FTIR) were used to characterise and understand fundamental properties of the precipitates formed.

Pathological biomineralization from human aortic and mitral valve stenosis

Maras, A.[1*], Cottignoli, V.[1], Cavarretta, E.[2,3], Salvador, L.[2,4] & Valfrè, C.[2]
[1]Dept. of Earth Sciences, *La Sapienza* University of Rome, Italia ([*]adriana.maras@uniroma1.it)
[2]Div. of Cardiac Surgery, Treviso Regional Hospital, Italy
[3]*La Sapienza* University of Rome, Italy
[4]Div. of Cardiac Surgery, San Bortolo Hospital, Vicenza, Italy

Samples were collected as surgical waste from patients (demographic characteristics are shown in Table 1) undergoing valvular replacement caused by severe aortic (n=6) and mitral (n=2) stenosis. Pathological mineral formations have been investigated with XRPD and SEM-EDS, both in high and in low vacuum conditions. Samples were not coated because of metallic coating artifacts.

Table 1: Cell parameters of pathologic bioapatite ($P6_3/m$)

Samples	*a*(Å)	*c*(Å)	Sex/Age
2a	9.4172(5)	6.8954(4)	M 73
3m	9.4161(8)	6.8948(6)	F 75
6a	9.4153(8)	6.8952(7)	M 75
9a	9.4165(7)	6.8957(6)	M 71
12a	9.4165(8)	6.8951(7)	M 68
14a	9.4161(9)	6.8958(7)	M 69
15m	9.4161(9)	6.8961(7)	M 64
18a	9.4158(5)	6.8958(4)	M 41

a = aortic valve, m = mitral valve
a = 9.441(2)Å; *c* = 6.878(1)Å dental enamel apatite [1]

The *a* cell parameters were found to be smaller than the *a* parameter of human dental enamel apatite, while the *c* parameters were greater.

High resolution images show a complex relationship between inorganic component and organic matrix as well as particular morphologies of the pathogenic biomineralization. Bioapatite appears as lamellar crystals, globular aggregated and massive; at high magnification it appears to be constituted of spherical particles of variable size (Fig. 1).

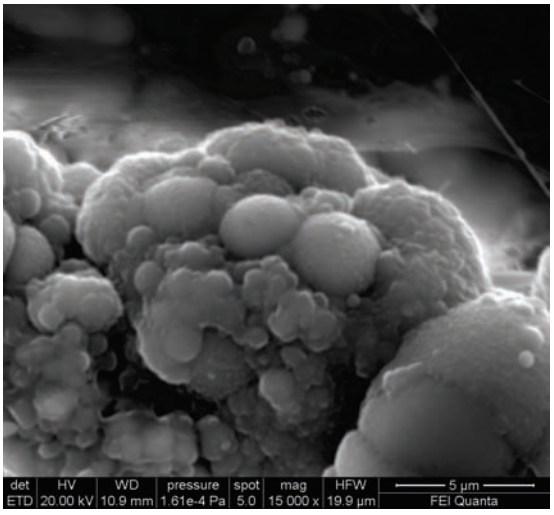

Fig. 1: SEM micrograph of pathologic bioapatite.

Bioapatite morphology observed in this study appears to be different from biogenic calcium phosphate crystals and from inorganically produced counterparts. The small spheres could be considered as nanobacterial-like [2,3] structures (?) This attractive hypothesis has not been confirmed yet.

[4]Max Planck Institute for Chemistry, Mainz, Germany
[5]Savaria University Center, Szombathely, Hungary
[6]Eötvös Loránd University, Budapest, Hungary

Cathodoluminescence (CL) imaging and spectroscopy have been used to clarify growth fabric textures observed in authigenic and biogenic minerals during diagenetic process. A cathodomicrofacies analysis has been developed in the field of environmental geology and archaeology, especially for the study of biogenic carbonates. Few investigations of silicified fossils have been conducted so far. In this study a microfacies analysis of petrified wood has been carried out by CL imaging and spectroscopy combined with Raman spectroscopy.

A unique sample of petrified wood with bright CL emission was obtained from the conglomerate in the Omori Formation (middle Miocene), Kurihara, Izumo City, southwest Japan. It has a diameter of around 5 cm in section, which shows concentric rings of clear silicified layers filling the cracks among a black layer including carbonaceous materials. The polished sections were examined by CL method. CL color images were recorded using the Luminoscope (ELM-3R). CL scanning images at high magnification were obtained by a Mini-CL detector (Gatan) installed in a SEM (JEOL: JSM-5410). CL spectroscopy was made by a SEM-CL systemcomprising an SEM combined with a grating monochromator (OXFORD: Mono CL2).

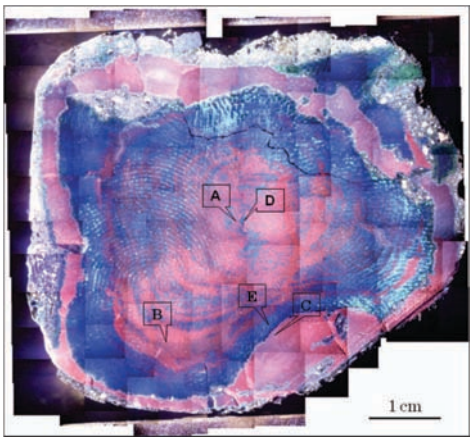

Fig. 1: CL image of petrified wood with analytical positions.

The black layer contains remnants of a carbon phase exhibiting many radial clear lines, which should be divided into two areas: (1) red CL and blue CL parts as shown in Figure 1. Compared to the reflected optical microscope image, the CL image shows two rings. Raman spectra and CL spectra at A (center red CL), B (fringe, red CL), C (outside of silicified wood, red CL), D (center, blue CL), and E (fringe, blue CL) points were obtained in this silicified wood. As a result, we recognized quartz signal at all red CL points (A, B, C). We also recognize D and G bands of amorphous carbon at A, B, D, and E inside of silicified wood. The red CL has a peak at 650 nm, and the blue CL exhibits a peak at 450 nm. These CL spectral features are related to agate [1].

Investigation of bone apatites by thermoanalytical methods

Papp, I.[1*], Buday, T.[1] & Pap, L.[2]
[1]Dept. of Mineralogy and Geology, University of Debrecen, Hungary ([*]asvanypista@citromail.hu)
[2]Dept. of Inorganic and Analytical Chemistry, University of Debrecen, Hungary

There is much controversy on the crystal structure of bone apatites, especially regarding the carbonate substitutions. In this study, swine and poultry bone samples were examined by thermoanalytical methods (thermogravimetry, differential thermal analysis and evolving gas analysis, EGA), in order to determine the amount of carbonate ions and their position in the crystal lattice. Although calcite is a common mineral in fossil bones, it may be present in living bones as well. The role of these phases is unclear, probably related to degenerative effects. Carbonate ions may play a significant role in the biocompatibility of bone prostheses as well.

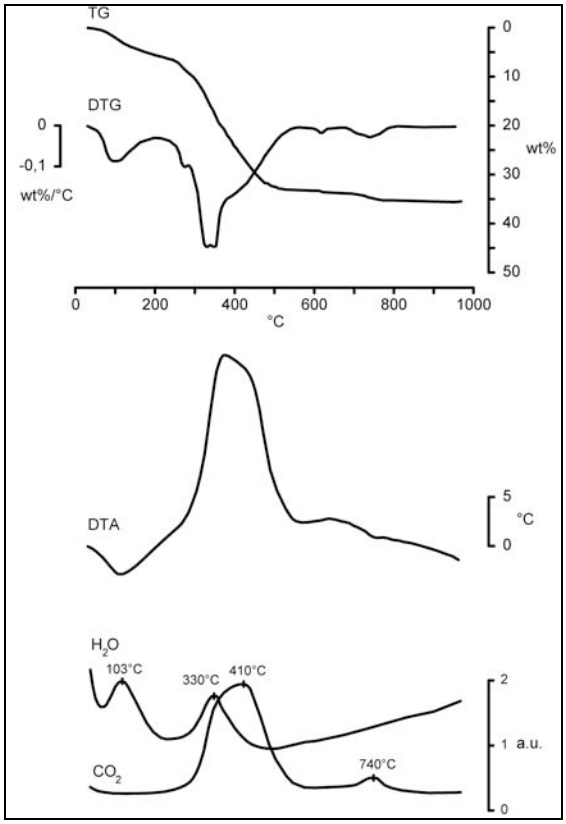

Fig. 1: Thermoanalytical curves of the bone sample Sk4.

The EGA results show CO_2 elimination above the temperature of burning of organic material. The shapes of the thermoanalytical curves imply that CO_2 derives from the dissociation of the carbonate ions. In some samples the high carbonate content and the temperature of the dissociation may imply the presence both of carbonate apatite and calcite phases (Fig. 1) in the inorganic bone material.

The calcium phosphate binding properties of the serum protein fetuin-A explored with SANS contrast variation technique

Schwahn, D.[1*], Heiss, A.[2], Pipich, V.[3] &Jahnen-Dechent, W.[2]
[1]Institute of Solid State Research of the Helmholtz Research Center Jülich GmbH, Jülich, Germany ([*]d.schwahn@fz-juelich.de)
[2]Biomedical Engineering, Biointerface Group, RWTH University, Aachen, Germany
[3]JCNS – Jülich Centre for Neutron Research at the FRM II, Garching, Germany

The patho-physiologic relevance of the serum protein fetuin-A/alpha$_2$ HS-glycoprotein as a systemic inhibitor of uncontrolled mineral deposition in the soft tissue has been demonstrated in fetuin-A knockout mice [1]. Moreover, clinical studies showed that patients with a low fetuin-A serum level are exposed to an increased calcification risk [2]. To elucidate the inhibition mechanism of calcification by the protein fetuin-A, we explored several *in vitro* model systems with SANS contrast variation technique [3]. The principle outcome was a two stage formation process of transiently stable nanometer sized colloidal composites of fetuin-A and calcium phosphate, which we denoted as calciprotein particles (CPPs); the initial form is spherical with a diameter in the 500Å range which, after several hours at room temperature, transform to elongated particles of about twice the initial size. The CPPs consist of fetuin of about 25% volume fraction and of the octacalcium phosphate (OCP) polymorph representing the mineral phase [3]. The secondary CPPs are stable for at least 24 hours, which can be explained by a dense fetuin monolayer covering the mineral as determined from SANS contrast variation experiments [3].

However, a detailed analysis suggested that the buffering of calcium and phosphate ion super saturation by the CPPs is not the whole story of the inhibition mechanism. The analysis of the SANS scattering patterns revealed that 3-5% of the total fetuin-A and about half of the total mineral can only be attributed to the CPPs. As SANS reflects the presence of fetuin monomers at large momentum transfer, we speculated that the other half of the mineral is attached to the monomers. Recent contrast variation experiments indeed identified these particles as calciprotein monomers (CPM) with varying amount of the mineral when changing the fetuin concentration. So, the inhibition mechanism of mineralization in the presence of the protein fetuin-A proceeds on two pathways, namely by CPP and CPM formation.

Biomimetic synthesis and characterization of Zn-substituted calcium phosphates

Titorenkova, R.[1*], Rabadjieva, D.[2], Petrov, O.[1], Gergulova, R.[2], Tepavitcharova, St.[2], Dyulgerova, E.[3] & Konstantinov, L.[1]
[1]Central Laboratory of Mineralogy and Crystallography, BAS, Sofia, Bulgaria ([*]rosititorenkova@dir.bg)
[2]Institute of General and Inorganic Chemistry, BAS, Sofia, Bulgaria
[3]Dental Medicine Faculty, University of Medicine, Sofia, Bulgaria

Biomimetic methods are often applied instead of conventional ones to synthesize calcium phosphates resembling the composition and structure of biological apatite.

A biomimetic approach was applied to synthesize Zn-substituted amorphous calcium phosphates (ACP) with Zn/Ca ratios of 0, 0.03, 0.05, 0.07, 0.10 and 0.13. The method includes quick mixing of calcium chloride, zinc chloride and potassium hydrogen phosphate solutions prepared by dissolution of the salts in a simulated body fluid (SBF). The initial molar ratio (Ca+Zn)/P was 1.67. The reaction pH was kept at about 11 by the addition of 25% NH_4OH. The precipitates were filtered, washed with water and with acetone (solid-to-liquid ratio 1:1) and then dried for a week at a temperature of -18°C in the presence of silica gel. The applied method allows obtaining apatite precursor containing impurities of Mg, Na, K and Cl in concentrations similar to those in the mineral part of the hard bone tissues. The addition of Zn was chosen in order to improve the specific bioactivity of calcium phosphate, as zinc activates bone formation and has inhibitory effect on the osteoclast differentiation.

The initial precipitates were calcified for 2 h at 600 and at 800°C under atmospheric pressure. The effect of Zn-concentration on the phase composition and structural characteristics of the obtained ceramics was investigated. After calcification at 600°C, amorphous calcium phosphate with a ratio Zn/Ca = 0 transforms into hydroxyapatite, samples with Zn/Ca = 0.03 and 0.05 into mixture of hydroxyapatite and Zn-substituted β-TCP while those with Zn/Ca = 0.07, 0.1 and 0.13 into Zn-substituted β-TCP. After calcification at 800°C all the samples with various Zn/Ca ratios transformed into Zn-substituted β-TCP.

The results obtained indicate that the addition of Zn promotes the formation of single-phase β-TCP ceramics. XRD and IR absorption data reveal that the isomorphic substitution of Zn^{2+} for Ca^{2+} in the β-TCP structure proceeded in a stepwise manner. The increase of the concentration of Zn is followed by a decrease in the unit cell parameters and volume.

Applying this method of synthesis leads to ion (Zn, Mg, Na, K and Cl) modified single- and bi-phase calcium-phosphate materials with potential to be used as biomaterial.

A study on psammoma body mineralization in meningioma

Wang Changqiu[1*], Yang Ruochen[1], Lu Anhuai[1], Zhao Wenwen[1], Li Yan[1], Liu Jianying[2] & Zhang Bo[2]
[1]School of Earth and Space Sciences, Key Laboratory of Orogenic Belts and Crustal Evolution, MOE, Peking University, Beijing, China ([*]cqwang@pku.edu.cn)
[2]Pathology Dept. in School of Basic Medical Science, Peking University Health Science Center, Beijing, China

The psammoma body mineralization is a common type of pathological mineralization in human meningioma (Fig.1 upper left). The mineralogical studies of the psammoma body mineralization may provide some supporting information in finding the reason of the origin and development of the disease. In this paper, mineralogical characteristics of psammoma bodies in the mineralized focus from a meniningioma patient are investigated in terms of their composition, structure and morphology, using HRSEM, ESEM, EDAX, EPMA, HRTEM, XRD and FTIR. The formation mechanism of the psammoma bodies is also discussed.

The results show that in the early stage of psammoma body mineralization in meningiomas, many small mineralized balls composed of octacalcium phosphate were precipitated on the collagen fibers (Fig.1 upper right). These balls continued to grow and aggregate, and were gradually hydrolyzed to become dahllite nano-crystals. The continuing mineralization resulted also in mineralization of the collagen fibers (Fig.1 lower). The study reveals that the concentric layered structure of the psammoma bodies in meningiomas is formed by a spiral arrangement of the mineralized collagen fibers on which the mineralized grains precipitated.

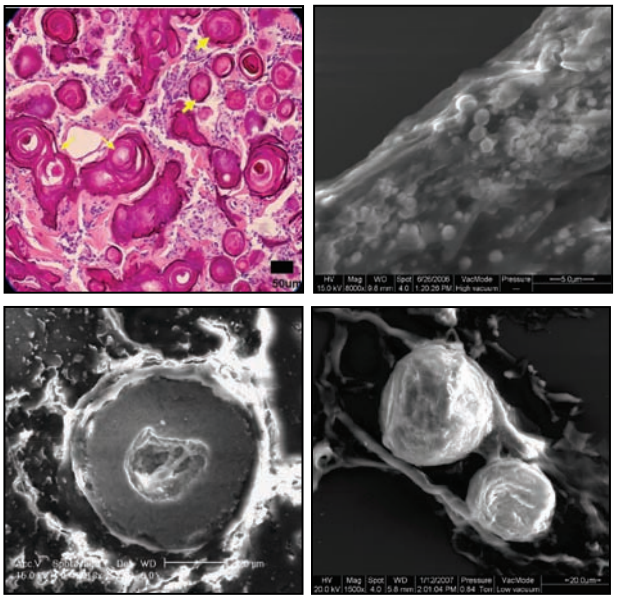

Fig. 1: The photomicrograph (upper left) and ESEM morphology (lower left, and right) of the meningiomas organizations with psammoma bodies.

Thermal stability of bio-aragonite and the textural characteristics of cuttlefish shell

Wang Hejing[1*] & Zhou Jian[2]
[1]School of Earth and Space Sciences, Peking University, Beijing, P.R. China ([*]hjwang@pku.edu.cn)
[2]Chinese Academy of Geological Sciences, Beijing, P.R. China

The internal shell of cuttlefish is composed of aragonite and plays two important roles in the life of the animal: providing it with buoyancy and withstanding the external hydrostatic pressure e.g. a maximum pressure of 2.1 - 6.2 MPa at 200 to 600 meter depths, respectively [1].

The *in-situ* XRD technique was used to investigate the thermal stability and phase transition of bio-aragonite from cuttlefish bone under both vacuum and air non-ambient conditions. From room-temperature to 900ºC bio-aragonite changes via calcite to lime in both vacuum and air conditions (Table 1). The coexisting range of aragonite-calcite in vacuum condition is 365-475ºC and that of calcite-lime is 475-625ºC respectively, whilst the coexisting range of aragonite-calcite in air condition is 385-435ºC and that of calcite-lime as 625-750ºC respectively.

Table 1: Phase transitions of bio-aragonite and corresponding temperatures under non-ambient vacuum and air conditions

		25 100 200 300 400 500 600 700 800 900 ºC
Vac	CaO	475----------
	Cc	365----------625
	Arg	----------475
Air	CaO	625----------
	Cc	385----------750
	Arg	----------435

Vac: vacuum, Cc: calcite, Arg: aragonite

SEM analysis demonstrates that the cuttlefish bone possesses the characteristic of a floor-pillar-like architecture. XRD textural analysis reveals that the aragonite crystallites of cuttlefish bone prefer growing in a comb-like habit between layers (orientation distribution function (ODF) parallel to psi-phi plane) and in a 45º crossing angle within both the comb-like pillars and the layers (Fig. 1), producing a strong interlace texture of the internal shell.

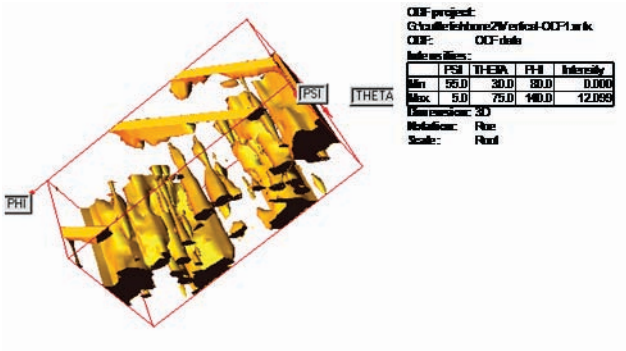

Fig. 1: ODF of bio-aragonite calculated from pole data of reflections (020), (111), (122) and (220).

It is concluded that the bio-aragonite of cuttlefish bone possesses high temperature stability up to 365ºC and a crossgrowth habit both in layers and in vertical pillars which well supports the cuttlefish to withstand high pressure condition up to 6 MPa.

Determination of amorphous and nano-crystalline calcium carbonate polymorphs in pearls by Raman spectroscopy

Wehrmeister, U.[1,3], Jacob, D.E.[1*], Soldati, A.L.[1,2], Loges, N.[1], Häger, T.[3] & Hofmeister, W.[3]

[1]Dept. of Geosciences and Earth System Science Research Centre, Johannes Gutenberg- Universität, Mainz, Germany ([*]jacobd@uni-mainz.de)

[2]CONICET, Grupo Caracterización de Materiales, Centro Atómico Bariloche, S.C. de Bariloche, Argentina

[3]Dept. of Gemstone Research, Johannes Gutenberg-Universität, Mainz, Germany

The nacre of pearls and mussels is well known to display a "brick and mortar" – structure which is a challenging composite organic-inorganic model system for research in nanotechnology. FIB/TEM and AFM methods show that nacre presents a nanostructure with the smallest structures in the range of 50 – 100 nm [1]. The $CaCO_3$ vesicles, extruded by the mantle epithelial tissue cells of the bivalve are primarily composed of amorphous calcium carbonate (ACC) before being transformed into the crystalline phase [2].

Micro Raman spectroscopy is a powerful tool in identifying the different calcium carbonate polymorphs [3, 4]. Analyses were carried out on cultured pearls from freshwater (genus *Hyriopsis*) and marine bivalve species (*Pinctada maxima*). Raman spectra for vaterite and ACC are discussed. Results for ACC are compared to synthetically produced ACC and to Raman spectroscopic features of stable biogenic ACC from the crustacean *Porcellio scaber*.

ACC in the pearls is confined to areas close to the centre of the pearls [1]. Decomposition of the most intense signal of the calcium carbonate polymorphs – the ν_1 symmetric stretching mode of the carbonate ion, leads to the identification of two polymorphs within the ACC areas: a mix of an amorphous and a nanocrystalline fraction.

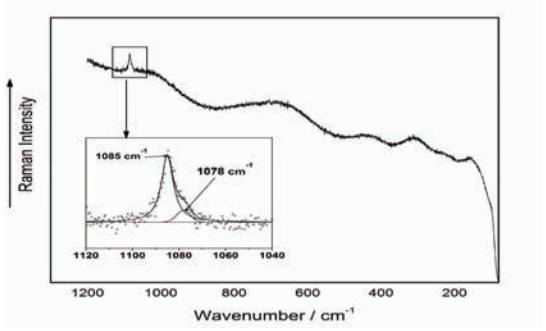

Fig. 1: Raw Raman spectrum of ACC in a South Sea cultured pearl (*Pinctada maxima*). Inset: The ν_1-mode is clearly to decompose into an amorphous (Gaussian line profile, centred at 1078cm^{-1}) and a nanocrystalline fraction (Lorentzian line profile, centred at 1085 cm^{-1}).

As a rule, the degree of mineral crystallinity is mirrored by the FWHM, the broader the spectral bandwidth, the lower the degree of the mineral crystallinity. The amorphous phase in the samples is characterised by a broad peak (FWHM of ca. 120 cm^{-1}) in the region of the lattice modes. While for monocrystalline and biogenic aragonite typically FWHMs of 1.3 cm^{-1} and 2.2 cm^{-1} are measured, nanocrystalline aragonite in paragenesis with ACC shows an FWHM between 5 cm^{-1} and 10 cm^{-1} of the ν_1 – Raman band. A shift to lower wavenumbers is clearly related to the peak broadening.

EPS composition and calcification potential of filamentous cyanobacteria

Zippel, B.[1*], Dynes, J.J.[2], Obst, M.[3], Lawrence, J.R.[4] & Neu, T.R.[1]
[1]Dept. of River Ecology, Helmholtz Centre for Environmental Research – UFZ, Magdeburg, Germany
([*]barbara.zippel@ufz.de)
[2]Dept. of Soil Science, University of Saskatchewan, Saskatoon, Canada
[3]Center for Applied Geoscience, Tuebingen University, Tuebingen, Germany
[4]Environment Canada, Saskatoon, Canada

Tufa deposits in freshwater habitats are often the result of calcium carbonate precipitation within interfacial microbial ecosystems. Calcite precipitation is influenced by the saturation index and the occurrence of extracellular polymeric substances (EPS), which are produced by a variety of microorganisms [1]. STXM has been used at the C K-edge to map the major biomolecules (proteins, lipids, and polysaccharides) in complex microbial biofilms [2]. Furthermore, by means of STXM it is possible to differentiate between different species and calcium carbonate phases at the Ca L-edge [3]. The purpose of this study is to determine if there are differences in calcium adsorption dependent on the specific composition of the EPS produced by filamentous cyanobacteria isolated from a hard water creek (Westerhöfer Bach, Harz Mountains, Germany).

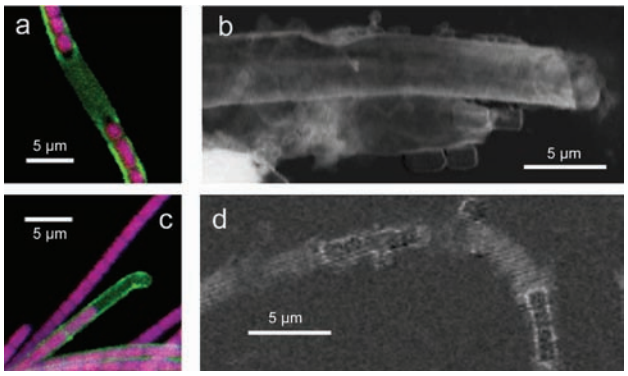

Fig. 1: (a, c) Maximum Intensity Projection of Laser Scanning Microscopy images represent lectin-specific EPS glycoconjugates (green) associated with the investigated cyanobacteria (pink). (b, d) STXM Ca maps $OD_{352,3eV} - OD_{350,3eV}$ showing the presence of extracellular Ca accumulations in close association with cells or in cyanobacterial sheaths.

The sheaths of the cyanobacteria contained mainly polysaccharides and proteins, and a small amount of lipids (Fig. 1). Both cyanobacterial sheaths contained spectral signatures of Ca^{2+} adsorbed to EPS. In *Pseudanabaena* sp. sheaths, the adsorbed Ca was distributed more homogeneously. Aragonite-like $CaCO_3$ in close association with the cyanobacterial cell surface was detected in *Leptolyngbya* sp. only. In the same region, polysaccharides were detectable. In the case of *Pseudanabaena* sp., only very small aragonite-like spots were recorded in association with accompaning cells of heterotrophic bacteria.

EPS produced by cyanobacteria were shown to be a component for calcium adsorption. Depending on the spatial composition of EPS, different components potentially participate to various extents in nucleation processes of calcium carbonate in close association with the cells.

Microbial induced calcite precipitation and its application in remediation technologies

Phoenix, V.R.[*] & Tobler, D.J.
Dept. of Geographical and Earth Sciences, University of Glasgow, UK ([*]Vernon.Phoenix@ges.gla.ac.uk)

The precipitation of calcite by ureolytic bacteria has potential in a wide range of environmental applications. The strength of this approach lies within its ability to precipitate considerable quantities of calcite. This approach has been shown to, for example, efficiently scavenge radionuclides (^{90}Sr) [1], seal fractures and permeable zones in concrete and rock [2,3] and protect and repair building materials [4].

Here we explore its potential to (a) seal fractures in rock around nuclear waste repositories and (b) immobilize nanoparticles.

Thus far, most studies on ureolysis and its impact on calcite precipitation have been perfomed in artificial groundwater using single species of urease positive bacteria, such as *Sporosarcina pasteurii*. While *S. pasteurii* may be used as an innoculum to seal fractures around nuclear waste repositories, indigenous communities also have potential to drive ureolytic calcite precipitation. Here we compare (in laboratory microcosms) urea hydrolysis and calcite recipitation rates by *S. pasteurii* with those of indigenous groundwater communities. In this particular groundwater, ureolytic activity of indigenous groundwater communities was almost zero. However, stimulation with dilute nutrients such as BHI or molasses promoted a notable increase in rates of urea hydrolysis. However, these rates were significantly lower than those obtained from aerobic experiments with *S. pasteurii* and may thus well be too low to plug soils and fractured rocks. However, when an innolculum of aerobically grown *S. pasteurii* was added to the anaerobic groundwaters, the ureolysis rates by *S. pasteurii* were significantly higher than those produced by stimulated groundwater communites. Significantly, this suggests *S. pasteurii* can be grown in large densities aerobically, and then injected into anaerobic groundwaters where the sudden change in fO_2 does not inhibnit the ureolytic activity of this facultative anaerobe.

We also examined the potential of microbial calcite precipitation to remediate nanoparticulate pollution, by trapping nanoparticles into the mineral precipitate. Batch microcosms were built containing articifial groundwater, urea, *S. pasteurii* and Fe_2O_3 nanoparticles as a model nanoparticle. Although some loss of nanoparticles from solution did occur due to floculation and settling, calcite precipitation showed much faster immobilization of the nanoparticles compared to controls, immobilizing 100% in just 1 day.

Marine Mn nodules as stromatolites with fractal signature: examination by X-ray, TEM, SEM and mathematical simulation

Akai, J.
Dept. of Geology, Faculty of Science, Niigata University, Niigata, Japan (akai@sc.niigata-u.ac.jp)

Mn nodules are very problematic materials since the first finding: Why are the shapes nodular? Why are they not buried? Is the origin fundamentally biogenic or abiogenic? Many bio signatures containing bacteria have been found on the surface and within nodules. Although many suggestions are present, the genesis has not been fully confirmed.

Mn nodule samples from Clarion-Clipperton Fracture zone in other 4 localities in Pacific Ocean were mineralogically examined. Two types of constituent Mn oxide minerals were identified: 10A buserite-like phase and 2.5A vernadite-like phase. Mineralized bacteria and their possible traces were observed by SEM and TEM (Fig. 1a-d). The mineralized bacteria with Mn oxides (Fig. 1a) and Fe hydroxides (Fig. 1b) may be Mn-oxidizing bacteria and Fe-oxidizing bacteria, respectively. HRTEM images of constituent Mn minerals showed low crystalline layer structures (Fig. 1e).

Under the optical microscope, cross sections of the nodules were studied and characteristic columnar stromatolite structures were found. These thin rhythmic bands have often been described as stromatolitic. However, here, we refer to this structure as the stromatolite structure itself. The term 'stromatolite' has a genetic meaning, i.e., biogenesis. The rhythmic band structure found in the manganese stromatolite may be induced biomineralization products. Surface morphology of botryoidal characteristics was described. The characteristics bear fractal-like nature. Forms of four different orders are recognizable (Fig. 2a-d). The 1st order is the nodule forms themselves (several up to 10 cm in size), the 2nd order represents aggregated dome-like forms (several cm); the 3rd order dome-like forms are very clearly found (5mm to 1cm) i.e. the main morphological parts of botryoidal textures; 4th order (~0.2~ 1mm) dome forms correspond to stromatolite top form. X-ray CT images also resulted in confirmation of inner dome-like textures in Mn nodules. Mathematical simulation based on fractal models using basic sphere unit (Fig. 3a) reproduced similar morphological characteristics (Fig. 3b,c) to the natural samples.

So, we arrive at the concluding hypothesis that Mn nodules are aggregated stromatolite with fractal-like characteristics.

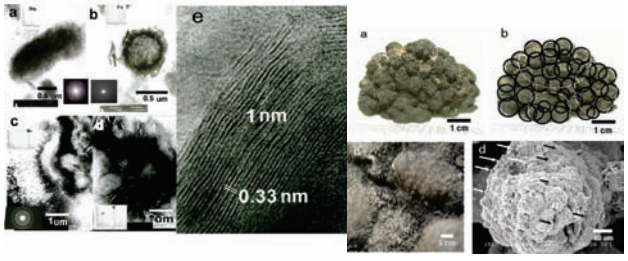

Fig. 1: (left) TEM image of Mn nodules.
Fig. 2: (right) Fractal-like features.

Biominerals of greigites (Fe_3S_4) in sediments – formation, stability and reaction in sea water

Preisinger, A.*, Aslanian, S. & Wernisch, J.
Vienna University of Technology, Vienna, Austria
(*anton.preisinger@tuwien.ac.at)

The widespread occurrence of a stable ferrimagnetic spinel structure of Fe_3S_4 (greigite) in sulfate reducing bacteria is well-established [1]. We analyzed nanocrystals of greigites in gravity cores of the Black Sea (BS), the Marmara Sea (MS) and the Caspian Sea (CS), as well as in the K/T-fallout in the former Tethys by utilizing X-ray diffraction, ore microscopy, transmission electron microscopy, and scanning electron microscopy. Two types of clusters of ferrimagnetic nanocrystalline structures were found [2]. They can be categorized as magnetotactic and framboidal greigites (Fig. 1 and 2).

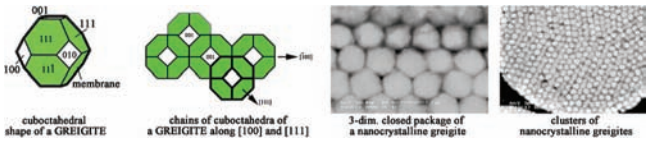

Fig. 1: Closed packed chains of greigite nanocrystals called "magnetotactic greigites".

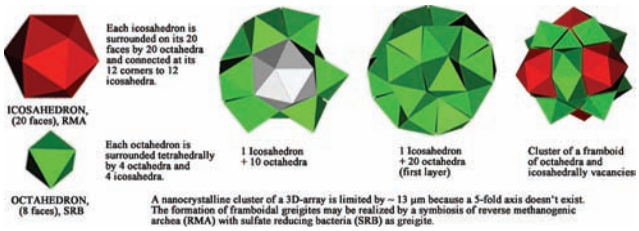

Fig. 2: Regular three dimensional array of greigite nanocrystals called "framboidal greigites".

From the MS over the sill in strait of Bosporus, clusters of magnetotactic greigites entering the BS since 9.300 yrs BP, which was at this time in an oxic state. The greigites are only stable under anoxic conditions. Under oxic conditions, the greigite reacts to non-magnetic pyrite (FeS_2) and FeOOH (Fig. 3).

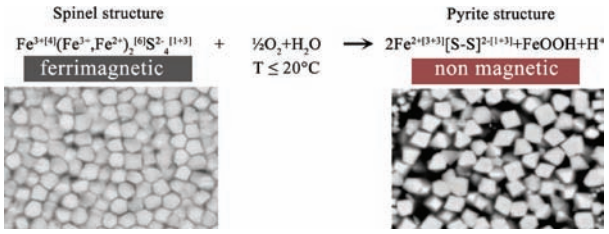

Fig. 3: Change of ferrimagnetic greigites (Fe_3S_4) + Oxygen → nonmagnetic Pyrite (FeS_2) + FeOOH.

In comparison to the climatic time scale, the quantitative counting of the greigites in gravity cores shows that water kept entering the BS from the MS stepwise between 9.300-8.500 yrs BP. The change of ferrimagnetic greigites to non-magnetic pyrites under oxic conditions in the BS reveals this clearly. Besides the more recently formed clusters of framboidal greigites under the chemocline of the BS, we also found such clusters in the former Tethis, which were built after the Cretaceous/Paleogene (K/T)-impact of Chicxulub (Mexico) as a consequence of the sulfuric acid rain in the worldwide K/T-fallout [3].

Bacterially induced micro- and nano-textures of massive sulphides, Silvermines Zn-Pb deposit, Ireland

Kucha, H.[1*], Raith, J.G.[2] & Southam, G.[3]
[1]University of Mining & Metallurgy, Krakow, Poland
([*]kucha@geol.agh.edu.pl)
[2]Dept. of Applied Earth Sciences & Geophysics, University of Leoben, Austria
[3]Dept. of Earth Sciences, The University of Western Ontario, London, Ontario, Canada

At Silvermines Zn-Pb ores occur in two forms: 1) Epigenetic ores (zones G, K) present within or close to the Silvermines fault with 4.74 Mt ore at 2.4wt.% Pb and 5.9wt.% Zn [1]. Sulphur isotopes of sulfides from these ores are typically in the range $\delta^{34}S$= +4 to –5‰, while barite values are between $\delta^{34}S$= +18 to +23‰. 2) Stratiform ores are developed within the pyrite, siderite and barite facies. Ore reserves amounted to 12.94 Mt with 2.6wt.% Pb, 6.8wt.% Zn and 5.0 Mt of barite [1]. These sulphides have $\delta^{34}S$= –4 to –43‰. Barite falls in the range of $\delta^{34}S$= +12 to +23‰. Stratiform ores contain ubiquitous bacterially induced micro- and nano-textures (Figs. 1 & 2), as well as compounds with intermediate and mixed sulphur valences. Bacterially induced textures occur in up to a few cm thick patchy to layered ZnS accumulations. Sulphur isotope data and biogenic textures suggest a massive involvement of sulphate reducing bacteria in the accumulation of the stratiform massive sulphide ores at Silvermines [2].

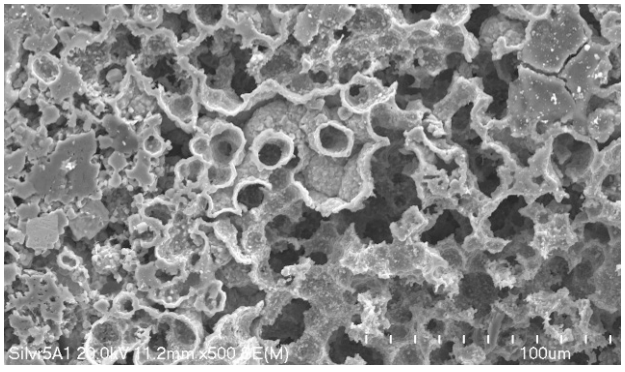

Fig. 1: FESEM image of etched biogenic ZnS aggregate with tubiform to sub-circular micro-texture.

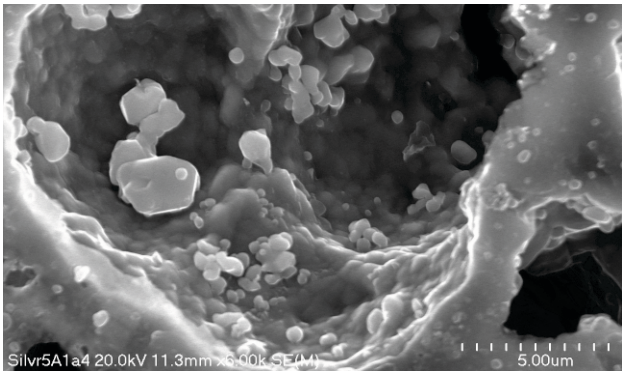

Fig. 2: FESEM image showing detail of biogenic micro-texture in Fig.1. The ZnS aggregate is composed of small mostly circular nanoforms. The smallest globules are ~100nm in size.

Microbially enhanced dissolution of pyrrhotite polytypes: surface roughness, reactivity and rates

Pollok, K.[1*], Hopf, J.[1], Harries, D.[1], Chust, T.[1], Hochella, M.F.[2] & Langenhorst, F.[1]
[1]Bayerisches Geoinstitut, Universität Bayreuth, Germany
([*]kilian.pollok@uni-bayreuth.de)
[2]Center for NanoBioEarth, Dept. of Geosciences, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, USA

Chemical and biological dissolution and oxidation of pyrrhotite ($Fe_{1-x}S$) can significantly contribute to acid mine drainage (AMD) from sulphidic mine heaps and tailings [1] which is an environmental concern to the water quality of ground and surface waters worldwide. Dissolution rates for this mineral are less constrained especially for biologically enhanced dissolution but they are always considerably faster compared to pyrite. An important complication for studies on pyrrhotite dissolution is the variable iron deficiency that results in various polytypes and superstructures which in turn affect surface reactivity. Furthermore, almost all natural pyrrhotites are intergrowths of different polytypes down to a submicroscopic scale which limits the ease of use of powders in bulk dissolution studies, but allows a direct comparison of surface reactivity in abiotic/biotic experiments.

Here, we show results adapted from completed dissolution experiments on natural pyrrhotite (Tysfjord, Norway) in presence of *Acidithiobacillus ferrooxidans* at pH 2 over 40 days which were conducted together with an abiotic control. The polished samples show an intergrowth of 1-3 µm wide lamellae of the ordered 2C type in a matrix of NC type. The lamellae are close to stoichiometric FeS (troilite) while the matrix contains about 2 wt% less iron. Abiotic pyrrhotite dissolution yielded almost no morphological changes on the mineral surface. In contrast, *Acidithiobacillus ferrooxidans* developed a thick whitish biofilm on the samples. The underlying mineral surface showed deep and extremely long trenches with a width of ca. 3.5 µm and a depth of several µm. Obviously, bacterial activity preferentially dissolved the more iron-rich lamellae of the 2C type pyrrhotite. However, whether this effect indicates a preference of the microorganisms to the higher iron content or an enhanced kinetic effect due to lower mineral stability is arguable.

To quantify the evolution of the altered surface area we used confocal microscopy which allows to collect 3D topographic data from a large field of view (160 x 160 µm) with a submicrometer resolution in x, y, and z. The approach of converged surface roughness parameters [2] was used to explore how different surface components impact roughness parameters over a range of lateral scales. The calculation of the surface roughness in relation to the size of the sampling area has been automated in order to minimize the bias of choosing 'representative' areas and to visualize the roughness distribution. Furthermore, the topographic data allow us to evaluate the difference in dissolution rates of the 2C and NC polytype which may offer a way to predict overall dissolution rates of complex pyrrhotite intergrowths.

Biomineralization of magnetite: implications in the search for life in Mars

Jiménez-Lopez, C.[1*], Perez-Gonzalez, T.[1], Valverde Tercedor, C.[1], Romanek, C.S.[2] & Bazylinski, D.A.[3]
[1]Dpto. Microbiología, Facultad de Ciencias, Universidad de Granada, Spain ([*]cjl@ugr.es)
[2]Dept. of Earth & Environmental Sciences, University of Kentucky, Lexington, Kentucky, USA
[3]School of Life Science, University of Nevada-Las Vegas, USA

Nanometer-sized magnetite (Fe_3O_4) crystals have been recovered from many modern and ancient environments and even meteorites. In some cases these crystals have been used as magnetofossils for evidence of the past presence of specific microbes. The rationale behind that is that magnetite nanocrystals can be formed by biological and inorganic mechanisms. Prokaryotes (bacteria) biomineralize magnetite through a biologically-induced mineralization (BIM) and biologically-controlled mineralization (BCM) [1]. Magnetite nanocrystals produced by BIM synthesized by the dissimilatory iron-reducing bacteria, are deposited external to the cell and generally are though to be indistinguishable from magnetite particles formed inorganically. BCM magnetites, in contrast, synthesized by the magnetotactic bacteria, are precipitated intracellularly as membrane-bounded structures called magnetosomes. These magnetites have unique properties, leading to their use as magnetofossils. Because of the discovery of nanometer-sized crystals of magnetite in the Martian meteorite ALH84001, the use of these criteria for the determination of whether magnetite crystals could constitute a prokaryotic biomarker was questioned. In this study we have formed BIM magnetite induced by *Shewanella oneidensis* and we have observed that organic material incorporates into the crystal structure, altering such a structure. This alteration could be used as a biosignature. Moreover, and regarding the inorganic pathway proposed by [2] for the formation of ALH84001 magnetites, based on the thermal decomposition of the carbonate matrix in which those magnetites are embedded, we have also demonstrated that: (1) the thermal decomposition of $(Fe,Ca,Mg)CO_3$ yields magnetites that incorporate Ca and Mg into their crystalline structure, and (2) such a decomposition is topotactic, conferring a specific structural relationship between the precursor ankerites and the newly formed magnetites as well as between the magnetite crystals (Fig. 1). Such a relationship differs substantially from that observed in the magnetosomes of the magnetotactic bacteria and from that of the ALH84001 magnetites. Therefore, the decomposition of the carbonate matrix does not explain ALH84001 magnetites.

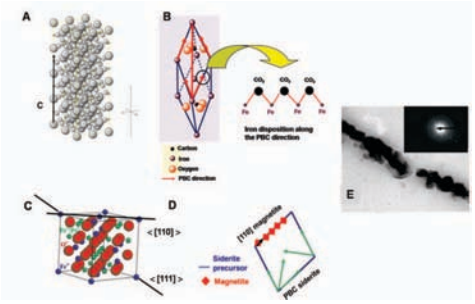

Fig. 1: A) Siderite cell unit; B) PBC directions and atomic distribution along those directions; C) Magnetite cell unit; D) Structural relationship between the precursor (siderite, in blue) and the product (magnetite, in red), and within the newly formed magnetite crystals; E) HRTEM image showing magnetite crystal formed by the thermal decomposition of an ankerite, aligned by facing their corners.

Characterization of ferric iron oxyhydrosulfate compounds precipitated in different cultivations of *Acidithiobacillus ferrooxidans*

Wang Xin, Li Yan, Lu Anhuai[*] & Wang Changqiu
School of Earth and Space Sciences, Peking University, Beijing, China ([*]ahlu@pku.edu.cn)

This study focused on the ferric iron oxyhydrosulfate compounds precipitated during the culture of *Acidithiobacillus ferrooxidans* in a modified 9K medium by applying a potential control on the electrode. X-ray diffraction (XRD), environmental scanning electron microscope (ESEM), Raman spectroscopy (Raman) and Fourier Transform Infrared spectroscopy (FTIR) were performed to characterize and identify the ferric iron oxyhydrosulfate precipitates formed, respectively, in the electrolysis cultivation using a fixed cathode potential (bias-experiment) and in the conventional batch cultivation without cathode potential control (no-bias-experiment).

The results showed that K-jarosite appeared in both experiments while NH_4-jarosite and schwertmannite were only turned up in the no-bias-experiment (Fig. 1). The formation of different precipitates was supposed to be attributed to the different growth status and rates of *A. ferrooxidans* and the different concentrations of Fe^{3+} (Fig. 2). In the bias-experiment, external electrons recycled Fe^{2+} promoting the growth of *A. ferrooxidans*, thus resulting in the low Fe^{3+} concentration and rapid depletion of NH_4^+ as the nitrogen source, in which K-jarosite was preferential to be formed. In the no-bias-experiment, the lower concentration of *A. ferrooxidans* was observed, which was due to the rapid consumption of Fe^{2+} by *A. ferrooxidans*, thus resulting in the relatively higher Fe^{3+} and NH_4^+ concentrations in culture. The high concentration of Fe^{3+} favored the precipitation of the solid solution of K-NH_4-H_3O jarosite and led to schwertmannite precipitation after K^+ and NH_4^+ were depleted.

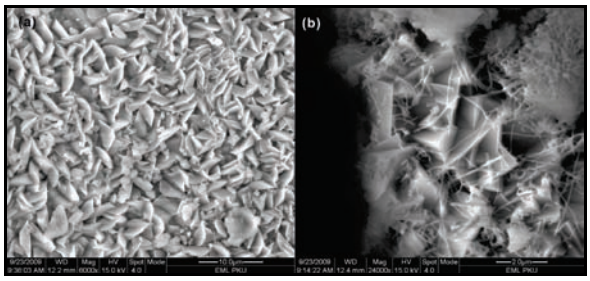

Fig. 1: ESEM images of the precipitates obtained in bias- (a) and no-bias- (b) experiments.

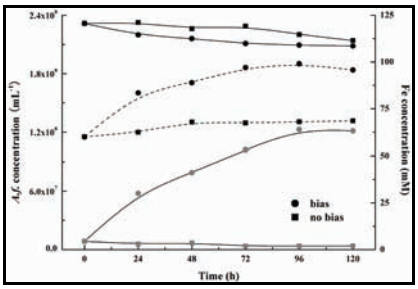

Fig. 2: *A. ferrooxidans* growth curves and ferrous/total ferric concentrations in the bias and no-bias experiments (black solid dots - ferric, gray solid dots - ferrous, solid lines - Fe concentration, dash lines - *A.f.* concentration).

Iron biomineralization by neutrophilic iron-oxidizing bacteria

Miot, J.[1], Benzerara, K.[1*], Morin, G.[1], Kappler, A.[2], Obst, M.[2] & Brown, G.E. Jr.[3]
[1]IMPMC, IPGP, Paris, France
([*]karim.benzerara@impmc.jussieu.fr)
[2]Geomicrobiology Center for Applied Geoscience, ZAG, University of Tuebingen, Germany
[3]Surface & Aqueous Geochemistry Group - Stanford University, Stanford & SSRL, Menlo Park, CA, USA

The processes of Fe biomineralization induced by Fe(II) bio-oxidation at neutral pH under anoxic conditions remain poorly understood. We present here a spectro-microscopic study of the biominerals produced by the nitrate-reducing iron-oxidizing bacteria Acidovorax sp. strain BoFeN1 cultured in the presence of dissolved [1] or solid Fe(II) [2]. We present also for comparison a spectromicroscopy study of the biominerals produced by the phototrophic iron-oxidizing Rhodobacter sp. strain SW2 [3]. As characterized by bulk X-ray Absorption Spectroscopy (EXAFS), the final products of Fe(II) oxidation consisted of amorphous Fe(III)-phosphate in the presence of BoFeN1 and goethite in the presence of SW2. Transmission Electron Microscopy (TEM) and Scanning Transmission X-ray Microscopy (STXM) highlighted the progressive periplasmic encrustation of BoFeN1 cells by iron minerals, accompanied by an accumulation of protein moieties while precipitates form outside SW2 cells. For both SW2 and BoFeN1 cells, extracellular iron precipitated in association with exo-polysaccharides. For BoFeN1, solid Fe(II) (composing extracellular abiotic vivianite precipitates formed during medium preparation) was partly oxidized with a few day delay compared to dissolved Fe(II). For SW2 Fe redox gradients were observed around the cells. This led to strong redox heterogeneities at the nano-scale within the sample. Direct or indirect mechanisms can be proposed to account for these observations. All these findings provide new information to further the understanding of molecular processes involved in iron biomineralization by anaerobic iron-oxidizing bacteria.

Microbially-mediated uranium reduction: role of solutes and biomolecules in product formation

Bernier-Latmani, R.[*], Alessi, D.S., Uster, B., Dalla Vecchia, E., Suvorova, E.I., Lezama-Pacheco, J.S., Bargar, J.R. & Persson, P.
Environmental Microbiology Laboratory, Ecole Polytechnique Federale de Lausanne, Switzerland
([*]rizlan.bernier-latmani@epfl.ch)

Uranium is a contaminant of concern at a number of sites around the world as a result of mining, milling and processing of the radionuclide for nuclear weapons and fuel production. Uranium is typically encountered in the hexavalent valence state in these contaminated sites. This is particularly problematic because U(VI) is very soluble and can thus be quickly transported off site via groundwater flow. Microbially-mediated U(VI) reduction is considered as a potential strategy for the immobilization of uranium *in situ*. It relies on the natural activity of a variety of metal- and sulfate-reducing bacteria and the formation of U(IV) species that are less mobile than U(VI) species. Previous work [1] has shown that the product of microbially-mediated U(VI) reduction varies as a function of the chemical composition of the reduction medium. The products identified to date include the mineral uraninite (UO_2), the mineral ningyoite ($CaU(PO_4)_2$) and sorbed U(IV) species referred to as molecular U(IV).

This work explores the role of inorganic solutes such as Ca^{2+}, Mg^{2+}, NH_4^+ and PO_4^{3-} as well as biomolecules such as extracellular polymeric substances (EPS), phospholipids and lipoteichoic acids in the formation of reduced uranium products as a result of microbial U(VI) reduction. In particular, we tackle the question of whether nucleation and precipitation of U(IV) minerals is controlled directly by the chemical composition of the medium or by biological effects induced/caused by the chemical composition of the medium.

We use a variety of techniques to characterize the product of U(VI) reduction under the conditions considered including a selective chemical extraction method that we developed [2], electron microscopy, x-ray absorption spectroscopy and Fourier transform infrared spectroscopy to interrogate the role of solutes and biomolecules in UO_2 formation or inhibition.

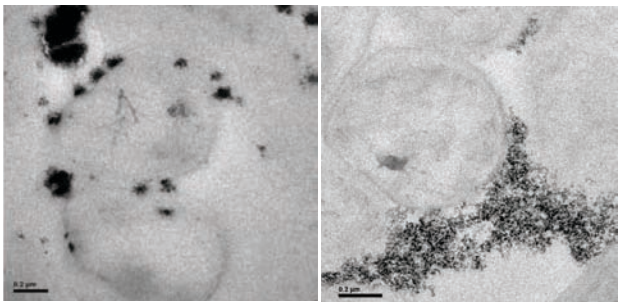

Fig. 1: Transmission electron micrographs of *Shewanella oneidensis* MR-1 cells after U(VI) reduction under variable chemical conditions. In the right panel, the product is a sorbed species molecular U(IV) species and in the left panel is the mineral UO_2. Morphological differences between the sorbed species and the mineral are readily observable.

Mycomineralization: fungal deterioration and transformation of metal and mineral-based substrates

Gadd, G.M.* & Fomina, M.
Division of Molecular Microbiology, College of Life Sciences, University of Dundee, Dundee, Scotland, UK
(*g.m.gadd@dundee.ac.uk)

"Geomycology" can be considered a subset of "geomicrobiology" and simply defined as the impact of fungi on geological processes, including the alteration and weathering of rocks and minerals, the accumulation of metals, and their roles in element and nutrient cycling. Although the main focus of geomicrobiology is on prokaryotes, it is clear that epi- and endolithic fungi comprise a significant component of the microbiota in a range of rocks and mineral-based substrata. Our research seeks to understand the mechanisms of metal and mineral biotransformations, and their environmental and applied significance in bioremediation and biodeterioration. This presentation will include examples of our research on fungi inhabiting certain rock types, soil, including the mycorrhizosphere, particularly regarding mineral dissolution and transformation, and the formation of secondary mycogenic minerals. An important mechanism of metal mobilization from minerals is a combination of acidification and ligand-promoted dissolution: if oxalic acid is produced, the production of metal oxalate biominerals may result. In other cases, mobilized metal species may interact with phosphate. Examples outlined in this presentation will include fungal communities and roles in degradation and transformations of rocks and metal-containing minerals, depleted uranium and uranium oxides, and fungal biodeterioration of concrete, the latter being of general biodeteriorative significance regarding built concrete structures.

Assessing the contribution of acidolysis and complexolysis in the microbial dissolution of colloidal size silicates particles

Grybos, M.[1,3*], Billard, P.[1], Desobry, S.[1], Michot, L.[2] & Mustin, C.[1]
[1]LIMOS (Lab. des Interactions Microorganismes-Minéraux-Matière Organique dans les Sols), UMR 7137 CNRS, Vandoeuvre-lès-Nancy, France
[2]LEM (Lab. Environnement et Minéralurgie), UMR 7569 INPL & CNRS, ENSG, Vandoeuvre-lès-Nancy, France
[3]GRESE (Groupement de Recherche Eau Sol Environement), Université de Limoges, France (*malgorzata.grybos@unilim.fr)

In soils and near subsurface environments, heterotrophic bacteria play an important role in the dissolution of colloidal-size mineral particles. They accelerate mineral dissolution directly through the acquisition of limiting nutrients from mineral surfaces or indirectly through the release of metabolic by-products that can lower pH, thereby enhancing proton-promoted dissolution and/or withdraw cationic constituents from the mineral lattice through the complexation (1). To assess the respective role of acidolysis and complexolysis processes in the microbial dissolution of colloidal-size mineral particles, we performed controlled incubations of 600 nm length and 60 nm width particles of Fe-rich phyllosilicate (nontronite, NAu2) in the presence of a set of phylogenetically diverse heterotrophic soil bacteria. To prevent any uncontrolled particle aggregation and adsorption onto bacterial cells, the colloids were homogeneously dispersed in a biologically friendly, porous TEOS-derived silica gel by a sol-gel procedure (2).

The results showed that NAu2 incubation in presence of bacteria released from 0.1 to 2% of the total Fe and was accompanied by a pH decrease. Higher Nau2 dissolution rates were observed for highly acidifying bacteria. For a given pH value, the amount of released Fe varied between the strains and was two to ten fold greater than under abiotic conditions (i.e. HNO_3) indicating that complexing metabolites play an important role in the overall dissolution process. We conclude that the dominant mechanisms by which Nau2 was dissolved was complexolysis accounting from 50 to 90% of the total Fe released in the solution.

A novel solar-powered device for studying the synergistic effects of natural semiconducting minerals and microorganisms

Lu Anhuai*, Li Yan & Wang Changqiu
School of Earth and Space Sciences, Peking University, Beijing, China (*ahlu@pku.edu.cn)

Microbial fuel cell (MFC) is a popular bio-electrochemical device in which microorganisms catalyze electrons transport from avaible substrates towards terminal electron acceptors through a circuit containing a solid-state anode, an external load and a cathode. Photofuel cell (PFC), which consists of a semiconductor photoanode and a species-reducing cathode, is the similar electrochemical device as the operation of MFC. Enlightened by both MFC and PFC, we reported here a novel solar energy-powered device (Fig. 1), which realized the biocatalytic oxidation (anode) and photocatalytic reduction (cathode) of pollutants while producing electrical energy.

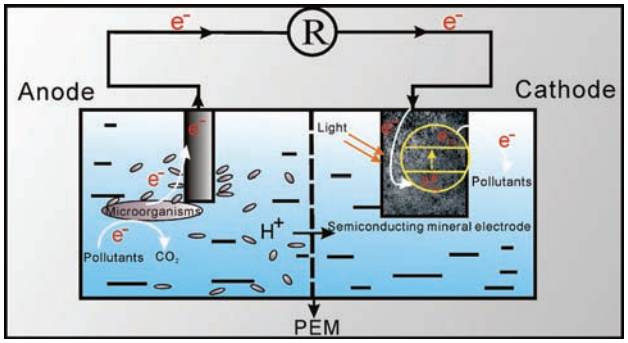

Fig. 1: The configuration of the solar-powered device by using natural semiconducting minerals as cathodic catalysts for wastewater treatment and electricity generation.

In this device, a class of semiconducting mineral-based catalysts (rutile, sphalerite, pyrrhotite) were used as the cathodes. The open circuit voltage (V_{OCV}), maximum power density (P_{max}), fill factor (FF), incident monochromatic photon to current conversion efficiency (IPCE) and coulombic efficiency (CE) was calculated to characterize and compare the performance of the device by using different minerals. Then, the influences of mineral species, cathode fabrication methods, terminal electron acceptors, pH and equipment configuration on the power output were discussed. Further experiments were conducted to evaluate its prospects in environmental application. The results showed that a solar photocatalytic treatment of a broad range of pollutants (e.g., hexavalent chromium, chlorinated ethenes, azo dyes and landfill leachate) was achieved.

This kind of solar-powered device offered a potential strategy for strengthening pollutant treatment and simultaneously harvesting electricity. In order to distinguish this novel system from the conventional MFC and PFC, we refer to this system as the bioelectrochemical-photoelectrochemical cell (BPC). BPC is driven by solar energy and believed to be effectively applied in environmental fields, because it succeeds in arranging energy flow between two different pollutants via two different catalytic mechanisms.

Quantification of plant-driven fungal alteration at the surface of biotite

Bonneville, S.[1*], Morgan, D.[1], Bray, A.W.[1], Duran, A.[2], Brown, A.[3], Schmalenberger, A.[4], Gonzales-Romero, M.[4] & Benning, L.G.[1]
[1]School of Earth and Environment, University of Leeds, UK (*earscb@leeds.ac.uk)
[2]Institute for Materials Research, University of Leeds, UK
[3]Dept. for Animal and Plant Sciences, Univ. of Sheffield, UK
[4]Kroto Research Institute, University of Sheffield, UK

Initially thought mainly in term of abiotic dissolution reactions, weathering science now integrate the role of plant and their root associated micro-organisms. In particular, mycorrhiza (fungi in mutualistic symbiosis with roots) are the object of intense research because of their position at the interface between the lithosphere and biosphere. Fuelled by a significant fraction of energy from plant photosynthesis, fungi expand into soils via a vast network of microscopic filaments (5 µm in width and up to 1 mm in length). The mycelium developed around the roots is responsible for extracting and transfering a large spectrum of elements and nutrient to the plant. In doing so, mycorrhiza alter rock-forming minerals and help form our soils. Here, we present the results of a liquid-free culture in which a freshly-cleaved biotite flake was exposed for three months to a fungus (*Paxillus involutus*) grown in symbiosis with a tree (*Pinus sylvestris*) under controlled but close-to-natural conditions. Fungal hypha, similar to the majority of soil microbes, strongly adhere to and interact with the mineral surface (Fig. 1).

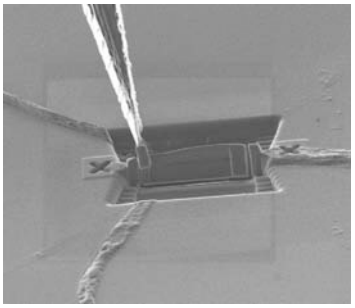

Fig. 1: Lift-off of the hypha-biotite ultrathin Focused Ion Beam (FIB) section from a biotite where the fungal strands were firmly attached. Scale bar is 20 µm.

Along a single hyphae, we sampled the interface between the mycorrhiza and the biotite using FIB (Fig 1) in order to capture the temporal evolution of the weathering process. The FIB sections were analyzed for mineralogical and chemical changes by TEM (SAED and STEM-EDS) and synchrotron-based STXM. Additionally, on a parallel incubation, the spatial distribution of functional groups along single hyphae was quantified using synchrotron µ-FTIR. Finally, confocal microscopy was used to determine the pH variations in the microenvironment near the hyphae.

Our results show that a mechanical constraint operates in the first stage of contact between hypha and biotite causing a mis-orientation of the most superficial 500 nm to 1µm of the mineral in contact with the hypha. In a later stage, significant export of elements from the mineral (namely K, Al, Mg and Fe) occurs concomitantly with a mineralogical transformation of the interfacial biotite into vermiculite and Fe oxide [1]. The pH measurement around the hypha revealed values between 4-5 and the µ-FTIR showed marked differences in functional group distribution along the hyphae. Using this dataset, a model based upon solid state diffusion in biotite was established which permit the first quantification of chemical alteration in relation to mycorrhizal and plant growth.

[4]Laboratoire Interface et Systèmes Electrochimiques , UPR 15 CNRS, Ivry sur Seine, France
[5] Laboratoire de Chimie et Microbiologie de l'Eau, UMR CNRS 6008, Poitiers, France

Enstatite chondrites (E chondrites) are the most reduced existing natural materials. Studying their aqueous alteration could provide useful data about the low temperature evolution of these potentially important Earth forming chondritic blocks. Moreover, finding specific signatures of their bio-alteration could be important for the astrobiological issue of detecting traces of life in such reduced materials. The aim of this study was thus to investigate the mineralogical and chemical processes which take place during the aqueous oxidative and acidic weathering of an E chondrite without or in presence of bacteria. Synthetic E chondrites were made in laboratory in order to begin this complex study with simplified and well-defined materials. Synthesis conditions of 0.8 GPa and 1473 K (4 to 7 days in a piston-cylinder apparatus) were suitable to achieve well-equilibrated E chondrite analogs. A simplified CI chondritic glass mixed with FeS and metallic Si was used as starting material. These analogs were shown to contain the major phases of E chondrites: enstatite, Si-rich kamacite, troilite, SiO_2 and unusual sulfides such as oldhamite or niningerite. In order to better understand the global E chondrite alteration, each major phase (also synthesized in a piston-cylinder apparatus) was separately submitted to aqueous alteration with or without bacteria.

Pure cultures of an iron oxidizing bacterium (*Acidithiobacillus ferrooxidans DSM 14882- DSMZ Germany*) and of a sulfur oxidizing bacterium (*Acidithiobacillus thioooxidans*), were used for the bioweathering experiments (42 to 48 days of weathering). Abiotic alteration was also systematically studied. All the experiments were buffered at pH of ≈2. The culture media were initially Fe and S-deficient in order to maximize the bacterial extraction of these elements from the starting solid material. All experiments were characterized before and after alteration using scanning electron microscopy (SEM), transmission electron microscopy (TEM), electron microprobe analysis, Raman spectroscopy and X-Ray diffraction. Compositions in major and trace elements were analyzed by inductively coupled plasma optical emission spectrometry (ICP-OES) in filtered leachates recovered from different bioweathering experiments.

Bacterial activity leads to the formation of P and S–rich biofilms on the minerals. The presence of the bacteria also modifies the chemical composition of the medium: ICP-OES data show that, in the leachates, the concentration of Si is lower in the biotic experiments than in the abiotic ones. The bacteria indeed restrict the dissolution of silicon from the minerals probably as a consequence of a protective effect of the biolfilms against the acidic solution. After weathering, monosulfides are no longer present in the samples showing their dissolution in the aqueous medium in both the bioweathering experiments and the abiotic controls. Important phosphate and sulfate precipitations from the interaction of the culture medium with ions dissolved from the minerals also occur. A thermodynamic and kinetic model rationalizing these observations will be discussed.

Synergistic effect of natural rutile and electricigens on azo dye decolourization

Ding Hongrui, Li Yan, Lu Anhuai[*] & Wang Changqiu
School of Earth and Space Sciences, Peking University, Beijing, China ([*]ahlu@pku.edu.cn)

Photocatalytically reductive decolorization of azo dye in wastewater was investigated in a dual-chambered electrochemical setup equipped with a rutile-coated cathode and a microorganism anode. When the visible light irradiated on the rutile-coated cathode, a rapid decolourization of a model azo dye, methyl orange (MO), was achieved, coupled by electrical energy generation. The electrochemical impedance spectra (EIS) showed the polarization resistance (R_p) of the rutile-coated cathode decreased by 67.8 % from dark to light (Table 1), indicating the photocatalysis of rutile-cathode can enhance the electron transfer process and promote the cathodic reduction.

Table 1: Fit parameters for EIS of the graphite and rutile-coated cathode under different light controls.

Parameter	Rutile-coated cathode		Graphite cathode	
	Light	Dark	Light	Dark
R_p (Ω)	443.4	1378	1429	1844
R_s (Ω)	2.706	1.336	6.063	6.922

As compared with the sole biocatalysis by microorganisms or photocatalysis by rutile, the co-catalysis of electrons transfer by microorganisms in the anode and natural rutile in the cathode resulted in higher MO degradation efficiency and more power generation. By analyzing the decolorization products with UV-Vis spectra, the azo bond of MO was fully cleaved due to the photocatalytic reduction of natural rutile (Fig. 1).

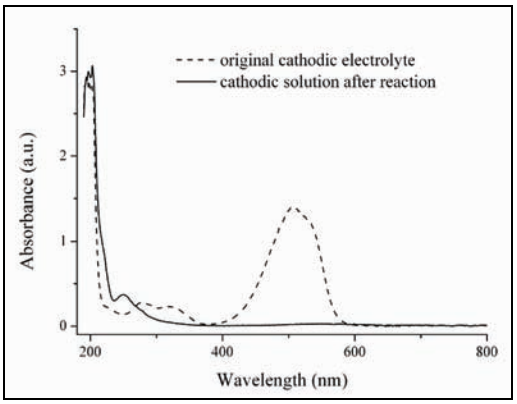

Fig. 1: UV-Vis spectra of cathodic electrolytes when using an irradiated rutile-coated cathode.

This research provided insightful viewpoint of integrating a bioelectrochemical process with a photoelectrochemical process, which offered a novel and cost-effective remedy for treating azo dye wastewater with simultaneous electrical power generation.

Minerals dissolution: from ions to eukaryotes

Gazze, A.S.[1*], Saccone, L.[1], Ragnarsdottir, K.V.[2] & McMaster, T.J.[1]
[1]H.H. Wills Physics Laboratory, University of Bristol, UK ([*]andrea.gazze@bristol.ac.uk)
[2]Institute of Earth Sciences, School of Engineering and Natural Sciences, University of Iceland, Reykjavik, Iceland

Atomic Force Microscopy (AFM) was used to visualize the effects of a wide range of weathering agents, from protons to filamentous fungi, on phyllosilicates. The effects of protons and oxalate on the basal and {hk0} surfaces of these minerals have been followed in *real-time*. On biotite, weathering process consisted in the retreat of {hk0} surfaces and in the formation of etch-pits on basal surface. For the first time, we have been able to follow the dynamics of the formation of etch-pits which consisted in a progressive removal of the first tetrahedral layer, followed by the octahedral and then the second tetrahedral sheet. The removal of the first tetrahedral layer takes place through the detachments of building blocks, suggesting that some Si-O-Si bonds are not broken. The presence of the underlying octahedral layers also implies that even if some cations could have been removed, this layer is still present before the removal of the first tetrahedral sheet.

AFM have been also used to extensively characterize an ectomycorrhizal fungus, *Paxillus involutus*, colonizing mineral surfaces. Basal surfaces of both biotite and chlorite present channels created by the fungus. High-resolution imaging allowed us to detect channels that are only one basal layer deep (1.5 nm) and to identify non-mineral material, probably of fungal origin, associated with the channels. The latter often presented lateral, smaller channels. While the central part of hypha could be involved in the formation of the main channels, the lateral channels could participate to their enlargment.

Here we show how the direct visualization of mineral surfaces during weathering processes is fundamental in order to interpret the possible mechanisms involved in the process, both at the atomic (protons on surface) and multicellular (fungi on surface) levels.

Photocatalytic reduction of carbon dioxide by natural sphalerite in a bioelectrochemically assisted reactor

Li Yan, Lu Anhuai[*] & Wang Changqiu
School of Earth and Space Sciences, Peking University, Beijing, China ([*]ahlu@pku.edu.cn)

Mineral-microbial interactions and their role in energy transformation play an important role in the earth surface. This paper presents a novel viewpoint of interactions between semiconductor minerals and microorganisms. Electron transfer pathways were hypothesized for such interactions. During the electron transfer, photogenerated electron-hole pairs can be well separated by accepting/donating electrons from/to microorganisms. On one hand, microorganisms could gain energy from oxidation of organic/inorganic compounds and use visible light-excited semiconductor minerals as electron acceptor for the electron transport chain. The separated photoelectrons of semiconductor minerals could be used to photo-reduce carbon dioxide.

Experiments were conducted to demonstrate the proposed viewpoint. In a dural-chambered electrochemical equipment, natural sphalerite was employed as a photocatalyst in the cathode to reduce carbon dioxide, while electrochemically active bacteria was involved in the anode to provide driving force to separate photogenerated electron-hole pairs. With the addition of a small voltage between the anode and the cathode, carbon dioxide was photoreduced at the sphalerite cathode. The effects of various experimental paraments, e.g., amount of sphlaerite, additional voltage, catholyte species, pH, light intensity and reaction time were investigated. Further, the mechanism of carbon dioxide reduction was proposed basing on the analysis of intermediates and products.

Cyanobacterial calcite cementation in a tidal channel of the Bay of Cádiz Natural Park: a field experimental study

Mata, M.P.[1*], García Robledo, E.[2], Corzo, A.[2], Jimenez Arias, J.L.[2] & Perez-Outeiral, F.J.[2]
[1]Dept. Investigación y prospectiva geocientífica, Instituto Geológico y Minero de España, Tres Cantos, Madrid, Spain
([*]p.mata@igme.es)
[2]Dept. Biología, Fac. Ciencias del Mar y Ambientales, Universidad de Cádiz, Puerto Real (Cádiz), Spain

Beachrocks are formed in the intertidal zone by a rapid cementation of sandy beach sediments. The proposed origins are: physico-chemical or biological processes being the last one related to micro-environments created by microbial metabolisms. Carbonate crusts located along a tidal channel close to a hypersaline tidal lagoon in the Bay of Cádiz Natural Park (Spain) have been studied to determine their formation mechanism. In order to differentiate between the effects of physico-chemical or microbial processes that give rise to beachrock-like concretions, an experimental field study has been performed.

Carbonate crust is found at the bottom of a tidal channel and occurs making up to centimetric-thick consolidated fragments. The petrographic and mineralogic study has been done by means of XRD and SEM study of fragments and polished thin sections, and show that the crust is made of coarse calcite crystals cementing sandy sediments and biogenic debris with minor authigenic pyrite and clay crystals.

The field experimental study has been conducted during a period of a month and a tidal cycle in four different locations along the channel. A series of glass slides, where a carbonate-free sandy substrate was added, were located on the surface of the tidal channel and a posterior mineralogical and textural study was done. SEM images of the slides showed a fast growing (in the order of days) of calcium carbonate crystals, as indicated by EDS and XRD analyses. The precipitates are composed of uniform micron-size calcite crystals and are clearly related to cyanobacterial and exopolymer remains.

The results of the microelectrodes study, made on the marginal sediments of the channel, reveal also an incipient calcification process and show how the photosynthetic activity of biofilms dominated by cyanobacteria and diatoms growing in the sediment surface seems to control the calcite precipitation on the intertidal sediments.

Well cemented older fragments from the inner part of the channel, may have the same origin and therefore have undergone several diagenetic phases, each one producing calcite cements exhibiting evolved textures and where biological remains and smaller calcite crystals are absent. Active currents of a tidal channel can erode, broke and move the calcified marginal sediments and place them in a different chemical environment leading to an evolution in a diagenetic context different of which they were formed. From this experiment, biological processes such as bacterial mat developments may control calcification processes and can be more important in beachrock formation on marsh areas than previously considered as proposed by several previous studies in other coastal environments.

Hematite formation catalyzed by organic matter in banded iron formations

Orberger, B.[1*], Wagner, C.[2], Wirth, R.[3], Derré, C.[2], Quirico, E.[4], Montagnac, G.[5], Noret, A.[1], Jayananda, M.[6], Massault, M.[1] & Rouchon, V[7]

[7]IFP, Rueil Malmaison, France

Carbonaceous matter is rarely detected intergrown in Fe-(Mn) oxides and its origin and role in the formation and subsequent transformation of BIFs is little discussed and/or understood. For the first time, carbonaceous matter was detected in hematite spherules hosted in one of the thickest (~ 500 m) mid-Archean (2.9 Ga) banded iron formation from the Dharwar craton in Southern India. The BIF is composed of millimetric to centimetric alternating quartz and iron oxide bands. The mineral paragenesis at the time of deposition is still present as relicts and consisted of quartz, magnetite, Fe-sulphides and Ca-Mg or Fe-Mg-carbonates. The iron oxides evolved from magnetite into martite (hematite), but occur also as hematite spherules in microquartz cavities. Carbonaceous matter of semi-anthracitic maturity and low N/C ratios occurs encapsuled in the quartz grains and hematite spherules, and of lower maturity degree (higher N/C ratios), as wall fillings of the cavities. The carbone isotopic composition ($\delta^{13}C$) of the total CM ranges from -19.98 to -26.15 ‰ and indicates an organic origin, although no distinction is possible between mature and immature organic matter. The fertilizing conditions during the BIF formation were favorable for plankton production, which was later mainly remineralized in the water column. Relict organic matter was incorporated within the magnetite layers and in the adjacent quartz grain, and it was transformed into semi- anthracite during the greenschist facies metamorphism at ~2.5 - 2.6 Ga. Post-metamorphic oxidizing hydrothermal fluids of about 150°C, circulated preferential along permeable zones, martitized most of the magnetite, and dissolved interstitial carbonates and sulphides leaving cavities behind. These isolated or connected cavities compartmentalized the Fe-rich fluids, which supersaturated, precipitated abiotically hematite spherules around the semi-anthracite. Organic matter served as a catalyzer and hematite as a protector against organic matter complete oxidation. Immature organic matter was introduced after the hematite spherule formation either during paleo-or modern weathering.

Biomineralization of iron and calcium: their role in biogeochemical processes of sedimentary sequences in the coastal sector of the Argentine Pampean Plains

Osterrieth, M.
Instituto de Geología de Costas y del Cuaternario, FCEyN – UNMdP, CC 722, Mar del Plata, Argentina
(mosterri@yahoo.com.ar)

The biomineralizations present in every level of the biosphere are the result of the metabolic function of the biota. The goal of this paper is the mineral-chemical characterization of the biomineraizations of iron and calcium in pedosedimentary sequences in the south east sector of the Pampean Plains of the province of Buenos Aires. Work was completed on meso-, micro- and sub-microscopic scales on disturbed and undisturbed samples. Biomineralizations of iron we found in the form of framboidal and polyframboidal pyrite, greigite, mackinawite and iron oxyhydroxides associated with gypsum, barite, calcite and halite, which permit us to define the redoxymorphic conditions in paleoestuary pedosedimentary sequences [1,2]. The biofilms are recurrent, which is a product of the intense microbiological and multifunctional activity. Besides the development of the ability to precipitate minerals, these organisms have also acquired the ability to dissolve or erode minerals; the bioerosion occurs on the surface, in the cracks and through the direct perforation in the interior of the minerals and/or biominerals. This is how the biomineralizations of calcium we found in the bioclastic and calcretized levels, associated with the processes of dissolution and reprecipitation of calcium carbonates and oxalates via biogenic action. The genetic sequence of the calcite was defined via weddellite and whewellite associated with biomineralizing hyphas and bacteria in the soil. The morphology and mineral chemistry would indicate different origins, within the fungi biomineralization of the process, coexisting in the same pedosedimentary levels. Also present were calcified bacteria in the micro and mesopores and the matrix of the peds of calcium and petrocalcium horizons of the alluvial paleosoils. These biomineralizations demonstrate the complex biogeochemistry that occurs in the temperate-wet paleoesturaries of the Pampean Plains. Furthermore they contribute to a greater comprehension of the significant effects of microorganisms on the mineral texture, microstructure and on the biogeochemistry of the surrounding microenvironment and they transfer to present-day and past environments.

Use of hybrid silica gels containing natural clay colloidal particles for bioweathering kinetic study versus abiotic process

Oulkadi, D., Billard, P., Grybos, M., Mustin, C. & Desobry, S.*
LIMOS (Laboratoire des Interactions Microorganismes-Minéraux-Matière Organique dans les Sols), UMR 7137 CNRS, Université Henri Poincaré, Vandoeuvre-lès-Nancy, France
(*sylvie.desobry@limos.uhp-nancy.fr)

It is well known that silicates dissolution by microorganisms is related to proton, organic acids and other metabolites production [1-4].

In order to precise role of bacteria in dissolution by comparison with the abiotic process and to characterize the mechanisms involved, artificial materials were used in this study. They consisted in natural colloidal clays particles homogeneously dispersed in TEOS-derived silica gels [5].

Montmorillonite and nontronite size-selected particles were the species chosen for bioweathering kinetics by soil bacteria. Cultures of pure strain were performed in batch or in Petri dishes with clays-gels in minimum salt medium and with glucose as sole carbon source.

The interactions of microorganisms with minerals were analyzed by comparison with cultures minerals-deprived and abiotic conditions (HNO_3). For these Fe-rich phyllosilicates, iron dissolution was used as bioweathering indicator. Organic acids profile was analyzed by ionic chromatography and an O-CAS method was performed for siderophore detection.

The results showed a larger iron dissolution under biological conditions than in abiotic conditions for a moderate pH variation down to pH 4,0. The organic acids mainly produced in these conditions were lactate, acetate, citrate, pyruvate, oxalate, and gluconate. They were proposed to play a major role in the bio-dissolution process by complexolyse.

[4]Université de Poitiers, Poitiers, France

[5]Nancy Université-INPL, Vandoeuvre-les-Nancy, France

Although relatively abundant in Earth materials, the effect of Mg in bioalteration processes is not well known. In this study, we investigated the biotic vs abiotic alteration processes of glasses of variable polymerization degree and Mg coordinance [1] (Na_2O-MgO-$2SiO_2$, Na_2O-0.9MgO-0.1FeO-$2SiO_2$, Na_2O-MgO-$3SiO_2$, Na_2O-0.9MgO-0.1FeO-$3SiO_2$, K_2O-MgO-$2SiO_2$, K_2O-MgO-$3SiO_2$).

The synthesis of the silicate glasses were performed in a vertical furnace allowing a fast and reproducible quenching rate and the use of a variable atmosphere (H_2, air or O_2). Glasses were prepared either as sections polished down to 3□m (SEM observations) or as powders of controlled granulometry (kinetic experiments). The specific area of powders was characterized by BET experiment using Kr gas. The samples have been bioweathered by *Pseudomonas aeruginosa* (Psa) under conditions similar to the natural environment (pH 7.8 and 20 °C). Psa was chosen because it is widespread in nature and because of its ability to form biofilm on solid surfaces [2]. Two kinds of experiments were performed. (i) Short term experiments were performed during 14 days without renewal of the growth medium aiming at the monitoring of the kinetic of glasses element leaching (ii) Long term experiments have been performed in order to study the rates of dissolution of these glasses in batch mode in presence and absence of microbial activity. In both cases, Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) has been used to determine aqueous concentrations for the calculation of dissolution rates normalized to the initial specific surface of the studied materials.

As expected the alteration was more intense for disilicate glasses than for trisilicates in biotic and abiotic conditions. Concerning microbial activity, it strongly modified the leaching kinetic and the solubility of the leached elements expected to precipitate with the medium compounds. The leached surface was analysed by Scanning Electron Microscopy-Energy Dispersive Spectrometry, μ-Raman and μ-XANES measurements at the Mg *K*-edge.

X-ray powder diffraction analysis of biogenic manganese and iron oxides

Seyama, H.[1*], Watanabe, J.[2], Miyata, N.[3], Tani, Y.[2] & Iwahori, K.[2]

[1]National Institute for Environmental Studies, Ibaraki, Japan ([*]seyamah@nies.go.jp)

[2] University of Shizuoka, Shizuoka, Japan

[3] Akita Prefectural University, Akita, Japan

Various microorganisms such as bacteria and fungi in aquatic environments have the ability to produce minerals (micro-biomineralization). Biomineralization is an important geochemical process to control deposition of elements composing the biominerals. In addition, a number of biominerals produced by microorganisms are fine particles having large reactive surface areas and highly effective scavengers of a variety of metals and molecular species in natural systems. Therefore naturally occurring biominerals play important roles in the geochemical cycling of elements on the earth's surface. In this study, we will report characterization of biogenic manganese and iron oxides by X-ray diffraction (XRD) analysis. X-Ray diffraction patterns of powder samples, deposited on a low background quartz plate, were recorded using a Rigaku ultima+ diffractometer with a Cu X-ray source.

Biogenic manganese nodules (5 - 20 mm) collected from the ground water in the Oppu mine, Aomori, Japan were preserved in water. The wet manganese nodule sample was powdered and examined by XRD. Its XRD pattern showed characteristic diffraction lines (d = 0.98 and 0.49 nm) of phyllomanganate with a 1 nm d-spacing (buserite). After air-drying for 10 days, these two lines of the wet sample disappeared and new diffraction lines (d = 0.72 and 0.36 nm) were observed, suggesting the formation of phyllomanganate with a 0.7 nm d-spacing (birnessite) due to the loss of interlayer water. This transformation of buserite into birnessite was irreversible dehydration.

Biogenic manganese oxides were produced by repeated-batch cultures of Mn(II)-oxidizing microorganisms with dissolved Mn(II). Fresh water epilithic biofilms were collected in the Kikukawa river system, Shizuoka, Japan and used as the initial inocula. Suspended manganese oxide deposits containing biomass, which were accumulated in the reactor for a few hundred days, were analyzed by XRD after separation and drying. Weak broad diffraction lines (d = ~1, ~0.5, 0.25 and 0.14 nm) were recorded in XRD patterns of the manganese oxide samples, indicating the formation of poorly crystallized phyllomanganate (buserite) by the Mn(II)-oxidizing microorganisms.

Biogenic iron oxides were produced by enrichment cultures of Fe(III)-reducing microorganisms with ferrihydrite under anaerobic condition. Sediment containing Fe(III)-reducing microorganisms was taken from Lake Sanaru, Shizuoka, Japan and used as the initial inocula. After cultivation for 3 - 14 days, ferrihydrite was reduced, resulting in the formation of magnetic iron oxides. The detected XRD lines of the biogenic iron oxide samples were broad, but characteristic of spinel group. Their interplanar spacings (d-values) were somewhat smaller than those of magnetite and comparable to those of maghemite (gamma-Fe_2O_3) suggesting the reduction of ferrihydrite to magnetite through maghemite by the Fe(III)-reducing microorganisms.

Role of heterotrophic bacteria on enhanced weathering of metallurgical slags: a chemical and mineralogical study

van Hullebusch, E.[1], Avril, C.[1], Romero Sanchez, S.[1], Combes, R.[1], Borensztajn, S.[3], Gauthier, A.[2], Labanowski, J.[4] & Rossano, S.[1*]

[4]Laboratoire de Chimie et Microbiologie de l'Eau, Université de Poitiers, France

Metallurgical activities generate high amount of industrial wastes bearing heavy metals. In most cases these wastes, partially vitrified during the metallurgical process, are landfilled or recycled. However, in the vicinity of former metallurgical plants sprawling abandoned slag heaps are prone to weathering. The tow studied slags come from a former metallurgical factory (Noyelles-Godault, Northern France) and were generated by the processing of lead and zinc ores, were studied. As lead and zinc ores are often mixed, the production of primary lead leads to the production of some primary zinc and vice versa. Therefore, the slags contain both lead and zinc but in different amounts. Our research uses a slag produced in the smelting of zinc using an imperial smelting furnace, termed the ISF slag, and a slag produced in the smelting of lead using a lead blast furnace, termed the LBF slag. Despite being the by-product of a lead production system, LBF slags (11 wt% ZnO and 3.5 wt% PbO) contain twice the amount of zinc of the ISF slags (7 wt% ZnO and 1 wt% PbO). LBF and ISF slags are granulated heterogeneous wastes. They are mostly composed of an iron–silica–lime glass matrix (80 vol.%), which still contains high quantities of lead and zinc. In order to mimic soil weathering conditions, LBF and ISF slags were submitted to a 6 months batch leaching procedure in bacterial growth medium solutions, in presence of a pure heterotrophic bacterial strain (*Pseudomonas aeruginosa*). This study presents a detailed description of the slag leaching kinetics up to reach equilibrium conditions. ICP-AES and SEM-EDS measurements have been used to monitor the evolution of the water chemistry and the slags (compositions and textures) during the experiments.

The leaching in both sterile and inoculated growth media showed that the microbial activity strongly increases the leaching of the dissolved Fe, Si, Ca, Mg concentrations. This higher release is ascribed to the presence of microbial complexing molecules. In contrast, the dissolved Pb concentration was much lower in the cultivated medium compared to the sterile medium. However, it was shown that most of lead release in the liquid phase was scavenged by the bacterial cell membrane which finally displays higher total lead content in the liquid phase compared to the sterile medium.

The ISF and LBF bioweathered slags samples were microscopically characterized and displayed that microscale mineral structure influences the weathering of specific area. In addition, the leaching experiments were coupled with the Visual-Minteq speciation-solubility modelling and mineralogical study of newly formed products (SEM/EDS and XRD).

Microbial community associated with Late Cenozoic desert varnish in Hungary

Varga, G.[1], Kovács, J.[2]* & Fábián, S.Á.[1]

[1]Dept. of Physical Geography, University of Pécs, Hungary

[2]Dept. of Geology, University of Pécs, Hungary

([*]jones@gamma.ttk.pte.hu)

Desert or rock varnish is a dark patina on stable rock surfaces in arid to semi-arid regions of the world [1]. Such coatings represent a fine mixture of clay minerals and Fe–Mn oxyhydroxides, which form micrometer-thick laminations that parallel the topography of the rock substrate [2]. The microbial diversity associated with desert varnish collected from Lower–Middle-Pleistocene sand in Hungary was investigated using SEM method.

It has often been suggested that the process of varnish formation may be microbially mediated. In the biogenic model, it has been shown that some adventitious Gram-negative bacteria, Gram-positive bacteria, and microcolonial fungi (MCF) that live on the surfaces of rocks can take manganese particles from atmospheric dust and oxidize them.

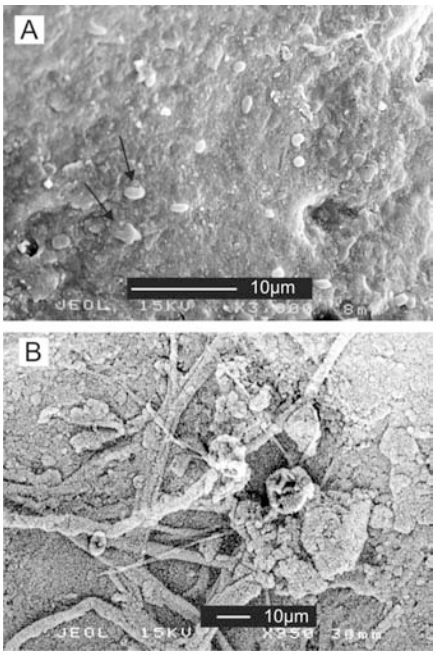

Fig. 1: SEM micrographs showing various morphologies of Mn-enhanced bacterial forms. The cocci "bacteria" in (A), and the hyphae "fungi or MCF" in (B).

Scanning electron micrographs of rock varnishes from Hungary show the surface of varnish to be inhabited by fungi and bacteria (Fig. 1). Perry et al. [3] have shown that MCF mineralize over time and as they degrade their appearance and chemistry becomes indistinguishable from varnish coatings. Large amounts of exopolymeric substances (EPS) are produced by the colonies. MCF become coated with detritus over time. Small wind-blown clay platelets can be oriented by EPSs (polysaccharides) and perhaps the encrustation of these grains and mineral plates provides additional protection from light and heat.

Our investigations have shown that MCF and various bacteria still play an important role in further development of relict desert varnish.

Growth of *Acidithiobacillus ferrooxidans* in the presence of natural limonite

Yan Yunhua, Li Yan, Lu Anhuai* & Wang Changqiu
School of Earth and Space Sciences, Peking University, Beijing, China (*ahlu@pku.edu.cn)

The growth of *Acidithiobacillus ferrooxidans* (*A.f.*) by indirectly accepting photoelectrons from the photocatalysis of natural limonite was studied in a dual-chambered system. X-ray diffraction analysis (XRD) showed the natural limonite sample was mainly composed of goethite and hematite. Both the UV-Vis diffuse reflectance spectra and time-current curve indicated the limonite sample had a good photoelectrochemical response. For evaluating the effects of limonite photocatalysis on *A.f.* growth, three sets of control experiments were conducted, depending on whether the light source was supplied or not and the circuit was open or closed.

The variation of Fe^{2+} concentration was consistent with the growth curve of *A.f.* in different controls (Fig. 1). It was obvious that *A.f.* grew better when external electrons were supplied by the photocatalysis of limonite, which revealed the natural limonite indirectly promoted the growth of *A.f.* The mechanism could be interpreted as follows: natural limonite produced photo-generated electron-hole pairs under visible light, then the photo-generated holes were captured by the electron donor (ascorbic acid in this study), while the separated photo-generated electrons transferred into the cathode chamber to reduce Fe^{3+} to Fe^{2+}. The process achieved the photoelectrochemical regeneration of Fe^{2+}, which provided adequate electron energy for the growth of *A.f.*

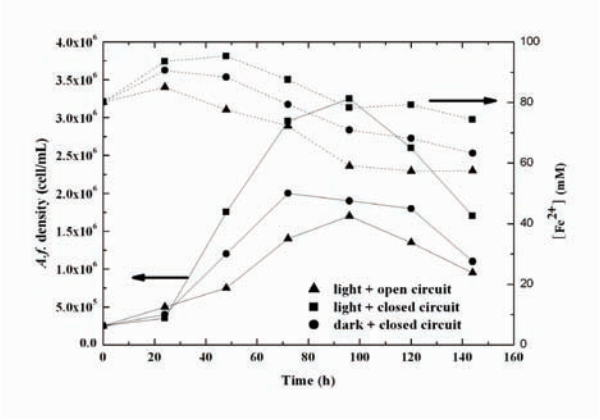

Fig. 1: The growth curves of *A.f.* and variation of ferrous concentration under different conditions (solid dots – ferrous concentration, lines - *A.f.* concentration).

The influence of the photocurrent on the growth of *Alcaligenes faecalis*

Zeng Cuiping, Li Yan, Lu Anhuai* & Wang Changqiu
School of Earth and Space Sciences, Peking University, Beijing, China (*ahlu@pku.edu.cn)

This study focused on the synergistic interaction between a natural semiconducting mineral, rutile and a heterotrophic bacteria, *Alcaligenes faecalis* by applying a potential control on the cathode to simulate the photocurrent of rutile photocatalysis. Scanning electron microscope (SEM), cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) were carried out to characterize the morphology, electrochemical activity and interfacial charge transfer resistance of the bacteria, which adhered to the electrode. The influence of the photocurrent on the growth of *Alcaligenes faecalis* was further identified and analyzed.

The results indicated that both the bacteria and the corresponding metabolites on the electrode were involved in the interfacial electron transport when external electrons were supplied. As influenced by the photocurrent, a significant increase in the biomass on the electrode was observed and the bacterial morphology changed from short rod to long slender rod (Fig. 1). The new redox peaks appearing in the cyclic voltammetry demonstrated that the photocurrent stimulated the electrochemical activity of *Alcaligenes faecalis* and the metabolites on the electrode. This study offered evidence for that the growth of the heterotrophic bacteria might be affected by the photoelectrons generated from the photocatalysis of natural semiconducting minerals.

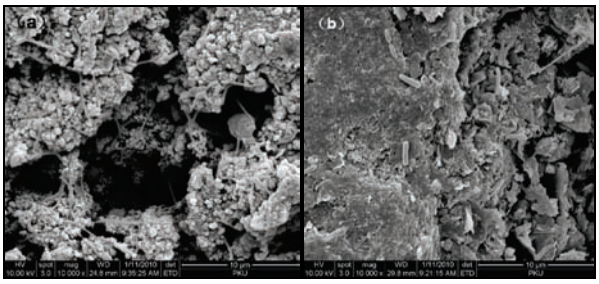

Fig. 1: SEM images of the *Alcaligenes faecalis* on the surface of the electrode with photocurrent(a) and without photocurrent (b).

Mineral stability of bentonites as potential barriers

Šucha, V.[1*], Osacký, M.[2], Striček, I.[3], Madejová, J.[4], Uhlík, P.[1] & Czímerová, A.[4]
[1]Faculty of Sciences, Comenius University, Bratislava, Slovakia ([*]sucha@fns.uniba.sk)
[2]Building Testing and Research Institute, Bratislava, Slovakia
[3]Slovak University of Technology, Bratislava, Slovakia
[4]Inst. of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia

Bentonites are widely tested and used as a barrier material, due to their exceptional properties like plasticity, very low hydraulic conductivity, expandability and cation retardation capacity. All these parameters are directly related to the smectite - bentonite's the most important mineral component. That is why its properties are so important, particularly if a very long-term stability is required (e.g. radioactive waste repositories).

In this study a variety of possible impacts on the smectite structure were tested focusing mostly on the material from two large Slovak bentonite deposits (Jelsovy Potok, Lieskovec). The Jelsovy Potok represents Al-Mg bentonite and the Lieskovec belongs to Fe-bentonite. Several additional well known bentonites were used for some specific comparative tests. Particular attention was focused on the effect of temperature, impact of the acid and the alkaline solutions, and the gamma radiation. A special attention was focused on the bentonite-iron interactions. Iron used in the study was in the form of a 99 % pure Fe^0 powder metal, as well as in the form of pyrite and Fe oxyhydroxide. Pure metal should represent the possible iron construction elements of the repository. The pyrite and the Fe-oxyhydroxide should represent the iron sources from the geological environment of the repository. The batch laboratory experiments, as well as the long-term mock-up test, on the compacted bentonite blocks, were used.

Several laboratory techniques were used to test the reaction products including the XRD, FTIR, UV-VIS, AAS, electron microscopy of the ultrathin sections etc. Basically a large stability of bentonites towards the acidity and the alkalinity at the moderate conditions was confirmed. The smectites lost their original properties only if the extensive treatments in the batch experiments were applied.

No effect of heavy doses (up to 1,5 MGy) of gamma-radiation on the structural and mineralogical parameters (crystal size distribution, specific surface area, cation exchange capacity, layer charge, etc.) of the smectites was identified. Equally no effect was observed during the interactions with the iron in the form of pyrite an/or Fe-oxyhydroxide. Neither batch nor the mock-up tests revealed the changes of the smectites.

Different situation was observed during the interactions of bentonites with a pure iron. The batch experiments showed the significant changes – formation of the magnetite and 7 Å phyllosilicate (berthierine-like), dissolution of the silica phases and deterioration of the smectite structure. Fe-rich smectites were affected more than the others. Mock-up tests with the iron did not show any impact on the bentonites.

Overall we can confirm a long term stability of the bentonites from both deposits at the moderate pH conditions (pH 4-8), resistance towards gamma radiation, and no interaction with the iron. Only potential risk could be linked to the Lieskovec Fe-bentonite extreme exposure to the interactions with pure Fe.

Seeking relations between metal fractions and clay mineralogy in the urban soils of Lisbon city (Portugal)

Patinha, C.[*], Reis, P., Dias, A.C., Terroso, D., Rocha, F. & Ferreira da Silva, E.
Geosciences Dept., Geobiotec Research Unit, University of Aveiro, Portugal ([*]cpatinha@ua.pt)

This study is a part of the working program of a research project untitled "PTDC/CTE-GEX/68523/2006: URBSOIL-LISBON_ Geochemical survey of Lisbon urban soils: a baseline for future human health studies". The aim of this research is to assess the control exert by soil clay mineralogy in the fixation of contaminants in the urban soils of Lisbon city, Portugal. To achieve this aim, the specific bonding forms of heavy metals (Cu, Zn, Pb, Ni and Co) to the clay minerals of several soil phases of Lisbon urban soils will be determined. A total of 51 soil samples were collected over Lisbon city. Figure 1 shows the sample sites and classed post map of the % of clay. Each sample site is labelled from 1 to 51. Thirteen samples were selected based on the percentage of the clay fraction in each sample.

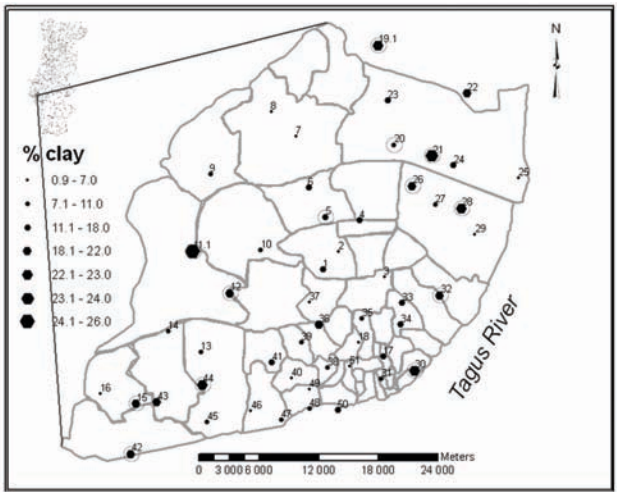

Fig. 1: Soil sampling sites and classed post map of the % of clay fraction; the circles identify the samples used in this study.

The results show that the clay minerals play different roles for the different metals in the soils. High concentrations of Co and Ni occur in samples with high contents in esmectite and low or null contents of illite. The role played by clay minerals in the fixation of Pb, Cu and Zn in the studied soils is still not clear, needing more research. Most of the Pb in these urban soils has an anthropogenic origin being present essentially in the extractable cation soil phase. Like Pb, Cu and Zn have also essentially an anthropogenic origin. The results suggest that organic matter plays an important role in the fixation of Cu while carbonates seem to be effective restraining the mobility of Zn.

Photosensitizer/clay mineral colloids as potential disinfection materials

Bujdák, J.[1,2*], Jurečeková, J.[2] & Bujdáková, H.[2]
[1]Inst. of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia ([*]uachjuro@savba.sk)
[2]Faculty of Natural Sciences, Comenius University in Bratislava, Slovakia

Methylene blue (MB) adsorbed on clay mineral surface forms molecular aggregates [1] and looses its photochemical (photosensitizer) activity [2]. Whereby MB dilute aqueous solutions produce large amounts of singlet oxygen ($^1O_2$), its production was significantly reduced in MB-clay colloids. The photoactivity of MB solution and hybrid MB/clay colloids was measured directly by luminescence measurements at near infrared region and by electron spin resonance spectroscopy (spin-trapping method).

Surprisingly, enhanced antimicrobial effects of MB were achieved in the colloids of montmorillonite. Under visible light irradiation, MB/montmorillonite dispersions prevented the sporulation of *Aspergillus niger* and *Penicillium* sp.

Fig. 1: Reduction of *Aspergilus* sporulation in methylene blue/montmorillonite colloid. No spurulation was observed in the dye/montmorillonite colloid. Sporulation was influenced neither in clay colloid without the dye (middle) nor in MB solution (right).

Moreover, the presence of clay mineral colloidal particles inhibited the growth of yeasts *Candida albicans* and bacteria *Escherichia coli*. *Staphylococcus aureus* proved to be the most susceptible to the MB/clay effects and its growth was significantly reduced even at the lowest dye concentrations ($1.1 \cdot 10^{-6}$ mol dm^{-3}).

The contradiction between enhanced antimicrobial properties and reduced $^1O_2$ formation in MB/clay colloids can be explained in terms of the mechanism of antimicrobial effect. The role of clay particles is most likely to promote the contact between the surface of microorganism cells and MB cations. Clay particles mediate the delivery of dye molecules on the surface or inside the cells. Dye solutions, although producing large amounts of $^1O_2$, were inefficient against microbes, because of a short lifetime of activated oxygen species. The enhanced activity of photosensitizers in clay colloids indicates new perspectives of the implementation of clay minerals in environmental industries for microbial disinfection [2].

Effect of particle preparation on intercalation of vermiculite using HDTMA cations

Plachá, D.[*], Barabaszová, K., Valášková, M. & Simha Martynková, G.
Nanotechnology Centre, VSB – Technical University of Ostrava, Czech Republic ([*]daniela.placha@vsb.cz)

Vermiculite has a significant commercial and technological importance. It is 2:1 planar hydrous phyllosilicate that can be modified using intercalation by various organic cations in the interlayer space similarly as smectites. This modification makes possible among others to use an organovermiculite as sorbent for nonpolar organic compounds from polluted water or gas in the environmental technologies. Organophylic vermiculites were prepared by using hexadecyltrimethylammonium and hexadecylpyridinium cations with various organic cation loadings and their effective sorption ability for non polar organic compounds from water and gas phase was studied [1,2].

Vermiculite particles were prepared for intercalation using two procedures: 1) Conventional sedimentation. Particle size fractions < 5 and < 2 μm were obtained (according to Stoke's law) and 2) Jet milling. Three different fractions under different conditions characterized with particle size < 5 μm. Particle size distribution and specific surface area were measured. Morphology of vermiculite particles was studied using SEM and AFM. It was found that morphology of particles after sedimentation did not change. Particles after jet milling had corrugated edges. This characteristic can contribute to the effective accessibility for organic cations between layers. The effectivity and intercalation rate of the synthesized vermiculite/hexadecyltrimethylammonium intercalates were determined based on the content of organic carbon and characteristics from IR spectrometry and XRD analysis. The results confirmed that intercalation rate of vermiculite size fraction prepared using sedimentation procedure was distinct from intercalation rate of those size fraction obtained using sedimentated and jet milling.

Effect of wetting and drying on metal-adsorbed montmorilonites

Németh, T.[1,2*], Dódony, I.[2] & Pekker, P.[3]
[1]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary ([*]ntibi@geochem.hu)
[2]Dept. of Mineralogy, Eötvös Lorand University, Budapest, Hungary
[3]BAY-NANO Institute for Nanotechnology, Miskolc, Hungary

It is well known that several subsequent wetting and drying (WD) causes the "illitization" of potassium saturated montmorillonite, and thus the loss of expansion and adsorption capacity of the original clay mineral. In this work heavy metal adsorbed (Cu, Pb, Zn, Cd, Co) montmorillonites with different layer charge were submitted to WD cycles. The aim of this study is to reveal the effect of WD on the mineralogical properties of montmorillonites by means of X-ray powder diffraction (XRD) and transmission electron microscopy (TEM).

Decrease of the intensity and broadening of 001 peak are general features on the XRD patterns for all metal-adsorbed montmorillonites indicating the decrease of the crystallite thickness with WD cycles (Fig. 1).

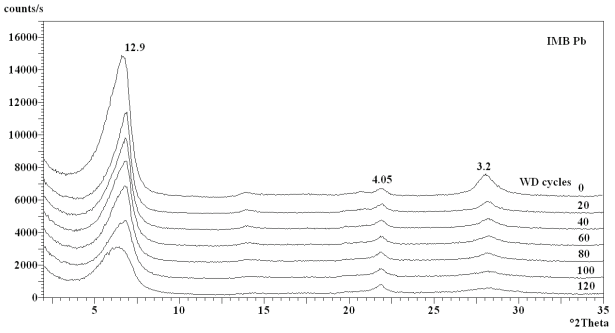

Fig. 1: X-ray patterns of Pb-adsorbed montmorillonite submitted to WD cycles.

TEM analyses revealed the significant decrease of the particle size and the thickness of montmorillonite grains. After 120 WD cycles one or two layer thick crystallites are not rare, and the lateral dimension does not exceed 20 nm. This decomposition due to WD is influenced by the number of WD cycles and by the nature of the metal ion. Pb-montmorillonites are the best affected, because Pb is fixed in the montmorillonite structure and becomes partially non-exchangeable. Chemical composition of montmorillonites also changes with the number of WD cycles, the heavy metal and Si content increase. A possible way of Contrary to K-montmorillonites, metal adsorbed montmorillonites do not lose their expansion capacity during WD. Mineralogical and physico-chemical changes due to WD have relevant application importance, for example in the characterization of the clay liners of waste deposits.

Photocatalytic degradation of anionic dye by Zn-substituting layered double hydroxide in water

Morimoto, K.[*], Tamura, K. & Yamada, H.
Photocatalytic Materials Center, National Institute for Materials Science, Tsukuba, Japan ([*]MORIMOTO.Kazuya@nims.go.jp)

Photocatalytic reactions are currently attracting a lot of attention as an efficient and sustainable purification procedure in water contamination. In photocatalytic reactions, degradations of some chemical substances are induced after an approaching or adsorption on the surfaces of photoactive materials. However, major photocatalysts such as TiO_2, ZnO and CdS show little adsorption performance for ions. On the other hand, layered double hydroxide (LDH) has extremely high anion adsorption capacities, and these are well known as anionic clays. Recently LDH has received considerable attention as environmentally-friendly materials because of its harmless composition. It is also noted that LDH has catalytic and photocatalytic properties associated with its solid basicity or modifications with various polyacids. However, the photocatalytic properties of LDH itself have not yet been fully elucidated. There are a few studies [1, 2] of photocatalytic behaviors of LDH for organic substances, but the actual photocatalytic function of raw LDH was not clearly marked in these previous studies. To examine the photocatalytic activity of non-treated LDH itself, this study focused on the photodegradation of anionic dye by synthetic Zn-Al LDH in aqueous solution under light irradiation. It is particularly expected that Zn-substituting LDH has a potentially photocatalytic activity since ZnO exhibits a remarkable photocatalytic ability.

Photocatalytic degradation of anionic dye, sulforhodamine B (SRB), was determined along the following method. SRB aqueous solution of 0.01 mmol/L was mixed with synthesized Zn-Al LDH in polypropylene centrifuge tube. The solid concentration was adjusted at 50 mg/L. The suspension was dispersed in an ultrasonic bath, and then placed in a shaker for 24 hours at room temperature. It was conducted under light shielding. The suspension was added in a quartz cell, and served to light irradiation experiments using a super-high pressure mercury lamp (250 W) or a xenon short-arc lamp (500 W). The absorbance of SRB was monitored with an UV-Vis spectrometer during light irradiation.

The absorption band of SRB was appeared from 450 to 620 nm, and SRB presented absorption peak at 565 nm. The absorbance of SRB with Zn-Al LDH was unchanged after leaving in a dark condition. The result suggests that Zn-Al LDH itself didn't have just a catalytic activity. On the other hand, it was observed that the absorbance of SRB with Zn-Al LDH gradually decreased during light irradiation. The degradation rate of SRB with Zn-Al LDH was reached approximately 50 % in 300 minutes of mercury lamp irradiation. After xenon lamp irradiation, more than 50 % of the initial SRB with Zn-Al LDH was decomposed within 60 minutes. And degradation rate of SRB with Zn-Al LDH was faster than in SRB without LDH during both lamps irradiation. Therefore, Zn-Al LDH certainly has the photocatalytic activity for SRB, and the degradation and decolorization reactions are accelerated without being stabilized under UV irradiation. It was expected that Zn-Al LDH could be utilized as an efficient photocatalyst for harmful organic anions.

Clay biopolymers matrix (montmorillonite modified by biofilms) to improve uranium uptake: adsorption isotherms models

Olivelli, M.[1,2], Curutchet, G.[2] & Torres Sanchez, R.M.[1*]
[1]Mineral Resources and Ceramic Technological Center (CETMIC), M.B.Gonnet, Argentina
([*]rosats@cetmic.unlp.edu.ar)
[2]Science and Technology School, The National University of General San Martín, S. Martín, Argentina and CONICET

Uranium is heavy metal, with noticeable toxicity associated with nuclear energy processes and acidic mine drainage. Conventional sorption techniques for heavy metals removal from wastewaters are not useful due to the great volumes treated and the low concentration of pollutants.

Biosorption is an alternative process where different types of biomass allow concentrating heavy metals from diluted solutions. Among the biomass described until now bacteria, algae and fungi were the most used.

Fungal biomass had the advantage of being easily and low cost generated. The main technological drawback in biosorption processes is getting a suitable immobilisation of the biomass to obtain efficient biofilters. A methodology to increase biosorption surface and retain biomass is to generate clay biopolymers matrix. Montmorillonite (MMT) clays have optimal characteristics to be used as innocuous sorbents, with the advantage to be able also to complex all kind of organic as well as inorganic compounds on its surface.

In this study, two fungi: *Aphanocladium* sp., *Acremonium* sp., and the acidophilic bacteria *Acidithiobacillus ferrooxidans* were used as microorganisms growth supported on MMT matrix (in P5 and K9 saline media, respectively). The Uranium adsorption isotherms on all MMT/biofilm studied were fitted to Langmuir, Freundlich, Tempkin, Redlich-Peterson, and Toth models, in order to determine monolayer coverage of adsorbate over homogeneous adsorbent surface; heterogeneous system; indirect adsorbate/adsorbate interactions; homogeneous/heterogeneous system and systems with submonolayer coverage, respectively.

MMT/microorganisms systems were characterized by specific surface area determined by water vapour adsorption (Sw). Also, XRD (analysis of the reflection peak d(001)) was applied on MMT/microorganisms systems and Uranium adsorbed on MMT/microorganisms systems.

Specific surface area (Sw) indicates differences from -5% to +50% for MMT in P5 and K9 saline media, respectively. While the different microorganisms growth on MMT evidenced only around 5-10% difference respect to the Sw value of MMT.

All MMT/microorganisms systems showed higher maximum Uranium adsorption that those obtained from microorganisms or MMT alone.

Adsorption isotherms for MMT+ *Aphanocladium* sp fitted with Freundlich model while MMT+ *Acremonium* sp. and MMT+ *Acidithiobacillus ferrooxidans* fitted with Toth adsorption model, indicating the presence of heterogenous and submonolayer coverage, respectively.

The XRD analysis of the reflection peak d(001) performed on MMT and MMT/micro organisms indicated: intensity decrease and interlayer space collapse with the microorganisms presence respect of that of raw MMT. This behaviour was mainly produced by the different saline growth media or an interlayer water displacement by the microorganism entrance in the interlayer space.

Uranium adsorption shift the MMT reflection peak d(001) around 3.5Å, indicating an Uranium entrance in the interlayer clay space.

Comparison of the physicochemical and catalytic properties of micro- and mesoporous Fe-containing materials in phenol oxidation

Timofeeva, M.N.[*], Mel'gunov, M.S., Malyshev, M.E., Panchenko, V.N. , Chesalov, Yu.A. & Shmakov, A.N.
Boreskov Institute of Catalysis, Novosibirsk, Russia
([*]timofeeva@catalysis.ru)

Nowadays, the increasing water utilization in industrial and agricultural activities leads to the expansion of wastewater containing pollutants, such as phenol, which is of the main chemical pollutants. Fenton type homogeneous catalytic systems ($Fe^{2+}/Fe^{3+}/H_2O_2$) are known active catalysts of PhOH complete oxidation with H_2O_2. Iron-containing solid materials have attracted considerable attention as heterogeneous replacement of homogeneous systems due to their Fenton like behaviour. We review herein major aspects of our research in this field for iron-containing high-surface-area pillared clays (Fe-PILC and Fe,Al-PILC) and iron-containing mesoporous molecular sieves (Fe-MMM and Fe,Al-MMM). Fe-PILCs and Fe,Al-PILCs were prepared from naturally occurring montmorillonites by exchanging interlayer ions to Fe^{3+} and Keggin type cation $[FeAl_{12}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ ($FeAl_{12}^{7+}$), correspondingly [1]. Fe-MMM and Fe,Al-MMM were synthesized via sol-mesophase rout under weak acidic conditions using Fe^{3+} and $FeAl_{12}^{7+}$ as Fe and Al source, correspondingly [2]. XRD, low-temperature N_2 adsorption, IR, DR-UV-vis and DRIFT spectroscopic techniques, were used for characterization of these materials.

Catalyst design principles are summarized and discussed to illustrate the effective development of catalysts that would meet the requirements of the catalytic application (Table 1).

Iron-containing materials have been tested as catalysts for wet phenol oxidation with H_2O_2 at pH = 6.2. The following parameters influencing catalytic properties of these materials and stability to leaching of metal from the solid are considered: *a)* Fe and Al content in the samples; *b)* agglomeration and isolation of iron ions; *c)* pH of the synthesis mixture. It was shown that the increase in Al/Fe ratio, which depends on pH of the synthesis mixture, reduces to the decrease in the formation of oligomeric iron species and favours the increase in reaction rate. The catalytic activity of Fe,Al-containing samples is higher than that of Fe-containing samples. The increase in Al content favours the increase of the strength of basic sites of Fe-containing samples detected with $CDCl_3$ adsorption. The insertion of Al leads to the changes in type and content of OH-groups which facilitate the sorption-desorption processes of reagents. Activity of Fe,Al-MMM(4.4) is higher than that of Fe,Al-PILC(4.4) at 40-50^{0}C due to the decrease of diffusion limitation.

Table 1: Phenol oxidation with H_2O_2 in the presence of Fe-containing samples

	S_{BET}	d_{001}	Fe/Al	Time[A]	Fe leaching
	$m^2 \cdot g^{-1}$		wt/wt	h	wt %
Na-clay	113	15	0.8/5.6	30	-
Fe-PILC	136	16	1.1/5.6	2.0	5.4
Fe,Al-PILC(4.4)	215	18	1.5/9.8	1.5	<0.1
				0[B]	-
Fe-MMM(2.4)	930	38	1.7/0	10.0[C]	0.2
Fe,Al-MMM(2.4)	1518	39	1.1/3.1	3.5[C]	6.7
Fe,Al-MMM(4.4)	1315	38	1.1/6.4	1.0	<0.1
				2.5[B]	<0.1

The reaction condition: PhOH 1 mM, H_2O_2 14 mM, Fe,Al-PILC 1 g·L^{-1}, pH 6.2, 60^{o}C; [A] Time of 100% conversion of PhOH; [B] 40^{0}C; [C] 60^{0}C (pH of the synthesis mixture is shown in parentheses)

Technological characterization of peloids maturated with montmorillonite and sepiolite

Aguzzi, C.[1], Cerezo, P.[1], Sanchez, R.[1], Salcedo, I.[1], Machado, J.[2], Alba, M.D.[3] & Viseras, C.[1,4*]
[1]Depto. de Farmacia y Tecnología Farmacéutica, Universidad de Granada, Granada, Spain
[2]Aguas Termales de Graena, Cortes y Graena, Granada, Spain
[3]Instituto de Ciencia de los Materiales, CSIC, Sevilla, Spain
[4]Instituto Andaluz de Ciencias de la Tierra, CSIC-Universidad de Granada, Granada, Spain ([*]cviseras@ugr.es).

Dermatological semisolid preparations such as thermal muds (peloids) require a suitable rheological profile in view of their manipulation and therapeutic efficacy. Indeed, the rheological properties of such preparations affect the entire life of the formulation, since the mixing, filling and packaging until use and "in vivo" behaviour [1]. From a broad point of view, these formulations must be consistent at rest and easily to pour and spread when applied. However, the rheological behaviour of a clay/water system may change over time, leading to unstable and inadequate formulations [2]. These semisolid systems must therefore be considered as complex materials whose stability must be evaluated on the basis of rheological analysis as complete as possible. With these premises, aim of this work was to study the rheological behaviour of thermal muds matured under different conditions as part of a wider research whose focus is on standardizing the development of therapeutic muds.

Peloids of montmorillonite or sepiolite in mineral water from Graena Spa (25 % w/w) were prepared by using a mechanical shaker (Ultraturrax T25, Janke and Kunkel GMBH & Co., G) at 10,000 rpm for 5 minutes. Peloids were maturated in static conditions (without agitation) and with manual agitation every seven days, for a maximum period of three months. At specific times (time zero, one, two and three months), complete rheological analysis of aliquots of the peloids were taken by means of a rotational rheometer (Bohlin ® CS, Bohlin Instrument Division, Metrics Group Ltd., UK). The analysis was conducted using a cone/plate (CP 4 / 20) measurement system at 25°C, applying increasing and decreasing shear rate in the range 70 - 800 s^{-1}.

Flow curves of standardized systems prepared with montmorillonite or sepiolite showed typical profiles of viscoplastic fluids, with yield values depending on the type of clay mineral and conditions of maturation. The samples also showed rheological time-dependent properties, with hysteresis areas. In particular, montmorillonite samples showed thixotropic behaviours, whereas sepiolite systems were anti-thixotropic when prepared, changing to thixotropic as a result of dynamic maturation. It can be concluded that dynamic maturation is preferable to static conditions, in view of the rheological behaviour (thixotropy) of peloids formulated with laminar and fibrous clays.

Removal of Cu^{2+} from aqueous solutions by using bentonites as adsorbents

Brtáňová, A.[1,2*], Melichová, Z.[3] & Komadel, P.[1]
[1]Institute of Inorganic Chemistry, SAS, Bratislava, Slovakia ([*]anna.brtanova@savba.sk)
[2]Dept. of Inorganic Chemistry, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
[3]Dept. of Chemistry, Faculty of Natural Sciences, Matej Bel University, Banská Bystrica, Slovakia

Adsorption of heavy metal cations on clays is of great scientific interest due to their toxicity and harmfulness. Numerous papers on the use of bentonites as adsorbents have been published, e.g. [1]. This work is focused on various effects on the sorption of Cu^{2+} on two commercial bentonite products prepared from two Slovak bentonites Lieskovec (S011) and Jelšový potok (S110).

They were characterized by powder X-ray diffraction (XRD) and infrared spectroscopy (FTIR). XRD analysis revealed smectite to be the major component present in both samples, while the accessory minerals were quartz, mica and feldspar in both samples and kaolinite in S011. FTIR spectra helped to identify montmorillonite compositions (Fig. 1).

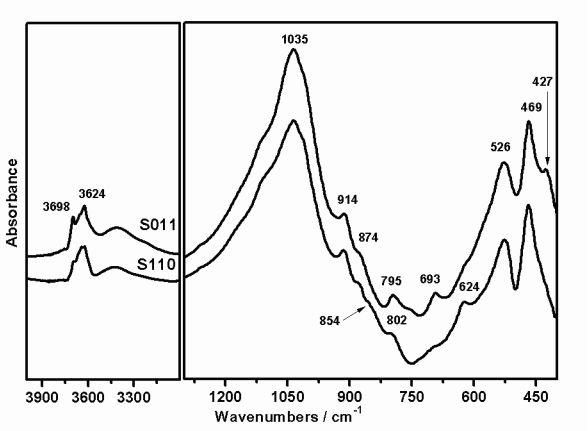

Fig. 1: The IR spectra of S011 and S110.

AlAlOH bending vibrations at 915 cm^{-1} show montmorillonite and the band at 854cm^{-1} (AlMgOH) confirm higher Mg for Al substitution in S110 while the AlFeOH component at 874 cm^{-1} and the absence of an AlMgOH band reflect higher Fe and lower Mg contents in S011, thus causing the lower cation exchange capacity (CEC) of S011. CEC as determined by the Cu-triethylenetetraamine method was 40 mmol/100 g for S011 and 79 mmol/100 g for S110. Specific surface area determined by EGME (Ethylene Glycol Monoethyl Ether) adsorption was 386 m^2/g for S011 and 459 m^2/g for S110.

The adsorption experiments were carried out using the batch technique. The effects of pH, contact time and initial Cu^{2+} concentration were tested. The adsorption was strongly dependent on pH of the medium; the uptake of Cu^{2+} was increasing from pH 2.0 to 7.0. At higher pH values, formation of copper hydroxyl compounds affected the sorption results. The uptake of Cu^{2+} was rapid and it increased with increasing metal concentrations. The sorption percentage decreased with increasing concentration of Cu^{2+}. Langmuir adsorption isotherms were found to fit best the obtained experimental data for both bentonites.

X-ray diffraction and desorption study of the phases formed upon calcinations synthetic layered double hydroxides

Butenko, E.* & Kapustin, A.
Chemical Technology and Engineering, Azov Sea State Technical University, Mariupol, Ukraine
(*butenkoeo@rambler.ru)

The thermal and kinetic parameters of heating processing of LDHs, providing a complete lack of transfer of sorbed substances into the liquid phase due to the formation spinel structures were determined.

Traditional sorbents can undergo the reverse process of desorption and ion exchange, resulting in a possible penetration of pollutants into the environment. Prevention of this process can be achieved by turning hydroxide sorbent in spinel. The purpose of this work is to define the area of formation spinels, ensuring the absence of pollutants desorption:

$$Mg_xAl_yCr_z(OH)_m \rightarrow xMgO \cdot y/2Al_2O_3 \cdot 2/zCr_2O_3$$

The thermogravimetric analysis allows to trace the processes occurring during heating of hydroxide materials. These experimental curves show the temperature of the beginning of thermal decomposition of the original samples and a deep restructuring of compounds. Thermogravimetric curves represent the mass loss of the sample during heating. These results allow to characterize the thermal stability of the hydroxide ion - exchangers. LDHs were saturated by solution containing of chromate ions. Then LDHs were dried. Samples of the sorbent with adsorbed chromate ions were selected and placed in a muffle at regular intervals, at certain temperatures.

The temperatures above 500°C the irreversible dehydration with the formation of spinel structure take place. This feature of LDHs, are essential for their use as adsorbents of toxic anions. Heat treatment can bond the layers to form insoluble compounds and burying without fear of the reverse process of desorption under the influence of external conditions. That may take place traditional for adsorbents such as activated, but not heat treatment LDHs take place. There is a formation of new oxides phases at the heat treatment.

Table 1: The concentration of chromate ions after desorption

τ\t	150°C	250°C	400°C	600°C	800°C	1000°C
5	$1{,}51\cdot10^{-5}$	$0{,}88\cdot10^{-5}$	$0{,}51\cdot10^{-5}$	$0{,}25\cdot10^{-5}$	$0{,}19\cdot10^{-5}$	**0**
15	$1{,}28\cdot10^{-5}$	$0{,}86\cdot10^{-5}$	$0{,}49\cdot10^{-5}$	$0{,}25\cdot10^{-5}$	$0{,}18\cdot10^{-5}$	**0**
30	$1{,}09\cdot10^{-5}$	$0{,}81\cdot10^{-5}$	$0{,}42\cdot10^{-5}$	$0{,}24\cdot10^{-5}$	$0{,}18\cdot10^{-5}$	**0**
60	$1{,}05\cdot10^{-5}$	$0{,}76\cdot10^{-5}$	$0{,}39\cdot10^{-5}$	$0{,}23\cdot10^{-5}$	**0**	**0**

In the table are shown the area of spinels formation. Analyzing the obtained data, we may say that with increasing of temperature and time of heat treatment the process of desorption is minimized. After 800°C the spinel structures formed and the process of desorption becomes impossible. We may assume that the used anionic sorbent can be subjected to heat treatment at 800°C, and after that the processes of burial of the sorbent is not risky. It was shown that at temperatures above 1000°C and the residence time more than 2 hours the shpinel structures will be disintegrate. The thermal and kinetic parameters of heating processing of LDHs, providing a complete lack of transfer of sorbed substances into the liquid phase due to the formation spinel structures were determined.

New insights on the humic acid uptake by homoionized montmorillonite and CTMA-montmorillonite

Fernández, M. & Torres Sánchez, R.M.*
Mineral Resources and Ceramic Technological Center (CETMIC), M.B.Gonnet, Argentina
(*rosats@cetmic.unlp.edu.ar)

Contaminated water is one of the biggest problems in the world, not just the low percentage (2.5%) of fresh water available, but also the unequal distribution in the world is still worrying. To improve the drinking water quality various procedures can be applied according to the characteristics of water contamination.

Particularly, the organic matter (OM) in water is responsible, among others, of the water turbidity and enables to the formation of stable aggregates with metals, commonly associated with high levels of microorganisms. The OM consists mainly of humic and fulvic acids, difficult to remove with conventional techniques used in flocculation water treatment processes. As an alternative to conventional drinking water treatment and to reduce the humic acid content, this paper presents the use of homoionic montmorillonites and a cetyl trimethyl ammoniun-montmorillonite (CTMA-MMT) to uptake humic acid of water.

The raw montmorillonite used (Rio Negro Province, denoted MMT), contains 84% montmorillonite and 4% quartz and 12% feldspar as impurities. Fractions of MMT sample were homoionized with Na, Ca, K and exchanged with CTMA (1 CEC). Zeta potential determinations of MMT, HA, CTMA-MMT and CTMA-MMT+HA were realized, to identifie their surface charge. The HA adsorption isotherms were determined on all samples in absence and presence of ionic strength (10^{-2}M of the respective chloride cation solutions). The samples without and with HA were characterized by XRD, specific surface determined by water and N_2 adsorption and apparent diameter (Dapp).

The Sw values showed an increase order related to the cations exchanged: CTMA-MMT <K-MMT <MMT <Na-MMT <Ca-MMT. The presence of HA causes a decrease in these values showing the hydrophobic character of the new surface with the HA complex. While the SN_2 values showed almost inverse correlation, confirming the non-polar status of N_2 and its difficulty to enter in the montmorillonite interlayer. The Dapp values follow inverse correlation to that found for Sw on all samples.

Negatives surface charge values were found for both HA and MMT in all pH range studied (from pH 3 to 10). The CTMA exchange originated in the CTMA-MMT sample shifted the surface charge to positive values and the HA adsorption decreases the positive surface charge values found in CTMA-MMT sample.

The XRD spectra showed a shift of the reflection peak d (001) respect to the MMT dependent of the water layer related to the interlayer cation in the following order: Na-MMT < K-MMT< MMT< Ca-MMT< CTMA-MMT. The presence of HA, in all samples causes a slight decrease in the interlayer spacing, possibly originated by the complex formed between the AH with the interlayer cation.

The HA adsorption, in the absence of ionic strength, for all homoionized samples showed a Langmuir type behavior, while the HA adsorption on CTMA-MMT showed a high adsorption at low HA concentrations and max adsorption kept constant with HA concentration increase.

In ionic strength presence (10^{-2} M) only the Ca-MMT sample showed a different behavior than that of Langmuir adsorption.

Formation of brom-pyromorphite as the effect of lead and phosphates sorption on surfactant-modified smectite

Figuła, A. & Bajda, T.*
Dept. of Geology, Geophysics and Environment Protection,
AGH University of Science and Technology, Krakow, Poland
(*bajda@geol.agh.edu.pl)

Sorption on organo-modified clays (e.g. smectites) is one of the methods used for the removal of toxic compounds (inorganic anions and cations, neutral organics) from solutions [1]. The objective of this study was to evaluate potential application of surfactant-modified smectite for sorption of PO_4^{3-} and Pb^{2+}. Precipitation of brom-pyromorphite $Pb_5(PO_4)_3Br$ is observed when Br-surfactant is used for modification.

Sample of smectite was modified with the use of amine hexadecyltrimethylammonium bromide (HDTMA-Br) in the amounts of 2.0 Cation Exchange Capacity (CEC) of the clay. HDTMA is a large organic cation, that in this experiment was used in bilayers form (surfactant concentration was higher than a critical micelle concentration). It changes the charge on natural smectite from negative to positive, but it does not use up all negative sites. Therefore, it is possible to use surfactant-modified smectite as a sorbent for various classes of aqueous solutes.

Modified smectite was reacted with solutions containing 5 to 20 mM/L of Pb or PO_4 ions at initial pH from 2 to 5. In the first step, surfactant-modified smectite was reacted with PO_4 or Pb ions. In the second step, Pb-sorbed samples from the first step were reacted with solution containing PO_4 while PO_4-sorbed samples from the first step were reacted with Pb ions.

Sorption of PO_4 was highest on Pb–surfactant-modified smectite, while sorption of Pb was highest on surfactant-modified smectite with no PO_4 pretreatment. In both cases sorption was highest at pH = 5. Also, formation of brom-pyromorphite $Pb_5(PO_4)_3Br$ was noted in the reaction products, which was identified with the use of X-ray diffraction and SEM. Pyromorphite forms crystals either in the volume of solution (homogeneous crystallization: reaction of aqueous PO_4 with Pb desorbed from ion-exchange positions) or on the surface of a surfactant-modified smectite (heterogeneous crystallization: Pb ions from solution react with PO_4 absorbed and still present on the organic HDTMA bilayers) (Fig. 1).

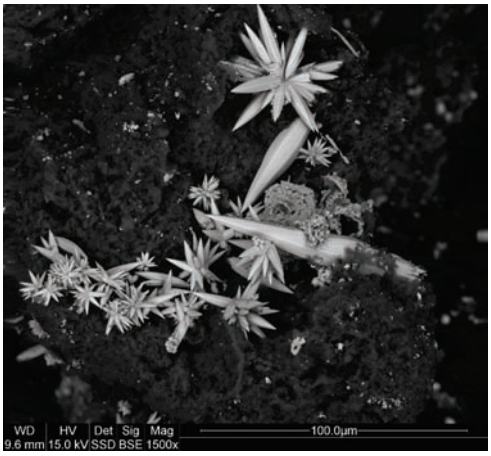

Fig. 1: SEM microphotographs of brom-pyromorphite formed in the reaction of aqueous Pb^{2+} and PO_4–surfactant-modified smectite (heterogeneous crystallization).

Clay characterization in sediment cores from Novigrad sea area, Croatia

Fiket, Ž.[1*], Bermanec, V.[2] & Kniewald, G.[1]
[1]Division for Marine and Environmental Research, Ruđer Bošković Institute, Zagreb, Croatia (*zeljka.fiket@irb.hr)
[2]Institute of Mineralogy and Petrology, Faculty of Science, University of Zagreb, Croatia

The Novigrad sea is a small, semi-closed bay located in the central part of the eastern Adriatic coast, about 20 km north of Zadar (Fig. 1). It is connected to the Adriatic sea in the northwest by Velebit channel and the Karin sea in the southeast. In the surrounding area several bauxite deposits have been exploited for many years with the transshipment port situated in the Novigrad sea. Assessment of the influence of dispersion of bauxite dust by wind and water from dozens of open bauxite pits and waste disposal site of an abandoned alumina plant in the vicinity of the Novigrad sea on the environment is necessary.

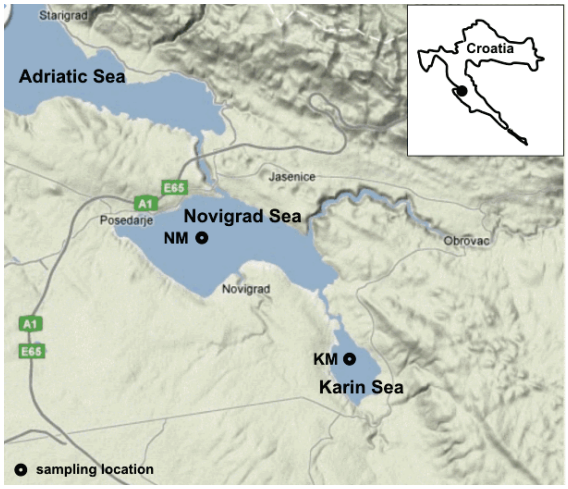

Fig 1: Map of the Novigrad sea area.

Clay minerals have an important role in aquatic systems, as both a carrier and source of pollutants. Therefore, detailed characterization of clay content in recent marine sediments is a prerequisite for an assessment of source and distribution pathways of contaminants. In case of high carbonate content of studied sediments, removal of carbonate phases prior to detailed clay analysis is necessary.

Removal of carbonate minerals from sediments at room temperature was investigated by three different acids, hydrochloric acid (0.5M HCl), acetic acid (4M CH_3COOH) and formic acid (4M HCOOH). Our aim was to evaluate the effects of different chemicals on the properties and structures of present clay minerals in order to develop the optimal procedure for further detailed characterization of clay minerals in marine sediments of the Novigrad sea area.

The analysis was performed on two sediment cores of different carbonate content, one from Novigrad sea **NM** (~19% $CaCO_3$) and one from Karin sea **KM** (~31% $CaCO_3$) (see Figure 1). X-ray diffraction was used to obtain mineralogical composition of the bulk, carbonate free, as well as glycolated and heat-treated (at 450°C and 550°C) samples.

Results indicate that the bulk samples are dominantly made up of carbonates (calcite – Ca and dolomite – D), quartz (Q) and halite (H), while clay minerals (chlorite – Cl, illite/mica – I/M) occur as minor phases. Detailed characterization of clay content of samples after the carbonate removal by different acids will be discussed.

The surface modification of clays for removal of toxic Se-oxyanions

Herzogová, L.[1*], Doušová, B.[1], Lhotka, M.[2], Koloušek, D.[1], Krejčová, S.[1], Jakubíková, B.[1] & Grygar, T.[3]
[1]Dept. of Solid State Chemistry, Institute of Chemical Technology, Prague, Czech Republic

[2]Dept. of Inorganic Technology, Institute of Chemical Technology, Prague, Czech Republic
[3]Dept. of Inorganic Chemistry, Academy of Sciences, Řež, Czech Republic

Selenium compounds represent serious threat for environment and human health. They arise mostly anthropogenically and occur in organic or inorganic forms (predominantly as SeO_3^{2-}, SeO_4^{2-}) in natural systems [1]. The adsorption is one of the applicable methods of these toxic substances removal. Clays (kaolines, bentonites) can be classed as technologically important adsorbents. They are characterized by the low value of pH_{ZPC} (zero point of charge) and attract mostly cations. It is possible to increase their anionic affinity for obtaining the efficient and inexpensive adsorbents by a simple chemical Fe, Al, Mn-modification [2-4]. The aims of this work is the preparation of new low-cost adsorbents, their qualitative and quantitative description, the adsorption of toxic SeO_3^{2-}, SeO_4^{2-} oxyanions and the verification of their stability on prepared adsorbents.

Mineralogically pure clays were used for surface changes study – two kaolines from West Bohemia with higher content of kaolinite (> 60 %), bentonite (Riedel de Haën, Germany) containing mostly montmorillonite and standard Ca-rich montmorillonite SAz-2 (Arizona, USA).

The initial concentration of Se in model aqueous solutions was 10 - 40 mg/L and the amount of solid samples ranged from 1 - 10 g/L. Sorption processes ran 72 h. Kinetic experiments were carried out as well.

The sorption capacities of clays increased markedly after the modification (from 0 to 20 mg/g). The kinetic study revealed that 8 h was needed for Se removal. The stability of Se on the solid surface was checked by leaching tests which confirmed the release of it in the range of 0.1 – 2 %.

XRD, XRF, S_{BET}, IR and pH_{ZPC} measurements were used for the characterization of the surface changes during the treatment and next adsorption. The surface of newly prepared adsorbents was amorphous and porous. Specific surfaces (BET) did not change notably after the treatment. The pH_{ZPC} of treated clays moved from 6 to 10.

Bioleaching effects and binding of Zn on clay, iron and manganese minerals

Jablonovska, K.[*] & Styriakova, I.
Institute of Geotechnics SAS, Kosice, Slovakia
([*]jablonov@saske.sk)

Water reservoir Ruzin I in the region of Eastern Slovakia is a long – therm problem of sediments contaminated with heavy metals (Zn, Cd, Ni, Cu, Hg, As) as a result of mining and metallurgical activities in the basin. The focus of this work is to assess the mobility of Zn in sediment samples in the presence of clay minerals and iron oxides. X-ray diffraction analysis of sediment confirmed presence of quartz, illite, kaolinite and montmorillonite (Philips XPERT, Germany).

Table 1: The amount of Zn, Fe and Mn in the sediment (AAS, Varian AA-30, Australia), BL –bioleaching with Bacillus megaterium

Elements	Before BL (mg/kg)	After BL (mg/kg)	TV (mg/kg)
Zn	427	192	140
Fe	44 600	24 500	-
Mn	1315	1210	-

TV – Target value by MP MŽP SR No. 549/98-2

Sequential extraction method by Tessier was applied to obtain information about chemical binding Zn in the sediment matrix. Adsorption of Zn on Fe and Mn oxides was confirmed in 55% (wt) and in the structure of clay minerals of the so-called residual fraction of Zn was found in 28 % (wt). Heterotrophic bacterial species *Bacillus cereus* and *Bacillus megaterium* presented in the sediments were identified by biochemical BBL identification system. They control mobility of Zn in Fe – Mn oxides and clay minerals. Figure 1 presents kinetics of Zn dissolution in bioleaching medium (containing glucose as carbon source for active heterotrophic bacterial species) and comparing the effect of inoculation of *Bacillus megaterium* and *Bacillus cereus.*

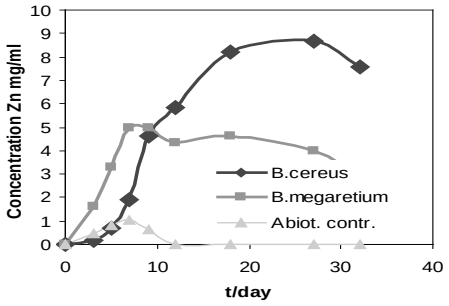

Fig. 1: Kinetics of bioleaching Zn from sediment inoculated with Bacillus cereus and Bacillus megaterium bacterial strains.

Efficiency of discontinous bioleaching Zn from contaminated sediments lasting 6 months with use selected bacterial species were as follows: *Bacillus cereus* 71 % > *Bacillus megaterium* 64 %. These bacterial strains use for their metabolism Fe/Mn oxides and clay minerals therefore they increase the mobility of Zn in aquatic sediments. This principle is usable in prospective *in-situ* remediation of contaminated bottom sediments.

Decontamination processes for removal of some pharmaceuticals from aqueous systems

Jakubikova, B.*, Dousova, B., Herzogova, L. & Krejcova, S.
Dept. of Solid State Chemistry, Institute of Chemical Technology in Prague, Czech Republic
(*bohumila.jakubikova@vscht.cz)

Pharmaceuticals have become the inherent part of current modern society. Several pharmaceutical substances have been annually used in amounts up to hundreds of tons in some countries [1]. Therefore the big attention has been paid to the influence of these compounds on the environment. After their application, pharmaceutical substances are excreted in an unchanged form or eventually in the form of water-soluble metabolites [2].

The pharmaceutical industry, hospital facilities, private households and landfills are the next inconsiderable sources of these contaminants [3]. That´s how the pharmaceutical substances reaches the sewage water and regarding they are not completely eliminated in sewage treatment plant [4]. Therefore, they infiltrate into the ground water, surface water and drinking water. They also settle in river sediments and water reservoir sediments.

The aim of this work is to find suitable decontamination processes for the removal of mass-used pharmaceutical substances from aqueous systems. For this purpose, the sorption properties of natural inorganic materials (especially clay minerals) have been used. Sorptions have been carried out from the model solutions of analgetics representatives (e.g. paracetamol, salicylic acid). The sorption capacities of clay minerals have been determined. In the next part of this work, the influence of reaction conditions on the sorption process has been studied.

Acknowledgements: This work was the part of the project P210/10/0938 (Grant Agency of Czech Republic).

Modification of the montmorillonite with the cationic and non-ionic surfactants

Jankovic, L.
Institute of Inorganic Chemistry SAS, Bratislava, Slovakia
(Lubos.Jankovic@savba.sk)

Many industries give rise to dye-bearing effluents in their production processes. Textile industries, particularly, are major consumers of water and release a fair amount of color in their effluents. It follows that dyes need to be removed before the effluents are discharged into rivers. However, this has always been a major problem because of the difficulty of treating such wastewaters by conventional methods. Biological procedures, although widely utilized in the removal of color, are very inefficient because of the low biodegradability of dyes. A variety of other methods, including coagulation, chemical oxidation, photocatalysis, and electrochemical and adsorption techniques [1], has been examined.

Adsorption techniques have been widely applied to the treatment of industrial wastewater containing dyes, heavy metals, and other inorganic and organic impurities. In some cases, it is possible to recover the adsorbed dye through desorption and to reuse the large amounts of water employed by textile industries. The adsorption phenomenon has been known since the 17th century when it was discovered that porous materials have the property of adsorbing gases and, subsequently, the same phenomenon was observed for solutions. Adsorption has been found to be one of the most efficient physicochemical processes, superior to many other techniques for water reuse in terms of the simplicity of operation. If the adsorption system is designed correctly, it will produce a treated effluent of high quality. Activated carbon has been widely used for this purpose because of its high adsorption capacity. However, its high cost sometimes tends to limit its use. Several nonconventional, low-cost adsorbents have also been tried for dye removal.

The present work is aimed to study the adsorption capacity and mechanism of removal of industrial anionic textile dye Acid Red 88 by organobentonite. The organoclay adsorbent used was prepared by modification of commercial Nanocore montmorillonite with octadecyl ammonium bromide (ODTMA) and compared with materials prepared with the non-ionic surfactants [2] containing the same hydrophobic C_{18}- end-chain and various repetitive units of hydrophilic poly(ethylene oxide) (PEO) segments.

The layer spacing of the ODTMA- and $C_{18}PEO_n$ - smectite composite was well preserved during water washings, indicating stability of cationic organoclay and higher molecular weight non-ionic surfactant molecules in the interlayer galleries. The non-ionic surfactant treatment preserved >90% of the CEC of the smectite while ODTMA-clay lost almost all cation exchange capacity. The surfactant-montmorillonite composites effectively removed aromatic textile azo dye from water solution while untreated smectite did not adsorb these molecules. The enhanced adsorption of the aromatic compounds is attributed to the aliphatic segments (C_{18}) of the five surfactants, however ODTMA-montmorillonite showed highest sorption capacity for naphthalene based textile dye AR88.

Geopolymers: new products for sustainability of the environment

Khoury, H.[1*], Aldabsheh, I.[1], Slaty, F.[1], Esaifan, M.[2], Rahier, H.[3], Wastiels, J.[2] & Hourani, M.K.[4]
[1]Dept. of Geology, University of Jordan, Amman, Jordan ([*]khouryhn@ju.edu.jo)
[2]Dept. of Mechanics of Materials and Constructions, Vrije Universiteit Brussel, Brussels, Belgium
[3]Dept. of Physical Chemistry and Polymer Science, Vrije Universiteit Brussels, Brussels, Belgium
[4]Dept. of Chemistry, University of Jordan, Amman, Jordan

Geopolymerization is the process of polymerizing minerals with high silica and alumina at low temperature by the use of alkali solutions. Geopolymers could be a substitute for Portland cement and for advanced composite and ceramic applications. The geopolymer technology would eliminate the need for energy requirement as they may be cured at ambient temperature.

Current research at the University of Jordan concentrates on developing building products (geopolymers) through geopolymerization. The goal is to produce low cost construction materials for green housing. The produced construction materials are characterized by high strength, high heat resistance, low production cost, low energy consumption, and low CO_2 emissions.

The results have confirmed that natural kaolinite satisfy the criteria to be used as a precursor for the production of high quality inexpensive, stable materials. Geopolymeric products gave a high unconfined compressive strength values up to 52 N/ mm^2 for dry test. This value has been increased to 57 N/ mm^2 by the immersion of the geopolymerzed products in 10% solution of triethylene glycol.

The addition of rock wool gave the maximum unconfined compressive strength up to 90 N/ mm^2 after heating to 500°C for one day. The addition of zeolitic tuff as a filler has increased the adsorption capacity of the polymerized products towards heavy metals. This result enables the use of geopolymers in waste water treatment plants.

Environmental impacts associated with a landfill in the municipality of Zakynthos, Greece

Koutsopoulou, E.[*], Tsolis-Katagas, P. & Papoulis, D.
Dept. of Geology, Section of Earth Materials, University of Patras, Greece ([*]ekoutsop@upatras.gr)

Landfills are widely used as a disposal method for municipal solid waste in most European countries. However, landfills if not properly managed, may pose a serious threat to the environment due to leachate run-off and contaminant transport in the surrounding environment. Landfill leachates can contaminate groundwater and surface water [1]. The mineralogy of the clay material used in the landfill liners controls the mobility of contaminants therefore, clay mineralogy is important in order to minimize migration of pollutants in the environment.

To evaluate the environmental risks associated with a landfill in the municipality of Zakynthos, Western Greece, samples were collected from the material used in the landfill and from sediments from a stream system, in the vicinity of the waste disposal site. Surface and groundwater samples were collected and analysed to determine some geochemical parameters usually considered to be indicators of pollution from solid waste disposal. The mineralogical composition of all samples was determined by XRD and revealed the presence of calcite, quartz, albite, smectite, chlorite, illite and mixed-layer chlorite-smectite. Trace element analyses showed that the abundance in Cu and Zn is higher in the stream sediments compared to the uncontaminated samples and since stream sediments are in contact with run-off waters from the landfill this could be an indication of contamination from the landfill. According to drinking water standards, the concentrations of all trace elements in the studied waters were below the maximum contaminant level values given by European Council Directive [2] and WHO [3]. Finally, the concentrations of Cl^-, SO_4^{2-}, NO_3^- and NO_2^- in the water samples exceeded the average permissible concentrations and are considered as human induced contamination from the landfill.

ZnS particles deposited on montmorillonite and their photocatalytic efficiency for CO_2 reduction

Kozák, O.* & Praus, P.
Dept. of Analytical Chemistry and Material Testing, VŠB-Technical University of Ostrava, Ostrava, Czech Republic
(*ondrej.kozak@vsb.cz)

Semiconductors such as metal sulphides and metal oxides appear to be very promising materials for photocatalysis due to rapid generation of electron–hole pairs by photoexcitation and highly negative reduction potentials of the excited electrons. CO_2 is a well know greenhouse gas. To convert it by force, a severe condition of high pressure and high temperature is required. The reduction of CO_2 using photocatalysts is one of the most promising methods because CO_2 can be reduced to utilizable compounds (e.g., methanol, ethanol, methane, hydrogen) by irradiating with UV light at room temperatures and low pressure [1,2].

The ZnS nanoparticles were deposited on montmorillonite (MMT) in the presence of cetyltrimethylammonium (CTA). UV spectrometry and transmission electron microscopy proved the formation of nanoparticles with the diameter ranging from 3 nm to 5 nm. Selected area electron diffraction confirmed the existence of romboedric ZnS. Photoluminiscence spectra exhibited a strong emission band between 300 nm and 600 nm, which was assigned to transitions due to sulphur vacancies in ZnS. The prepared ZnS-montmorillonite (ZnS-MMT) nanocomposite was used for the photocatalytic reduction of CO_2 providing considerably high efficiency which exceeded the results of commercial TiO_2 Degussa P25 5-6 times. Methane, methanol, carbon monoxide and hydrogen were the main reduction products of the reduction. The stability of ZnS against oxidation was proved by the determination of sulphate by capillary isotachophoresis.

Effect of clay content on As, Se-adsorption in soils

Krejcova, S.*, Dousova, B., Herzogova, L. & Jakubikova, B.
Institute of Chemical Technology, Prague, Czech Republic
(*krejcova.s@quick.cz)

The aim of this work is the study of soil adsorption properties depending on the portion and characteristics of clay fraction. Soil samples from protected area Cesky Kras and Labe river basin (Middle Bohemia, Czech Republic) used in this research, where the elevated concentration of As and Se have been observed. The samples were dried at laboratory temperature, grinded, fractioned and digested in the microwave mineralization device MWS-2 Berghoff. The amount of As and Se in mineralised samples was assessed by HG AAS. The content and type of clay mineral presented in the soil samples were determined by X-ray diffraction and subsequently, the sorption capacity of soils and the stability of adsorbed As and Se under different conditions (pH, Eh) were investigated [1]. pH_{H2O}, pH_{KCl} [2] and pH_{ZPC} [3] were also measured.

Table 1: Concentration of arsenic and selenium in investigated soil samples; A1-A3 – Cesky Kras protected area, B1-B3 – Labe river basin

	c [mg/kg]		pH	
	As	Se	pH(H_2O)	pH(KCl)
A1		2.7	6.5	6.7
A2		2.1	7.2	6.9
A3		14.4	7.0	6.7
B1	25.1		7.5	7.1
B2	35.3		7.5	7.4
B3	26.5		7.2	7.1

The results in Table 1 show elevated As/Se concentration in all investigated samples. The presence of clay and hydrated oxides and/or Fe-oxyhydroxides influenced sorption properties of soils.

Clay minerals and landslides on the slopes of Medvednica Mt. in Zagreb city area (Croatia)

Miklin, Ž.[1], Hećimović, I.[1], Tibljaš, D.[2] & Grizelj, A.[1*]
[1]Croatian Geological Survey, Zagreb, Croatia
([*]anita.grizelj@hgi-cgs.hr)
[2]Faculty of Science, University of Zagreb, Croatia

The landslides problem is pronounced on the slopes of Medvednica Mt. in Zagreb city area. Therefore, in 2005-2007, Zagreb city government engaged Croatian Geological Survey to make detailed engineering geological map M 1:5.000 of this area.

The landslides problem occurrs in the Miocene and the Pleistocene deposits, so those sediments were the main object of investigation. Litological composition of the Miocene deposits varies from marls, limestones, silts, sands and sandstone to rarely represented coarser-grained sediments such as conglomerates and breccias. The Pleistocene sediments which discontinuously cover the older deposits consist of poorly sorted clays, silts, sands and gravels.

The aim of this study was to determine relationship between clay mineralogy and occurence of landslides. Apart from standard engineering-geological investigations (SPP tests, pocket penetrometar, wane shire tests, liquid limit and shrinkage limit, grain size distribution, uniaxial compressive strength test), mineralogical investigations of sediments (XRD, DTA, SEM and chemical analysis) were included.

It was found that the largest number of landslides is related with Pontian silty-marl deposits (7.1-5.6 Ma) and Pleistocene silty-clay deposits (1.8 Ma – 10.000 years). These deposits contain continuous layers with clay minerals having high to very high and extremely high plasticity. In the Pontian sediments the most common clay minerals are smectite and illite / muscovite, and in some samples small quantities kaolinite and chlorite appear [1] [2]. Vermiculite and illite / muscovite are the most common clay minerals in the Pleistocene deposits. Kaolinite is present in almost all Pleistocene samples [1]. Smectite occurs in very small quantities only in certain samples, while chlorite is present mainly in the sandy and the silty fraction of these deposits.

In the wider Zagreb city area landslides are activated mainly during the first spring months, which is associated with content of water in soil, high groundwater levels and increased yield sources. It is known that increasing the amount of water in soil leads to swelling of clay minerals such as vermiculite and smectite. The presence of swelling clay minerals in the Pontian and the Pleistocene depositescausee cause the instability of slopes in the wider Zagreb city area. Differences in levels of slope instability are related to the different amount of expandable clay minerals in sediments and differences in water content in soil that directly influence the behavior of expandable clay minerals. Other factors which have important influence on instability of slopes are tectonics, shear strength, increase of the incline slope and antropogenic influence.

Sorption of cadmium (II) by the natural bentonite and magnetic clay composite

Orolínová, Z.[*] & Mockovčiaková, A.
Institute of Geotechnics SAS, Kosice, Slovakia
([*]orolinova@saske.sk)

The objective of this work is to compare the removal of cadmium (II) by the natural bentonite and composite, prepared by magnetic modification of the clay. The composite material was prepared by the method of precipitation from the solution of ferrous and ferric salts (Fe^{2+}/Fe^{3+} = 0.5), where the bentonite was added prior to the reaction. The weight ratio of bentonite to iron oxides was 5 to 1. The structural and surface study realized by XRD method, FE-TEM and low nitrogen adsorption method showed that the surface properties of the composite (Table 1) were affected by the precipitation of maghemite and goethite in agglomerated form.

Table 1: Surface parameters of the investigated samples obtained from the low temperature nitrogen adsorption method (S_{BET} – specific surface area, V_a – total pore volume, V_{micro} – volume of micropores, S_t – external surface area)

Sample	S_{BET} [$m^2 g^{-1}$]	V_a [$cm^3 g^{-1}$] STP	V_{micro} [$cm^3 g^{-1}$] STP	S_t [$m^2 g^{-1}$]
bentonite	39.44	0.096	0.006	25.43
composite	90.68	0.187	0.002	84.23

The sorption properties were examined under different conditions such as pH of the model solutions, contact time and initial metal ion concentration. The adsorption of cadmium (II) was dependent on the pH of the solution as well as the concentration of ions. The optimal pH for removal of cadmium (II) was found equal 5. The batch type experiments with the natural bentonite and composite material were first conducting using metal ion solutions ranging from 10 to 700 mg L^{-1}. Maximum adsorption capacities (61.35 and 63.29 mg g^{-1} for the bentonite and composite, respectively) were calculated using linearized Langmuir isotherm. Different adsorption rates observed in the low initial metal ion concentrations indicated the further study of adsorption at lower ranges. The highest efficiency of the composite material (more than 98 %) was observed in the range from 1 to 10 mg L^{-1}, Fig. 1.

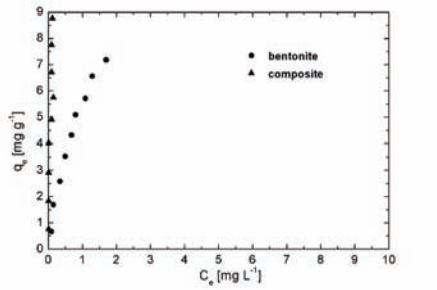

Fig. 1: Sorption of Cd(II) ions on the natural bentonite and composite material in the low initial metal ion concentration range 1 – 10 mg L^{-1}, sorbents dose 1 g L^{-1}, initial pH 5, contact time 24 hours.

Removal of heavy metals at low concentrations from aqueous environment is generally difficult, but the studied composite material showed very good sorption ability especially in these conditions. Therefore it seems to be convenient to use it in desposal of metals from aqueous solution, where their concentration is very low, but still harmful, as well as for the final purification of pre-treated waste waters.

Aquocomplex structure in the interlayer space of swelling high-charged micas

Pavón, E.[1*], Alba, M.D.[1], Castro, M.A.[1], Cota, A.[2], Naranjo, M.[1], Orta, M.M.[1] & Pazos, M.C.[1]
[1]Instituto Ciencia de los Materiales de Sevilla, CSIC-Universidad de Sevilla, Spain ([*]epavon@us.es)
[2]Laboratorio de Rayos-X. CITIUS, Universidad de Sevilla, Seville, Spain

The structure of the interlayer region of swelling high-charged micas is one of the fundamental problems of clay science. The mobility of the cations is important for describing chemical reactions in the environment as well as for estimating the environmental behaviour of metal ions. However, the chemical species of metal cations at solid-water interface in the interlayer space of swelling high-charged micas is still not clearly understood.

It is known that cation sorption is governed by cation size and charge, but the location of structural charge within a clay layer and the existence of hydrophobic patches on its surface provide important modulations. On one hand, larger the interlayer cation, greater the influence of clay mineral structure and hydrophobicity on the configurations of adsorbed water molecules. On the other hand, larger hydrated radius means that the cationic center of charge is farther from the clay surface so the clay-cation electrostatic interaction is weaker.

The aim of this research was the systematic study of hydrated swelling high-charged M-Mica-n,-where n represents the layer charge equal to n=2, 3, 4 and M is the interlayer cation, ($M=Na^{+}$, Li^{+}, Mg^{+2}, Al^{+3})- using Thermal Analysis (ATD/TG), X-ray Diffraction and Solid State NMR.

Na-Micas-n (n=2,3,4) prepared as reported by our research group were used as starting materials.[1] M-Micas-n were prepared by cation-exchange reaction, in accordance with the method described by Powell et al. [2]

The results obtained with TG measurements revealed that the cation hydration state did not only depend on the cation nature, as expected in solutions, but did on the Mica layer charge. Hence, an interaction between interlayer cation and the basal plane of the tetrahedral sheet of Mica could be infered. It was confirmed by ^{29}Si MAS NMR and the variation of the 060 reflection. Therefore, it can be concluded that the nature of the cations and Mica determine the equilibrium between inner-sphere and outer-sphere complex formation.

Vertical and horizontal distribution of ^{137}Cs in Pest County, Hungary

Szabó, K.Zs.[1*], Udvardi, B.[1], Horváth, Á.[2], Bakacsi, Zs.[3], Szabó, J.[3], Pásztor, L.[3] & Szabó, Cs.[1]
[1]Litosphere Fluid Research Lab, Eötvös University, Budapest, Hungary ([*]sz_k_zs@yahoo.de)
[2]Dept. of Atomic Physics, Eötvös University, Budapest, Hungary
[3]GIS Lab, Research Institute for Soil Science and Agricultural Chemistry of the Hungarian Academy of Sciences, Budapest, Hungary

This paper presents the results of measurements of ^{137}Cs in soils which were sampled in Pest County, Hungary. The studied soil samples of 45 soil monoliths from TIM (Soil Information and Monitoring System) were collected in 1992. The ^{137}Cs content has been determined for all locations by gamma spectroscopy and found that only the upper layer of soil (0-30 cm) contains ^{137}Cs from the all layers (0-30, 30-60, 60-90, 90-120, 120-150 cm). Cesium-137 concentration in these layers ranged 0.7 ± 0.5 Bq/kg to 41.3 ±1.5 Bq/kg. These activity values were illustrated on a map that can be consider as the first detailed cesium map in Hungary. We found salient value (31.7 Bq/kg and 41.3 Bq/kg) compared to the average activity (5.8 Bq/kg) at two points of the sampling sites. One of them is at Gödöllő Hills and the other is at the western foot of Buda Mountain. It is known that there is a strong relationship between ^{137}Cs concentration and clay, as well as organic matter content of the soils [1,2]. This relationship was studied in details in soil samples from drilling in brown forest soil from the same location as the highest activity concentration (41 Bq/kg) occurred. Aggregate size fractions were separated using dry sieving technique and their clay mineral contents were determined by differential thermal analysis and XRD techniques. According to the results of these analyses, an amount of organic matter less than 40% and prevailing illite and kaolinite were determined in the sample. The amount of clay minerals was found closely proportional to cesium-137 activity in the aggregate fractions, which indicates the cesium fixation to these clay minerals. For analyzing the vertical distribution and migration of cesium, a soil profile at the same locality was studied. It was found that it is present in the upper 20 cm of the soil, indicating that penetration of cesium into the soil is very slow process here. 23 years after the Chernobyl accident most of the cesium activity is still in the top 16 cm, and the 78% is located in the top 3 cm. This corresponds to results of other studies [3,4] and suggests slower cesium migration than predicted earlier [5]. This prediction was applied in the framework of convective-diffusional model using time independent diffusion coefficient and convection velocity. Our results demonstrated for this site that either the migration speed is very low, or it is time dependent and slowed down during the last 10 years.

Hungarian adobe as source of thoron

Szabó, Zs.[1*], Szabó, Cs.[1] & Horváth, Á.[2]
[1]Lithosphere Fluid Research Lab, Dept. of Petrology and Geochemistry, Eötvös University, Budapest, Hungary ([*]zsszabo86@gmail.com)
[2]Dept. of Atomic Physics, Eötvös University, Budapest, Hungary

Thorium (^{232}Th) is a naturally occurring radioactive element and thoron (^{220}Rn) isotope is the only one gaseous daughter of its decay chain. Thorium is estimated to be about three times higher abundance than uranium (^{235}U, ^{238}U) in natural environment including soils [1]. Thorium can also be quantifiable trace element like thoron source in clayey soils, which are the major raw materials of adobe houses beside straw.

Thoron, similar to radon (^{222}Rn) [2] in uranium (^{238}U) decay chain, has a high capability to enter the air of rooms from the walls of adobe houses, which makes possible to accumulate in indoor air, as well as its solid decay products as aerosols. Thoron has an effect in dose increasing which is underestimated in many cases. This is the reason why has not been done extended survey on it yet in Hungary.

The average of total annual effective dose from thoron is only 0.1 mSv [1], however, several studies [3-7] showed much higher values in dwellings made mostly by soil or soil bricks. Among these examples, annual effective dose goes up to about 5 mSv average [4]. It indicates that adobe houses in Hungary can be endangered by thoron more than other type of buildings, although they have several propitious features in many respects.

The main aim of this work is to obtain knowledge on possible risk from thoron and its source. Therefore, three distinct areas of Hungary have been selected to study. All of them have local soils suitable, experience and tradition for building adobe houses and a probability to be endangered by thoron. These areas are Sajó and Hernád Rivers' Valleys (NE-Hungary), where redeposited loess is typical, E-Mecsek Mts. (S-Hungary) and Békés County (SE-Hungary), where loess and alluvial sediments of Körös and Maros Rivers are prevailing, respectively [8].

Present work is focusing on Békés County where six settlements (Gyomaendrőd, Gyula, Kondoros, Sarkad, Újiráz, Vésztő) have been selected for detailed investigation based on geological and geographical differences and previous surveys, too. Experimental one-day indoor radon and thoron concentration measurement by RAD7 radon detector refers that fairly high thoron concentrations (even more than 400 Bq/m^3) can be detected in adobe houses of this area.

Soil samples of sought out adobe making places at selected six settlements have been collected, as well as abode samples at least from one dwelling of each sites. The origins of raw materials of adobe samples presumably are the mentioned adobe making places. Detailed study of the samples was done in laboratory, which refers that adobe can actually be a potential source of thoron.

Reduced leaching of the herbicide metribuzin by using clay-gel-based formulations

Undabeytia, T.[1*], Maqueda, C.[1], Morillo, E.[1], Villaverde, J.[1], Pérez-Sayago, M.[1] & Partal, P.[2]
[1]Institute of Natural Resources & Agrobiology, CSIC, Seville, Spain ([*]undabeyt@irnase.csic.es)
[2]Dept. of Chemical Engineering, University of Huelva, Huelva, Spain

Herbicide mobility in soils has long been of concern for many reasons, including the following: (i) contamination of groundwater; (ii) reduction in efficacy due to herbicide leaching below the weed seed zone, which can reduce herbicidal activity and crop yield; and (iii) surface migration of the herbicide which harms neighboring crops.

To reduce herbicide leaching and increase weed control, new slow release formulations were developed by entrapping metribuzin within a sepiolite-gel-based matrix using two clay/herbicide proportions (0.5/0.2 and 1/0.2) (loaded at 28.6 and 16.7% active ingredient) as a gel (G28, G16) or as powder after freeze-drying (LF28, LF16).

A rheological characterization of the formulated products showed a viscoelastic behaviour as noted in the higher storage modulus G' than the loss modulus G'', within the experimental frequency range employed. A more detailed analysis of the rheological properties such as the apparent yield stress and plateau modulus indicated that samples containing metribuzin up to 2% of sepiolite form a microstructure, which is independent of sepiolite concentration. Addition of metribuzin seemed to weaken the microstructure, and its release behaviour seemed to be related to the microstructure.

The release of metribuzin from the prepared formulations into water was retarded, when compared with the commercial formulation, except in the case of G28. These results were in accordance with those from soil column experiments where the G28 and the commercial formulation eluted almost completely after 4 pore volumes. On the contrary, the total leaching percentages of the other gel-clay based formulations were about half of the total applied amount. An extraction of the active ingredient along these soil columns showed a larger amount in the upper part of the soil column which is of prime interest for weed control (Fig. 1). Bioassays performed at different soil depths paralleled those of the extracted amounts showing a high herbicidal activity in the 0-8 cm depth.

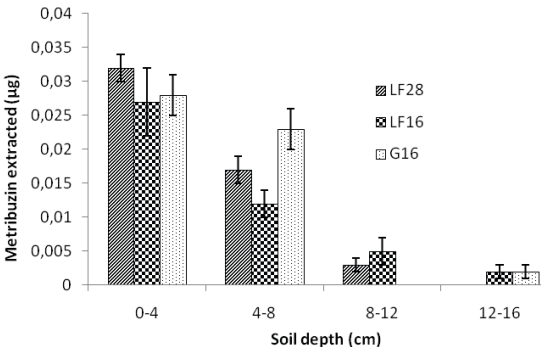

Fig. 1: Metribuzin residues extracted at different depths of the soil columns.

Hydration thermodynamics of SWy-1 montmorillonite saturated with alkali and alkaline-earth cations

Vieillard, P.[1*], Blanc, P.[2], Gailhanou, H.[2], Gaboreau, S.[2] & Fialips, Cl.[3]
[1]INSU-UMR6269, Hydrasa, Poitiers, France
([*]philippe.vieillard@univ-poitiers.fr)
[2]BRGM, BP 6009, Orléans, France
[3]ANDRA, Chatenay Malabry cedex, France

In the context of using clayey barriers, such as in the disposal of radioactive waste within clayey formations, the assessment of the long-term behavior of the clay materials by geochemical modeling requires a perfect knowledge of their thermodynamic properties. The "Thermochimie" database, created by ANDRA in 1996, provides coherent thermodynamic data sets for many minerals of interests, including clay minerals. However, the thermodynamic properties of clay minerals, which govern their stability in solution, are still poorly understood and few experimental data of hydration are available for smectites. A set of consistent data of hydration is proposed from numerous measurements of enthalpy of immersion, and isotherms of adsorption – desorption for SWy-1 montmorillonite saturated with alkali and alkaline-earth cations. To retrieve standard state thermodynamic properties for smectite hydration and dehydration from such data, the amount of H_2O in excess of that located in the interlayer space must be assessed and subtracted from the total amount taken up by the clay sample. Careful measurements of water uptake and release during the hydration and dehydration of the SWy-1 montmorillonite have therefore been taken into account [1,2].

Considering the following reaction: Smectite n_m H_2O = Smectite (0 H_2O) + n_m H_2O (l), the hydration of smectite is calculated by assuming a regular solid solution involving anhydrous and hydrous components in which n_m is the maximal number of moles of water in the fully hydrated end-member [3]. Paired hydration and dehydration isotherms in the one hand and enthalpy of immersion in the other hand, which characterize the equilibrium between water and smectite, can be regressed to assess standard state thermodynamic parameters (enthalpy and entropy) for the hydration - dehydration process.

Validation of standard state thermodynamic properties of hydration of the end members has been achieved by (1) comparing the behavior of hydration-dehydration with experimental measurements done on hetero-ionic SWy-1 and homo-ionic SWy-1 samples at different temperatures; (2) comparing experimental integral enthalpy and entropy of hydration of SWy1 samples with calculated values; and (3) comparing results with those obtained for various smectites with different layer charges (Upton, MX80).

The developed and validated model can predict the standard state thermodynamic properties of hydration and the number of moles of interlayer water in smectites for a given temperature and relative humidity. It may help solving many questions like: the mechanism of exchange between two cations, the number of moles of water transferred during exchange for a given temperature, and the cation selectivity at a given relative humidity. When a limited number of measurements are available, the predictive model can be applied to different compositions to provide theoretical thermodynamic values of formation for hydrated smectites and calibrated with measured data from the literature or acquired within the framework of the project.

Photocatalytic degradation of Rhodamine B in water by synthetic Zn-substituted phyllosilicates

Yamada, H.[1*], Morimoto, K.[1], Tamura, K.[1], Pascua, C.S.[2] & Hatta, T.[3]
[1]National Institute for Materials Science, Tsukuba, Japan
([*]YAMADA.Hirohisa@nims.go.jp)
[2]National Institute of Geological Sciences, UP-Diliman, Quezon City, Philippine
[3]Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

Nanolayer has been paid attentions as building block for novel photonic, electronic, environmental, and energy-related materials. Phyllosilicates are abundant in nature, and are layered materials that contain two-dimensional metal octahedral sheet and silica tetrahedral sheet. In another point of view, phyllosilicates are considered to be the self-assembled silicate nanolayers of octahedral and tetrahedral sheets. Phyllosilicates containing transition metal ions can be used for specific catalytic applications. In the present work, we have demonstrated the photocatalytic activity of Zn-substituted phyllosilicates (smectite, vermiculite and mica) which synthesized by "adaptation of processes in the formation of natural geologic analogues"; a new concept called Geonics [1].

The decomposition of organic dye, Rhodamine B (RhB) in aqueous suspensions of the synthetic Zn-substituted phyllosilicates, Zn-saponite and Zn-hectorite, Zn-vermiculite, Zn-mica and rutile under ultraviolet light illumination were monitored with a UV-visible absorption spectroscopy. In aqueous solution with Zn-smectites, the reduction of peak absorbance for RhB was observed in the adsorption spectra, although the shape and the width of their absorption bands were similar to that in aqueous solution. This adsorption behavior indicated that RhB molecules adsorbed onto the surface of Zn-smectites particles without discernible aggregation and the adsorbed RhB molecules were well dispersed. It was confirmed that the hybridization of RhB with the exfoliated Zn-smectites particles enhanced a photodegradation exponentially. On the other hand, Zn-vermiculite and Zn-mica in aqueous solution showed little photodegradation of RhB. The results indicated clearly that the high photocatalytic activity of smectites is attributed to the exfoliation behavior, that is, the nanosheet structure of the synthesized Zn-smectites. Furthermore, the characteristic stability of smectites in aqueous systems in a wide range of pH and redox conditions would make it an ideal nanomaterial in environmental purification.

Removal of silica impurities from bentonite by NaOH dissolution

Zhang Bingbing[1], Su Haiquan[1,2*], Li Jia[2], Pan Hui[2] & Huang Xiaoling[2]

[1]College of Life Science, Inner Mongolia University, Hohhot, P.R. China

[2]School of Chemistry and Chemical Engineering, Inner Mongolia University, Hohhot, P.R. China

([*]haiquansu@yahoo.com)

Bentonites usually contain quartz, α-cristobalite, opal-C, opal-CT, and opal-A as associated silica impurities, which must be removed from bentonites due to the designation of respirable quartz and cristobalite as 'type 1' human carcinogens. These silica impurities could hardly be separated from montmorillonite by conventional wet sedimentation.

In this paper, bentonite was sampled from Xinhe County, Inner Mongolia, China; the mineral composition is as follows: montmorillonite (65.1%), cristobalite (33.0%), and quartz (1.9%). The removal of cristobalite and quartz from bentonite by NaOH dissolution was explored in detail. The result (see Fig. 1 and Fig. 2) shows that the quartz had very different reactivity compared with the cristobalite, only the cristobalite could be separated from montmorillonite by this method.

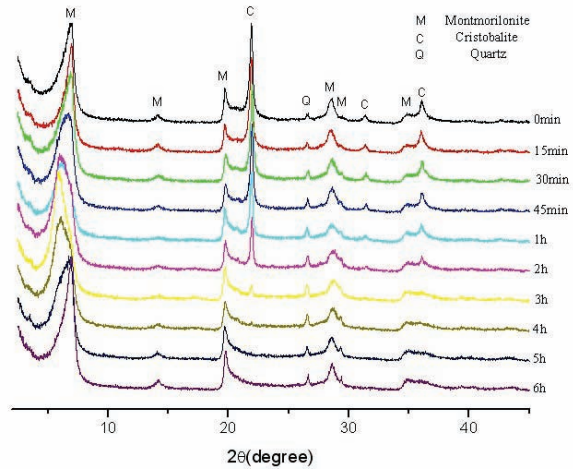

Fig. 1: XRD patterns of the bentonite samples reacted with 0.5 M NaOH at 90 °C with different reaction time.

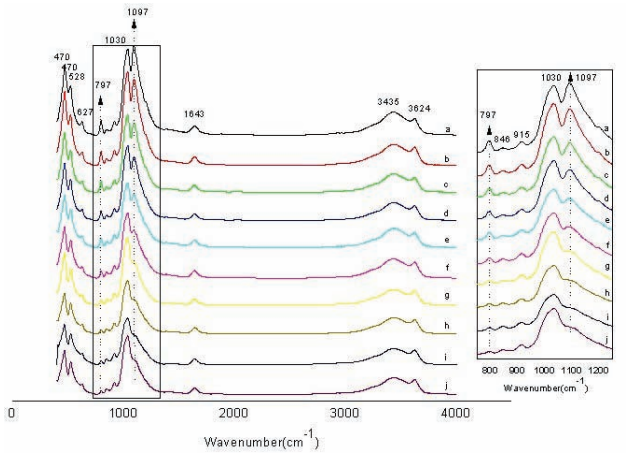

Fig. 2: FTIR spectra of the bentonite samples reacted with 0.5 M NaOH at 90 °C with different reaction time (a-j corresponding 0min-6h).

Layered minerals nanotopography and surface potential: biomedical and bioengineering applications

Valdrè, G.
Dept. of Earth And Geo-Environmental Sciences, University of Bologna, Italy (giovanni.valdre@unibo.it)

The knowledge of the surface properties of layered minerals is of great importance to understand basic and applied technology, such as, for example liquid/surface interactions, microfluidity, friction or tribology and biomolecules self-assembly and adhesion. Recent developments of Scanning Probe Microscopy (SPM) have widened the spectrum of possible investigations that can be performed at a nanometer-scale level on the surface of minerals. Investigations involve physical properties, such as surface potential and electric-field topological determinations, and chemical and spectroscopic analysis in air, in liquid or in a gaseous environment.

After a brief introduction of new technological developments relating to SPM, recent achievements are presented in characterization and application of nanomorphology and surface potential properties of minerals, in particular the behaviour of some layer silicates. Two general research directions are presented: application of bio/organic surface interactions of layer silicates, and mineral hydrophilicity/phobicity and friction/adhesion issues.

(1) The ability to control the binding of biological and organic molecules to a crystal surface is central in biotechnology, catalysis, molecular microarrays, biosensors and environmental sciences. For instance, recent achievements showed that DNA molecules have different binding affinities and assume different conformations when adsorbed to various layer silicate surfaces. On certain crystals, the electrostatic surface potential anisotropy can order and stretch the DNA filament, thus inducing a natural change in its conformation. The experimental results are in good agreement with simulations and mathematical modeling. The active stretching of DNA on extensive layer silicate surfaces is a clear indication of the potential in understanding basic behavior and developing technological uses of these minerals when used as substrates for biomolecules. Examples involving nucleotides, RNA and cells are presented also.

(2) Investigations of nano-confined adhesive and shear forces of water (and other liquids) onto layer silicate and other mineral surfaces are presented. The study of water in confined geometries is very important because it can provide simple models for nano-bio-tribology and fluid/mineral interactions. Nano-confinement is obtained between a resonating (oscillating) probe and layer mineral surfaces. When the liquid-film thickness is less then a critical value, the oscillation amplitude curve follows a step-like trend, suggesting that the liquid molecules are organized in layers. By using a harmonic oscillator model it is possible to calculate the variation in the elastic and viscous stress response of the confined liquid and to characterise its state respect to the mineral surface.

Montmorillonite as efficient carrier of Gentamicin used for antibiotic treatment: comparison of MD simulations with experiments

There is a strong demand to identify new strategies in order to set optimal drug delivery systems for antibiotic treatments. Intercalation of organic molecules into layered inorganic solids provides a useful and convenient route to prepare hybrids that show properties of both the inorganic host and organic guest in a single material [1,2]. Both natural and synthetic clays have been already used with success for this purpose. One of the main system widely investigated to modulate drug release, consider smectite clay particles, especially montmorillonite (Fig. 1).

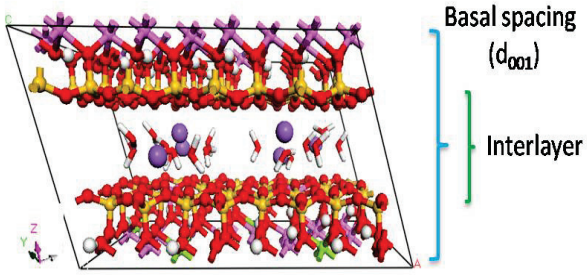

Fig. 1: Ideal model of a Wyoming-type montmorillonite.

High specific surface, adsorptive capacity, rheological properties, chemical inertness and low or null toxicity make clay minerals futuristic drug delivery vehicles [3].The presented work shows the potential of a montmorillonite-based clay mineral (bentonite) to contribute to the development of novel antibiotic materials. In our knowledge, it is the first time the have been tested the intercalation of gentamicin molecules in montmorillonite as a drug delivery carriers for antibiotic treatment (Fig.2).

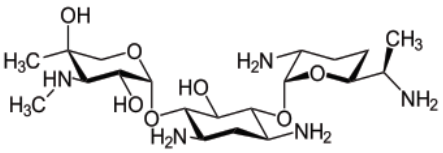

Fig. 2: Gentamicin.

Comparison of experimental measurements (XRD, TGA, DTA) with simulations (MD modelling) have provided a more detailed understanding of the geometry, organization of gentamicin molecules confined in the cationic clay. By MD simulations it has been possible obtain a further insight into the interactions between the organic guest and the clay framework in view to optimize the cationic exchange process.

[2]Chemical Dept., Buryat State University, Ulan-Ude, Russia

The use of natural sorbents can increase economic efficiency of sorption technologies due to their availability, relative cheapness and the possibility of recycling. Natural montmorillonite (MM) clays are effective cation exchangers. At present, an urgent task remains the development of anion-exchange sorbents, based on montmorillonite. Layer-pillar structured materials synthesized by intercalating metallic polyoxocomplexes between silicate layers of swelling clays, such as montmorillonites attract the interest as sorbents. Fe-, Al- and Fe/Al-montmorillonites were prepared from naturally occurring montmorillonite (clay deposit Mukhortala, Russia) by exchanging interlayer cations (Mg^{2+}, Na^{+}, K^{+}) with polyoxocations containing a) iron (Fe-MM), b) iron and aluminium within the complex with Fe/Al = 1:1 (Fe/Al-MM), c) $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ (Al-MM). The synthesized solids were calcined for 2 h at 400°C, 500°C and characterized by IR-spectroscopy, XRD, chemical analysis and BET surface area measurements.

The cation and anion exchanging properties of solids were studied in aqueous solutions using as adsorbates cationic (Methylene blue (MB)) and anionic (Acid chrome blue-black (ACBB), Congo red (CR)) organic dyes, NH4+, phosphate, chloride ions and anionic surfactants (Sodium dodecylsulphate and Sulphonole). An intercalation MM by Al, Fe and Fe / Al-polyoxocations reduces the cation exchange capacity (CEC) of ammonium cations and adsorption capacity (AC) of the cationic dye MB in comparison with natural MM. Adsorption of dye MB on studied sorbents depends not only on the number of cation-exchange centers, but also on the size of their accessible surface. Value of adsorption on the sorbents decreases in the series: Fe-MM> Fe/Al-MM> Al-MM, which corresponds to the decrease of the total surface area of meso- and macropores. Introduction of Al, Fe and Fe/Al-polyoxocations to the structure of MM leads to a significant increase in the adsorption properties with respect to anions (chloride, phosphate), due to an increase in the number of anion-exchange centers. Results on the adsorption of anionic surfactants also confirm the increase in anion-exchange capacity of MM for intercalation. Adsorption capacity of phosphate decreases in the series: Al-MM> Fe-MM> Fe/Al-MM> Natural MM, which corresponds to a change in the total specific surface of these sorbents, indicating the accessibility of micropores for adsorption of phosphates. Adsorption capacity for anions of organic dyes for sorbents were subjected to heat treatment at temperatures $\leq$ 300 °C, correlates with the number of anion-exchange centers and the total surface area. Calcining at temperatures$\geq$ 400 °C leads to a decrease in accessible pores surface for microporous adsorbent Al-MM and reduction of AC for large organic anions, whereas the adsorption of inorganic anions remains high and 3-6 times higher than AC for natural MM. Increasing the size of sorbed anions and their degree of association in aqueous solutions leads to a decrease in AC by steric factors, as was observed for the large anions of dyes ACBB and CR. Microporous sorbent Al-MM is effective for removal from aqueous solutions of inorganic anions, and for the removal of large organic anions are effective Fe-MM, Fe/Al-MM having mesoporous structure.

ACE anionic inhibitors-clay nanocomposites: synthesis and characterization

Alexa, I.F.*, Seftel, E.M., Păstrăvanu, C. & Popovici, E.
Dept. of Materials Chemistry, "Al. I. Cuza" University, Iaşi, Romania (*alexaiulianaflorentina@yahoo.com)

ACE inhibitors are used for controlling blood pressure, treating heart failure, preventing strokes, and preventing kidney damage to people with hypertension or diabetes. In the present study, the selected drug for loading onto the layered matrix was captopril (Fig. 1).

Layered double hydroxides (LDHs), also called hydrotalcite-type anionic clays, consist of cationic brucite-like layers and exchangeable interlayer anions [1]. Due to their biocompatibility, some LDHs having different cationic pairs, such as Mg/Al, Zn/Al, Fe/Al or Li/Al-LDH, can be used as host materials for drugs in order to obtain LDH host–guest supramolecular structures [2, 3].

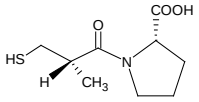

Fig. 1: The chemical structure of captopril, (*2S*)-1-[(*2S*)-2-methyl-3-sulfanylpropanoyl]pyrrolidine-2-carboxylic acid.

Calcined layered double oxide precursor (MgAl–LDO) used for intercalation was obtained by calcination of the layered double hydroxide containing Mg and Al (MgAl–LDH) at 500°C for 2h. Then, the calcined product was re-hydrated in the presence of a captopril solution under a N_2 atmosphere. The obtained material was analyzed by N_2 sorption, UV-vis DR and FTIR Spectroscopy methods.

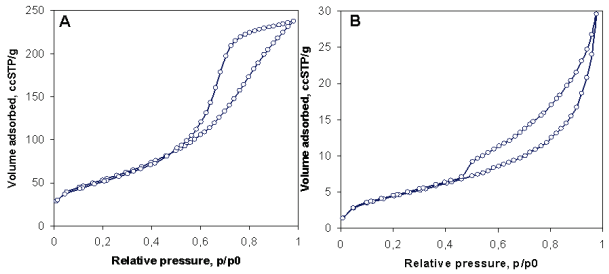

Fig. 2. The N_2 adsorption/desorption of (A) MgAl-LDO and (B) Captopril-MgAl-LDH.

The N_2 adsorption isotherms (Fig. 2) showed that the captopril molecules are successfully loaded into the layered matrix. The specific surface area and the pore volume decrease significantly after the drug loading (Table 1).

Table 1: Textural properties of the studied samples

Sample	S_{BET} (m^2/g)	V_p (cm^3/g)
MgAl-LDO	195.5	0.3571
Captopril-MgAl-LDH	16.2	0.0371

The FTIR and UV-vis DR spectra show the presence of the absorption bands characteristic to the organic captopril molecules. The present study may offer broad perspectives in utilizing MgAl-layered double hydroxides as an alternative biocompatible inorganic matrix for a feasible drug reservoir or a drug delivery carrier.

Effect of microbiological activity on the flow/rheologic properties of aqueous kaolin mineral suspensions

Papp, I.P.[1*], Babcsán, N.B.[1] & Tombácz, E.T.[2]
[1]Bay Zoltán Foundation for Applied Research Institute for Logistics and Production Systems, Miskolc, Hungary (*papp.ildiko@bay-logi.hu)
[2]Dept. of Colloid Chemistry, University of Szeged, Hungary

The aim of the present study was to investigate the rheologic properties of different type of kaolin infected by microorganisms.

Microorganisms are widespread in the different environmental systems, such as air, water and soil. However, interactions between industrial raw materials and microorganisms are not investigated in details [1]. It was found that these industrial raw materials (different type of kaolin) provide appropriate conditions for microorganisms especially sulfate reducing bacteria. Organic and inorganic compounds of kaolin can serve as nutrition source for microorganisms, accordingly of lignite for fungi and metals for specific bacteria. The organic additives (e.g. regulator substances, hydraulic oil, machine oil) that facilitate the processing serve as additional nutrition sources. Temperature, moisture and nutrition play a key role in the reproduction of microorganisms. Each long-term process involves the danger of proliferation of microorganisms, which phenomenon has an effect on the rheologic properties of kaolin suspensions. 30-40°C temperature for a long time had been creating ideal conditions for proliferation of microorganism, which caused drastic changes in the rheologic properties of kaolin samples. We investigated the rheologic changes of infected and uninfected kaolin samples depended on temperature. According to our results, sulfate reducing bacteria influenced significantly the rheologic properties of kaolin.

[3]Insituto de Ciencia de los Materiales, CSIC, Sevilla, Spain
[4]Instituto Andaluz de Ciencias de la Tierra, CSIC-Universidad de Granada, Spain ([*]cviseras@ugr.es)

Naturally occurring clays and clay minerals may be suitable to effectively modulate drug release. However, sometimes it is necessary to use modified or synthetic clay minerals and/or polymeric additives [1]. Clays and biopolymers have been proposed as interesting materials for new drug delivery systems [2]. Chitosan, a polymer derived from chitin used as a pharmaceutical excipient [3], have been added to montmorillonite dispersions to modify rheological properties related to flocculation state of the resultant dispersions [4]. Chitosan has been also proposed to be used in colon-specific drug delivery systems as regards of its degradation by colonic bacteria [5]. However, due to its high solubility and swelling properties in acidic media, chitosan alone is unable to prevent drug release in the stomach and small intestine, being desirable to get some strategies to avoid such problems. In particular, synthesis of composites with clay minerals may be a novel approach to modify swelling and water uptake of polysaccharides [6]

With these premises, biocomposites between chitosan base (CS) and a commercial montmorillonite (Veegum HS©, VHS) have been prepared by solid-liquid interaction and the water uptake profiles in acidic environment and mucoadhesive properties evaluated, in comparison with the single components. Water uptake measures were done by using a modified Enslin apparatus [7]. Mucoadhesive properties were investigated with a TA-XT2 Plus Texture Analyser (Stable Micro Systems, Enco, Italy) using porcine gastric mucin as biological substrate.

The CS/VHS composites showed lower solubility than pure chitosan in acidic environment and mucoadhesión followed the trend CS > CS/VHS > VHS. It can be concluded that the interaction between the clay particles and polymer chains results in a composite with good mucoadhesive properties, and promising solubility pattern to be used as colonic delivery excipient.

Iron-clay-bacteria interactions in quartz sands purification

Štyriaková, I.[1*], Kraus, I.[2], Mockovčiaková, A.[1], Orolínová, Z.[1] & Štyriak, I.[1]
[1]Institute of Geotechnics SAS, Kosice, Slovakia
([*]bacil@saske.sk)
[2]Comenius University, Bratislava, Slovakia

Several natural sands are brown for the presence of iron and clay minerals that coat or which are impregnated on quartz grain surfaces. *In-situ* washing and bioleaching processes can remove iron and clay minerals.

The following mineral composition (wt %) of the different grain sizes was obtained using Rock Jock software: 31 % quartz, 11 % K-feldspar, 15 % plagioclase, 20 % mica, 11 % kaolinite and 12 % chlorite in the fraction 0.002-0.063 mm and 15 % quartz, 8 % K-feldspar, 4 % plagioclase, 28 % mica, 19 % kaolinite and 26 % chlorite in the grain size fraction < 0.002 mm. Iron-clay-bacteria interaction was found during a laboratory bioleaching of separated iron-clay fraction. The impoverishment by fine-grained fraction is a result of bacterial destruction of silicate minerals. After bioleaching the amount of the fraction 0.9 - 25 μm μm decreased, on the other hand the distribution of the coarse-grained fraction with particle size from 25 to 87 μm increased in the clay sample.

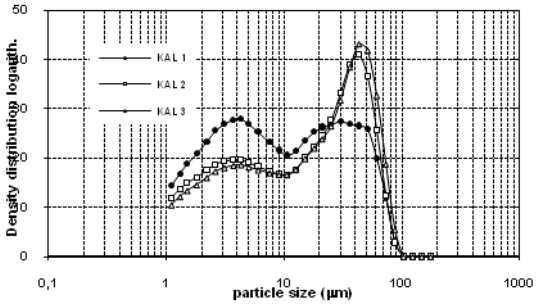

Fig. 1: Granulometric analysis of the clay fraction before (KAL 1) and after bioleaching (KAL2 – *Bacillus* spp., KAL3 – indigenous bacteria).

Dissolved Fe amount under pH ranging between 4 and 7 and in a nutrient-rich environment simulating the conditions of an *in-situ* quartz sands purification, was periodically monitored for 30 days. Mössbauer spectroscopy was used to detect the present iron cations in the natural sample (KAL 1); experimental data indicated that Fe^{3+} cations in KAL 1 can be ascribed to a ferrihydrite-like phase. In *Bacillus* spp., and indigenous bacteria treated samples (KAL 2 and KAL 3, respectively) Fe^{3+} was prior removed always from the same position and, in addition, higher Fe^{3+} decrease was obtained for sample KAL 2.

Table 1: Chemical composition of the clay fraction before (KAL 1) and after bioleaching (KAL2 – *Bacillus* spp., KAL3 – indigenous bacteria)

Elements (%)	KAL 1	KAL 2	KAL 3
SiO_2	56.9	57.5	57.3
Al_2O_3	18.5	18.1	18.5
Fe_2O_3	7.04	4.42	4.65
TiO_2	0.44	0.44	0.45
CaO	1.27	0.90	0.85
MgO	0.92	0.80	0.79
Na_2O	1.19	1.34	1.35
K_2O	2.01	2.33	2.38

The effect of iron-bacteria complexation by exudates caused the clay dissolution with the release of silica. Bacterial clay dissolution liberated iron to promote quartz sands purification.

Selection of protein amino acids in natural montmorillonite gel

Yushkin, N.P.
Institute of Geology, UB RAS, Syktyvkar, Russia
(yushkin@geo.komisc.ru)

At the studies of biomineral interactions the natural montmorillonite gels from mineral deposits provide the most versatile information on the real environments and processes of synthesis of nucleotides and other biomolecules.

We studied gel accumulations from hydrothermal fluorite deposit Palat in Bulgaria, where in 1983 the gel samples were selected and hermetically packed. The material of preserved and fresh samples is completely identical by their composition and properties.

The gel represents homogeneous jelly-like snow-white mass. The dispersed phase are two-dimensional (length 15 mcm, width 0.4-0.8 mcm) thin-banded individuals of Ca, Mg-montmorillonite, the dispersion medium-strongly mineralized water of chloride-sulphate-bicarbonate calcium-natrium composition.

The electronic microscopy studies of fresh or not long preserved (one-two years) samples of gel-montmorillonite showed numerous rod-like bacteria. In the long preserved gel living bacteria were not observed, however SEM studies showed bacterium-like forms of Cu-Fe-Zn composition without sulphur, which probable represent brass pseudomorphoses on fossilized bacteria.

The gel-montmorillonite contains 0.28% $C_{org.}$ Chromato-mass-spectrometry of organic matter extract from the montmorillonite testifies to its peculiar composition. The group of acyclic alkans and alkens are the most interesting, which are distinguished by the isomerism of carbon framework and position of multiple bonds. There is also a number of aromatic and heterocompounds. Such a composition of organic compounds is not characteristic for hydrocarbons (of geological nature), and seems to be consequence of montmorillonite selection. At the end of the chromatogram there are C_{26}-C_{35} n-alkans, which are typical components of petroleum series.

In the natural gel-montmorillonite the presence of a wide spectrum of amino acids (Glu, Gly, Ala, Val, Leu, Tyr, Phe, His, Lys, Arg) has been determined, which considerably differs from the corresponding spectra of sedimentary montmorillonite clays and is closer to the amino acid composition of abiogenous hydrocarbon ordered structures. It is not excluded that the formation of the amino acids results from catalytic action of montmorillonite to the structural transformation of the organic matter of mineral-forming solutions. In 12 years the total content of amino acids decreased by 5 times (from 8.9 to 1.72 mg/100 g of matter). The qualitative composition of the amino acids is practically the same, excluding tyrosine, which is not determined in the primary preservative even in trace quantities. All the amino acids, identified after 12 year-preservation, are represented exclusively by L-enantiomers; D-amino acids were not determined. It is quite reasonable that for the period between two studies the montmorillonite continued to directly select protein amino acids, and the complete chiral selection of left enantiomers passed.

Thus, the peculiarities of structural evolution of montmorillonite gel and its interaction with organic matter allow using the natural gel-montmorillonite both for simulation of possible environments of biomolecular formation and more complex protobiological structures, and as simulations of some biological processes responsible for transfer and transformation of information and feedback

Oxidation state of Fe and precipitates in olivine from scoria and lava of Kasayama volcano, Yamaguchi, Japan

Ejima, T.[1*], Akasaka, M.[2] & Nagao, T.[2]
[1]Dept. of Geosciences, Shimane University, Matsue, Japan
([*]olivinefe3@yahoo.co.jp)
[2]Dept. of Geosphere Sciences, Yamaguchi University, Japan

Oxidation states of Fe and precipitates in olivine from andesitic scoria and orthopyroxene-olivine-clinopyroxene andesite (Opx-Ol-Cpx andesite) lava of Kasayama volcano, Hagi, Yamaguchi Prefecture, Japan, were investigated in order to formulate the oxidation process in olivine by high temperature oxidation of the scoria and lava.

Kasayama volcano consists of Opx-Ol-Cpx andesite lava (L1), olivine-clinopyroxene basaltic andesite (Ol-Cpx-andesite) lava (L2, L3-l, L3-u), Opx-Ol-Cpx-andesite lava (L4), and scoria cone composed of Opx-Cpx-Ol andesitic scoria (S1) and Cpx-Ol andesitic scoria (S2) in the ascending order.

The inside of the Kasayama scoria cone is welded and red in color, whereas, on the outer surface of the cone, black or reddish black scorias are deposited. In olivine phenocrysts of the reddish black scoria, only a small amount of precipitates occur on the rim. However, olivine phenocrysts in the red scoria include a lot of precipitates, such as hematite, enstatite and magnesioferrite, which form simplectite zone on the rim, simplectite domain in the core, and fillings in fractures. Hematite occurs as vermicular rods or flame-like form. The Fo contents of olivine in the black scoria were 81-90, whereas those in the red scoria attaind 99 to 91 mol%. The ^{57}Fe Mössbauer spectrum of olivine in the reddish black scoria consists of three doublets assigned to Fe^{2+}(M1, M2) and Fe^{3+}(M2) in olivine, and Fe^{3+}(M2) in laihunite, and the Fe^{2+}(M1, M2):Fe^{3+}(M2)-ratio is 69:31. The resulted chemical formula of the olivine is $[^{M2}(Mg^{2+}_{0.83}\ Fe^{2+}_{0.06}Fe^{3+}_{0.11})\ ^{M1}(Mg_{0.84}Fe^{2+}_{0.17})]_{\sum 2.01}\ SiO_4$.

Although the Opx-Ol-Cpx andesite lava is generally black in color, there are some areas with red surface and reddish black subsurface. Olivine in the reddish black and red lavas includes precipitates consisting of titanohematite, magnesioferrite and enstatite, and tends to be Mg-rich. The stronger the red colors of the lavas, the more the amounts of the precipitates in olivine, which results in increase of Mg content in olivine: in olivine from the black lava, the cores and rims are $Fo_{68.54\text{-}74.89}$ and $Fo_{64.90\text{-}72.90}$, respectively, whereas olivine compositions of the red lava are $Fo_{91.01\text{-}95.43}$. Fe in olivine from the black lava is commonly ferrous, but, in some cases, Fe^{3+} was detected in the rim. Small amounts of Fe^{3+} (< 0.05 apfu) were inevitably detected in olivine from the reddish black and red lavas. The textures and chemical composition of the precipitates in olivine suggest that titanohematite and magnesioferrite may have been grown on primary titanomagnetite and chromian spinal, respectively.

High temperature oxidation process in olivine from the Kasayama scorias and lavas is as follows: 1. Primary olivine with normal zoning was crystallized from magma. Oxidation state of Fe was essentially ferrous. Primary titanomagnetite and chromian spinel were included; 2. By high temperature oxidation, a part of Fe^{2+} was changed to Fe^{3+}, hematite and magnesioferrite were crystallized on the margin of olivine, and Fo-contents became higher than those of the primary olivine; 3. With an advance of the high temperature oxidation, significant amounts of vermicular shaped hematite and cubic magnesio-ferrite were crystallized on the rim and around fractures in olivine, Fo-value on the mantle became higher than that in the core and a small amount of Fe changed from ferrous to ferric; 4. Fe^{3+}-rich precipitates consisting of hematite and magnesioferrite developed widely in olivine phenocrysts, and olivine became extremely Fo-rich.

Oscillatory zoned liddicoatite from central Madagascar: crystal chemistry, structure, and compositional variation

Lussier, A.J.[1*], Hawthorne, F.C.[1], Aguiar, P.M.[2], Michaelis, V.K.[2], Abdu, Y.[1] & Kroeker, S.[2]
[1]Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada ([*]aaron.j.lussier@gmail.com)
[2]Dept.of Chemistry, University of Manitoba, Winnipeg, Canada

The variation in composition, crystal structure, and crystal chemistry of Madagascar liddicoatite with complex oscillatory zoning in both pyramidal and prismatic crystal sectors is examined. The crystal structures of 23 samples are refined with $\langle R_1 \rangle$ = 1.78%, and cell parameters are: *a* 15.83-15.87 and *c* 7.10-7.12 Å. The crystal shows anomalous biaxiality, and spindle-stage measurement of 2*V* gave values of 0.0° for a fragment from the (001) zone and 8(3) and 18.9(5)° for fragments from the pyramidal zone of the crystal. ^{57}Fe Mössbauer spectroscopy gives $Fe^{3+}/\Sigma Fe$ = 5-10 %. Structure data gave <*T*-O> = 1.6175(7) and <*Z*-O> = 1.905(3) Å, and ^{27}Al and ^{11}B Magic Angle-Spinning Nuclear Magnetic Resonance (MAS NMR) shows all Al and B to be [6]- and [3]-coordinated, respectively. Hence, Si = 6.00 *apfu* and ^{Z}Al = 6.00 *apfu* throughout this complexly zoned crystal and all comp-ositional variation involves only *X*- and *Y*-site constituents.

In the crystal, four colours of zones are observed from core-to-rim: purple, light green, dark green and greenish-black, owing to an overall decrease in Mn and increase in Fe, respectively. The variation in bulk composition from core to edge of the crystal corresponds to the substitutions $^{X}Na + {}^{Y}Fe^* \rightarrow {}^{X}Ca + {}^{Y}Li$ and $^{Y}Fe^* + {}^{Y}Fe^* \rightarrow {}^{Y}Li + {}^{Y}Al$, ($Fe^* = Fe^{2+} + Mg + Mn^{2+}$). Oscillatory zoning is superimposed on a smooth monotonic variation in principal constituents: Fe and Mg show prominent oscillatory behaviour superimposed on background values of ~0 *apfu*, whereas Mn^{2+} decreases monotonically from 0.60 to < 0.05 *apfu* at the crystal centre, remaining ~0 to the edge (Fig 1).

The zoning pattern differs completely between the {201} and {110} sectors. The pyramidal sector shows zones of <1 to ~8 mm in thickness, each marked by a sharp, dark discontinuity, fading in colour toward the start of the next zone. Compositionally, this corresponds to a sharp increase in Fe and Mg which monotonically decreases to ~0 *apfu* across the zone. The prismatic sector shows only zones of <1 mm in thickness. Here, Fe and Mg are 0 *apfu* at the beginning of each zone and gradually increase to reach maximum values at the end of the zone, followed by a sharp drop back to ~0 *apfu*. The element-selective zoning pattern observed in Madagascar liddicoatite is consistent with the operation of a coupled-feedback mechanism at the crystal surface as opposed to rhythmic variation in melt properties. This requires a more complex model than those previously suggested for oscillatory zoning in crystals.

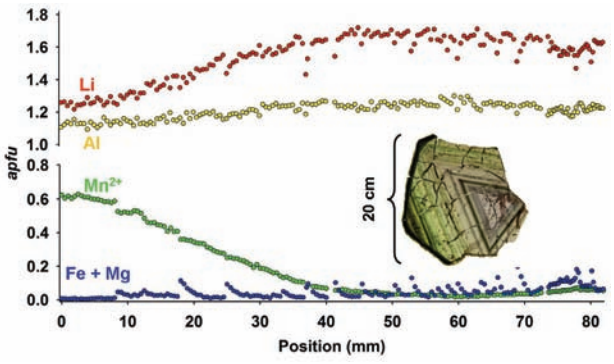

Fig. 1: *Y*-site cation variation from core to rim in Madagascar liddicoatite.

Relationship between optical anomalies, growth topography, and zoning in vesuvianite from Asbestos, Quebec, Canada

Smith, V.C.[*] & Paquette, J.
Dept. of Earth and Planetary Sciences, McGill University, Montreal, Canada ([*]varina.smith@mail.mcgill.ca)

Optical anomalies observed in vesuvianite have piqued mineralogists' interest for decades. The principal optical anomaly observed is the biaxial character, deviant from the uniaxial optical symmetry expected from a morphologically tetragonal crystal like vesuvianite. Such dissymmetrization has been explained in other minerals by different degrees of cation ordering during growth on faces bearing steps that are unrelated by (or oblique to) symmetry elements found in the bulk structure. However, to our knowledge, no studies have documented the relationship between growth step orientation, element partitioning, and optical properties in vesuvianite.

This was done in natural vesuvianite crystals from Jeffrey Mine, Asbestos, Quebec, by using optical microscopy, atomic force microscopy, electron microprobe analysis, and single-crystal X-ray diffraction. This study documents for the first time the selective uptake of the minor elements Fe and Al by non-equivalent growth steps on three forms of vesuvianite, {100}, {110}, and {121}, in addition to the sector-specific zoning of extinction angles and 2V angles in crystals that show a range of growth habits and step orientations. Electron microprobe analysis performed across vicinal faces of growth hillocks show step-specific incorporation of Al and Fe. On hillocks of {100} and {110} prisms, the vicinal faces grown on [001] steps consistently take up more Fe and less Al than those grown on [010] and <1 $\bar{1}$ 1> steps, and concentric (oscillatory?) zoning is detected only on the latter steps.

Unit cell parameters obtained from fragments of |100| and |110| sectors also suggest a symmetry lower than tetragonal. When the prisms {100} and {110} grew by non-equivalent steps, their cell parameters show sector-specific differences. These sector-specific differences diminish in crystals where both prisms grew dominantly by [001] steps.

A visual inspection of (100) and (110) slices suggests that the alternating orientation of Y1 sites at the edge of steps could be a factor in the kinetic disequilibrium of Al and Fe incorporation.

Extremely rich iodide mineralization at the Rubtsovskoe base metal deposit (North West Altay, Russia) and its genesis

Pekov, I.V.[1*], Lykova, I.S.[1], Bryzgalov, I.A.[1], Ksenofontov, D.A.[1], Zyryanova, L.A.[2] & Litvinov, N.D.[3]
[1]Faculty of Geology, Moscow State University, Moscow, Russia ([*]igorpekov@mail.ru)
[2]Faculty of Geography and Geology, Tomsk State University, Tomsk, Russia
[3]JSC "Sibir'-Polimetally", Altayskiy Kray, Russia

Unusual, extremely rich iodide mineralization was found in 2009 in the oxidation zone of the Rubtsovskoe VMS deposit (NW Altay, Russia) that is in operation by underground mine. Primary ores contain >50%, typically 80-90%, sulfides. The stratiform orebody is surrounded by wide aureole of the argillized rocks and covered by sedimentary clays of 80-100 m thick. The oxidation zone, formed in Miocene, occurs in head of the orebody (300 m long, 3-17 m thick; hypsometric interval from +144 to +163 m). Its upper part is a typical iron cap, while lower part contains very rich secondary ores with native copper, cuprite, chalcocite, cerussite, etc.

Iodide mineralization shows a clear zoning. Iodargyrite is distributed in the iron cap, from +156 to +163 m; length of the iodargyrite-rich zone is >150 m. Cu-rich iodides of the marshite-miersite series occur lower, in rich secondary Cu ores (mainly from +146 to +151 m; length of the marshite-richest zone is 50 m). Iodargyrite and Ag-poor marshite are "antagonistic", while miersite is assosiated with marshite or iodargyrite in different areas. Ag-bearing iodides only occur within the oxidized orebody while Ag-free marshite is also abundant in argillized zone near ore. Concentration of iodides in some areas is up to 5% (!) of a rock; 1% is their typical content.

Iodargyrite is a stoichiometric AgI represented by 2*H* polytype ($P6_3mc$, *a* 4.574, *c* 7.519 Å). Isostructural cubic marshite, CuI, and miersite, (Ag,Cu)I, form an isomorphous series in the compositional limits of $Mar_{100}Mie_0$ – Mar_9Mie_{91}, with main break at $Mar_{82.5}Mie_{17.5}$ – $Mar_{57}Mie_{43}$; the *a* parameter of the unit cell varies from 6.050 to 6.424 Å. Well-shaped crystals of marshite are up to 3 cm, iodargyrite – up to 1 cm in size. Iodides are ones of the latest minerals at Rubtsovskoe. Iodargyrite only occurs in cracks or cavities; marshite crystallizes in clay pockets, fulfills cavities or replaces azurite, cuprite, native copper, malachite and osarizawaite. Marshite formed under reducing conditions and does not occur in parageneses with O-bearing Cu minerals unlike Ag-rich iodides. Iodargyrite formed later than miersite that shows an increase of the I:Ag ratio. Distinctive feature of the oxidation zone of Rubtsovskoe is very low concentrations of Cl and Br and almost complete absence of their minerals, unlike other iodide-rich ore deposits (Australia, Chile, Kazakhstan, etc.).

In our genetic model, exhalations of ore-forming "seafloor fumaroles" are the most probable source of iodine. Furthermore, it was captured by clays of argillized aureole near ore and concentrated in absorbed forms and as I^0 and I^- in pore solutions. Surface waters do not seem as a probable source of iodine, because, in this case, it is a geochemical satellite of strongly prevailing Cl. Very important factor for iodine concentration at Rubtsovskoe is a high content of sulfides in primary ores. During first stages of oxidation, such ores produced much sulfuric acid that altered illite of argillized rocks to kaolinite, dickite and alunite. It also oxidized I^0 and I^- to $(I^{5+}O_3)^-$. Sulfate solutions containing much Cu^{2+} (and very mobile iodate ions) infiltrated down and formed, as a result of reactions with sulfides, extremely rich ores with native copper and cuprite. In this process, I^{5+} was reduced to I^0 and further to I^- that was fixed in hardly soluble iodides of Ag^+ and Cu^+.

Application of Fe oxidation kinetics to Precambrian paleosols for the estimation of atmospheric oxygen levels

Murakami, T.[1*] & Sreenivas, B.[2]
[1]Dept. of Earth and Planetary Science, University of Tokyo, Japan ([*]murakami@eps.s.u-tokyo.ac.jp)
[2]National Geophysical Research Inst., Hyderabad, India

Atmospheric oxygen increased irreversibly, first time in Earth's history, from $\leq \sim 10^{-6}$ atm at 2.5 Ga to $\geq \sim 10^{-3}$ atm at 2.0 Ga during the Paleoproterozoic [1,2]. Although the evolution of atmospheric oxygen during the Precambrian is a key to understand the co-evolution of life and environment, the precise nature of quantitative evolution of atmospheric oxygen during the Paleoproterozoic has remained elusive. Paleosols, ancient soils formed by weathering, can be a powerful tool to determine a quantitative pattern of oxygen evolution because they formed at the Earth's surface, in direct contact with the atmosphere at the time of their formation and redox sensitive elements such as Fe retained in weathering profiles should reflect the atmospheric oxygen levels. Applying Fe(II) oxidation kinetics to 2.8 - 1.8 Ga paleosols, we here report our quantitative estimation of atmospheric oxygen levels during the Paleoproterozoic.

Fe(II)-bearing primary minerals release Fe(II) in solution by weathering. Because of the solubilities of Fe(II) and Fe(III), some part of dissolved Fe(II) is oxidized to Fe(III) that forms Fe(III) (hydr)oxides and remains in a weathering profile while the other part is not oxidized and flows out of the profile. The oxidation rate of Fe(II) to Fe(III) is given by [3]:

$$\frac{-d[Fe^{2+}]}{dt} = k[Fe^{2+}](P_{O_2})^x[OH^-]^2$$

where k is the rate constant (temperature dependent) and x the variable (0 to 1). This equation becomes:

$$\frac{\psi}{\psi_A} = \frac{k_A[OH^-]_A^{\,2}(P_{O_2})_A^{\,x_A}}{k[OH^-]^2(P_{O_2})^x}$$

where ψ is the ratio of [flowing-out Fe(II)]/[dissolved Fe(II)] and the parameters with subscript A are values for reference paleosol A. Variations in P_{O_2} with time can be calculated using above equation if differences in the parameters between a given paleosol and reference paleosol A are known. Values of ψ can be obtained from the data set of Fe(II) and Fe(III) concentrations in paleosols in literature. We used the ψ_A and $(P_{O_2})_A$ values at 2.32 Ga [4]. The constraints of the atmospheric oxygen concentrations ($\leq 10^{-5.7}$ atm at 2.45 Ga, $\geq 10^{-5.7}$ atm at 2.32 Ga and $\geq 10^{-2.7}$ atm at 2.0 Ga) were obtained from references [2,4,5].

We assumed four cases for the calculations of P_{O_2} variations between 2.5 and 2.0 Ga: no change in either temperature or P_{CO_2} (affecting pH or OH^-), long-term change in only P_{CO_2}, long-term changes in both temperature and P_{CO_2}, and short-term fluctuations of both temperature and P_{CO_2} during the possible, multiple global-scale glaciations. The calculations indicated that P_{O_2} increased gradually, linearly on the logarithmic scale, from $< \sim 10^{-6}$ to $> \sim 10^{-3}$ atm between 2.5 and 2.0 Ga. Our model also rules out the possibility of a drastic rise at around 2.3 Ga. Our calculations imply, if intense, global glaciation(s) followed by greenhouse conditions are characteristic of the Paleoproterozoic, then P_{O_2} levels would have fluctuated significantly.

Smithsonite from sphalerite replacement fabric types in the Rudabánya base metal ore deposit (N-E Hungary)

Kristály, F[*], Németh, N., Földessy, J., Szakáll, S. & Zajzon, N.
Inst. of Mineralogy and Petrology, University of Miskolc, Hungary ([*]askkf@uni-miskolc.hu)

The Rudabánya base metal ore deposit has a long history of research and exploitation. First, it was an important copper (Bronze Age), then iron (20th c.) source. Native copper and Cu-carbonates, as well as Fe-bearing carbonates were extracted. Among these major components, sulphides and carbonates of Zn and Pb, along barite are abundant. Detailed investigation of their compositions and textures has never been performed.

Sphalerite and galena are common in the whole volume of the dolomite–ankerite–siderite-bound mineralization. Two types of textures are found: a massive, banded sulphide–carbonate, and a fragmented marl-like texture. The two types have very similar chemistries and mineralogies.

The direct replacement of sphalerite to smithsonite can be studied on samples from the massive ore type. Colour, texture and structure are diagnostic for the sulphide to carbonate transformations. Transitions from partly altered sulphide to totally carbonatized zones are detected on the level of centimeters. However, there are zones of the deposit where this process is more dominant and others where Zn and Pb are absent.

We applied analytical techniques including X-ray powder diffraction (XPD), scanning electron microscopy through back-scattered electron imaging (SEM-BSE), chemical analysis by energy dispersive spectrometry (EDS) and wavelength dispersive X-ray mapping (WXRM). Optical microscopy was applied for general fabric characterization. Slices of 3-4 cm in diameter and 0.5 cm in height were cut from the blocks, a pair for each sample. For XPD, color and texture-based manual separation was applied on one of the slices. A proper identification of minerals was possible for each fraction of the sample. On the other slice, SEM-BSE, EDS and WDXM were performed. Then, results of the different methods were easy to correlate.

Several regularities were detected for the carbonatization process of the investigated material. Both Zn and Pb are strongly bound to barite, regardless of their forms. Smithsonite with a cerussite corona, enclosed in barite, suggests selective diffusion during carbonatization. Direct replacement fabric is observed for both sphalerite and galena. For galena, the formation of a cerussite reaction corona is characteristic. On the contrary, sphalerite remnants can display a large variety of replacement patterns. Euhedral quartz, as inclusions, is characteristic for all samples, in all phases. K-dominant mica in ~10 μm-long flakes is frequent. Smithsonite has <1 wt.% Fe and Ca content, irregularly distributed (WDXM). Accidentally, micrometric zones of minrecordite – with $CaZn(CO_3)_2$ composition – are encountered.

The carbonatization process also affected the Fe sulphides, as reflected by the Fe-dominant coronas on dolomite, calcite and the presence of siderite. The detrital fabric of carbonaceous material, overprinted by chemical transformations suggests the combination of tectonic and chemical processes in the carbonatization process.

The fabric produced by replacement reactions shows that the main driving force was the presence of CO_2. Moderate contribution of fluids explains the lack of Mg and trace amounts of Fe and Ca in the carbonate phases of Zn and Pb. The volume of affected materials raises the question whether the carbonatization was driven by oxidation-zone or hydrothermal-related processes.

New hardness scale

Bezerra, U.T.[1*], Vasconcelos, K.K.F.[1] & Wegner, R.R.[2]
[1]Civil Construction, IFPB, João Pessoa-PB, Brasil
([*]dartarios@yahoo.com.br)
[2]Academic Unit of Mining and Geology, UFCG, Campina Grande-PB, Brasil

The most common hardness scale of minerals is the Mohs scale, created by Friedrich Mohs in the nineteenth century. Although it is useful for evaluating the hardness by a simple scratch, this scale has the disadvantage of irregular hardness (jumps) from one hardness to the next. When Mohs chose ten minerals to make up the scale, he probably had in mind the availability with respect to their common occurrence. The problem is, that the differences of the chosen minerals are neither linear nor logarithmic. The proposed new hardness scale comes closer to a more regular difference between its members. Typical examples of the Mohs scale are the significant differences in hardness between gypsum-calcite and calcite-fluorite in the Mohs scale - see Table 1. If the Mohs scale would be linear, these differences should be equal or nearly equal. However, the idea of Mohs remains ingenious and his scale is still used around the world. Looking for a scale that has more regularity, this paper presents the results of tests of Vickers microhardness of different minerals, with talc and diamond still at the extremes and choosing other eight minerals in order to create a more homogeneous scale (Table 1).

Table 1: Minerals of the new hardness scale compared with the Mohs scale, using Vickers microhardness results

New hardness scale	Hardness	Mohs scale	Hardness
Talc	0	Talc	0
Fluorite	196	Gypsum	82
Wollastonite	609	Calcite	180
Hematite	902	Fluorite	196
Tourmaline	1 408	Feldspar	320
Beryl	1 635	Quartz	520
Topaz	1 851	Apatite	564
Chalcopyrite	2 031	Corundum	685
Chrysoberyl	2 328	Topaz	1 851
Diamond	2 650	Diamond	2 650

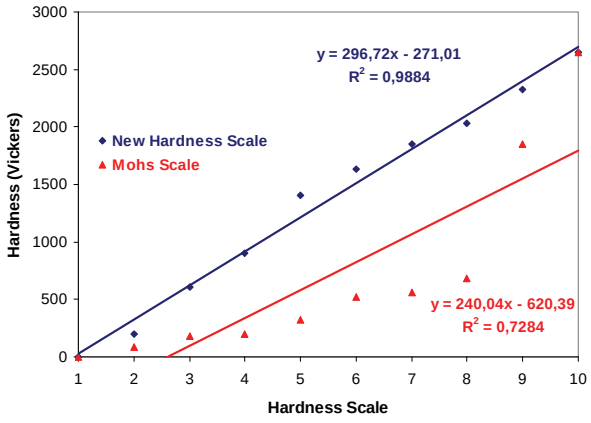

Fig. 1: Graphic of the differences of Vickers hardness between Mohs and the New Scale - see Table 1.

Using the numbers of Table 1, a better homogeneity between the hardness-steps is obvious (the correlation coefficient comes closer to unity). Between the minerals topaz and corundum, the Mohs scale shows a large difference; from topaz down these distances are much smaller, making it more difficult to differentiate minerals with inferior hardness. The main purpose, therefore, is to offer a scale of common minerals of easier application because of more similar differences among the chosen members.

Comparison of jarosite-group minerals formed on surface and subsurface environment of the abandoned base metal mine, Mátraszentimre – Gyöngyösoroszi (Mátra Mts., Hungary)

Jánosi, M. [*], Farkas, I.M. & Weiszburg, T.G.
Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary
([*]janosim@vipmail.hu)

The low-sulfidation epithermal type base metal deposit at Gyöngyösoroszi-Mátraszentimre was mined between the 1950s and 1986, and closed without any remediation. The mine and waste dumps were exposed to oxygen, water and certain colonies of bacteria, and the oxidation of sulphides (predominantly pyrite) resulted in extremely acidic mine drainage (AMD), also containing large amounts of Pb, Zn, Cd, Cu, As. Within the frame of current complex remediation measures, waste rock piles/dumps, underground shafts and adits of the mine have been opened up.

The mine opening contains huge stalagmite-stalactite structures that span from floor to ceiling. These are mostly composed of efflorescencent iron sulfate minerals (melanterite, halotrichite, copiapite etc.), while in the lower level of the mine and in the intensely fractured zones the stalagmite-stalactite structures are composed of jarosite and/or amorphous/fine-grained, poorly crystalline iron oxyhydroxides, sometimes covered with gypsum.

In this work, we have focused on the mineralogy and geochemistry of natural jarosite samples collected from the re-opened underground mine adits, and compared them with samples of excavated high-sulphide mine waste piles. X-ray powder diffraction and chemical (SEM-EDX, ICP-AES) methods were applied. Most of the samples consist of a mixture of phases. Jarosites are not pure end-member phases, as shown also by cell parameters (Fig. 1).

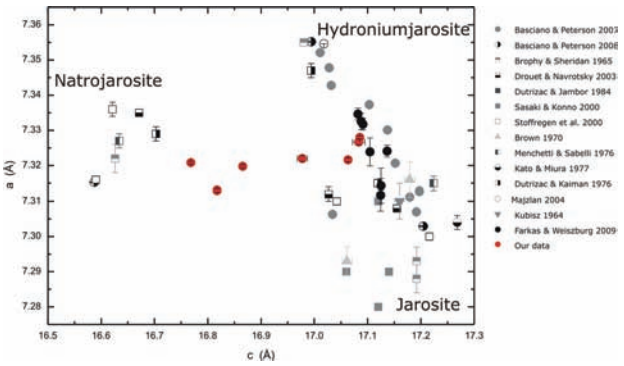

Fig. 1: Cell parameters of jarosites, red symbols indicating the underground samples of this study, black symbols representing the comparative surface samples of [1].

Analyses suggest complete solid solution between K-H_3O-Na-jarosites in the underground samples. The main difference between the surface and the underground jarosites is that the natrojarosite component occurs only in underground conditions.

Wolframite and cassiterite: age of forming and isotope characteristics Sr and Nd

Abushkevich, V.S.[1*], Badanina, E.V.[2] & Syritso, L.F.[2]
[1]Institute of Precambrian Geology, St-Petersburg, Russia
([*]v.s.abushkevich@ipgg.ru)
[2]State Universty of St.-Petersburg, Russia

Modern methods of isotope geochemistry and geochronology allow to bring to minerals research methodology a new quantitive parameter - estimation of age of its crystallisation - and to solve a problem of source of ore material and degree of mantle-core interaction during its forming. Such researches was performed on the basis of study of different genetic types of tin-tungsten mineralization, connected with Li-F granites (Orlovka), albitized greisenized granites (Spokoynoye) and quartz-topaz greisens with Li-micas (Sherlovaya Gora) (Eastern Transbaikalia).

Methodological basis of this research is a studying of isotope-geochemical (Rb-Sr, Sm-Nd, Pb-Pb) characteristics of wolframite (Wt) and cassiterite (Kas) and mineral-forming environment in quartz. Main results are coming to this: (1). It is ascertained, that on studied deposits a different age ratios between tin-tungsten mineralization and granites containing it are observed. Thus, age of crystallization of wolframite from Spokoinoye is 139,8±1,3Ma, on the same time forming of the massive is 144,5±1,4Ma [1]. It allows to consider the interval, at least, 2.5Ma, as a time necessary to form of hydrothermal solution. The age of ore mineralization (Wt, Kas) of Sherlovaya Gora (Wt (142,4±1,5Ma), Kas (141,1±1,5Ma)) and Orlovka (Wt (139,5±2,1Ma), Kas (138,5±1,6Ma)) is almost identical to the age of forming of mother granites (141,4±1,8Ma and 139,9±1,9Ma respectively). It is noteworthy, that age of cassiterite mineralization is conditionally younger than the age of wolframite one (in bounds of 1Ma error). (2). Ascertained differences in isotope characteristics Sr and Nd between mother granites of Spokoinoye (εNd(144) = -3,4), Orlovka (εNd(140) = -1,7), Sherlovaya Gora (εNd(141) = -0,3) massifs and associated mineralization (wolframite, cassiterite) (wt: εNd(T) от -1,9 до +2,1; kas εNd(T) от +0,9 до +3,2) are points out to participation of juvenile part during ore-material forming. At the same time, in the bounds of universal system, isotope composition of wolframite is characterized by more depleteness than cassiterite one. Thus, there is reason to believe, that possible mechanism of mineralization is remobilization of ore material from crystallized magma chamber(?) influenced by fluid with significantly mantle characteristics. (3). Estimation of W concentration in the melt of Spokoinoye massive on the basis of study of melt inclusions in quartz showed extremely low solubility of wolframite: log K_{sp} varying from -6,5 to -6,7 $mole^2/kg^2$ (from 8,78 up to 3,67 ppm W in melt).

Discovery of reasons of age ratios difference between ore mineralization and mother granites of different genetic types of deposits, also problems of ore material sources is an object of further research.

The Ashadze ultramafic hosted sea-floor sulfide deposits (Mid-Atlantic Ridge, 12°58'N): mineralogy and fluid inclusion study

Amplieva, E.E.[1*], Bortnikov, N.S.[1], Stavrova, O.O.[1], Simonov, V.A.[2] & Fouquet, Y.[3]
[1]IGEM RAS, Moscow, Russia ([*]Amplieva@igem.ru)
[2]Institute of Geology and Mineralogy, SB RAS, Novosibirsk, Russia
[3]FREMER, Centre de Brest, Plouzané, France

A mineral composition of sulfide edifices and fluid inclusions in anhydrite from the Ashadze fields were studied. Samples were collected in 2007 during the French-Russian *"Serpentine"* cruise of French R/V "*Pourquoi Pas?*" with the ROV *Victor 6000*. The Ashadze field is a deepest active hydrothermal area, which occurs at 3300 – 4530 m below the sea level. During the Serpentine cruise, two active "black smoker" sites were discovered, which consist of active discrete chimneys on sea-floor or small sulfide mounds, clusters of several dozens of active and inactive chimneys from several centimeters up to 2 m in height. Few chimneys vent fluids as "black smokes" and are shimmering warm water. Holes in the sea floor and "embryos" of chimneys venting "black smokes" occur in this area as well. Two morphological and mineral types are identified among the sulfide edifices.

Type I is represented by sulfide chimneys and diffusors. In general, they consist of pyrrhotite, isocubanite, sphalerite, and chalcopyrite with small amount of copper-glance, covellite, Fe-oxyhydroxides, hematite. Active chimneys are composed mainly of pyrrhotite, Cu-Fe sulfides, and rare sphalerite. Zn sulfides prevail in inactive or diffuse chimneys. Chimney spires all show radial changes in composition. Outer zones consist of porous sphalerite aggregates with minor hematite, marcasite, covellite, and bornite. Sphalerite occurs as euhedral and anhedral grains. Reniform, colloform and dendritic aggregates of sphalerite and marcasite were found. Anhydrite was found in outer zones of active chimneys. Intermediate zone contains pyrrhotite (occuring as tabular grains or radiate-fibrous aggregates) with minor isocubanite and chalcopyrite. The intimate lamellar intergrowths of chalcopyrite and isocubanite are typical. Chalcopyrite and isocubanite with sphalerite occur in inner zones. Relics of tabular pyrrhotite were found. Chalcopyrite and isocubanie form aggregates of isometric grains, colloform and concentrically-zoned aggregates. Two types of Fe-Zn sulfides and sphalerite intergrowths were identified: (1) sphalerite core rimmed with isocubanite and chalcopyrite aggregates overgrown by idiomorphic grains of sphalerite; (2) isometric chalcopyrite and isocubanite aggregates are overgrown with idiomorphic grains of sphalerite which are rimmed with isocubanite and chalcopyrite aggregates.

Type II is represented by sulfide mounds composed mainly of isocubanite and chalcopyrite, sphalerite, pyrite, pyrrhotite, and marcasite. Fine-grained texture is typical for massive sulfide ores. Isocubanite with chalcopyrite lamellae occur as aggregates of isometric grains and colloform segregations. Colloform, radial aggregates of marcasite, isometric grains of sphalerite, and relics of tabular pyrrhotite were found. Chalcosine develops as pseudomorphs after separate growth zones in colloform aggregates of isocubanite.

Primary three-phase (liquid + vapor + solid) fluid inclusions 5-40 μm in size and tabular in shape were found in anhydrite. Non-transparent solid phases are presumed to be sulfide minerals. Freezing of primary two-phase (liquid + vapor) fluid inclusions in anhydrite at the Ashadze field indicate that NaCl is a major dissolved constituent in the trapped fluid and its concentration is 4.7 to 7.8 wt. % NaCl-equiv. Homogenization temperatures of fluid inclusions vary from 265 to 324°C ("Long Chimney") and from 210 to 320°C ("Embrio" chimney).

Deformation mechanism of antigorite considered from microstructures of naturally deformed serpentinite

Ando, J.[1*], Urata, Y.[1], Soda, Y.[2] & Ohfuji, H.[3]
[1]Dept. of Earth and Planetary Systems Science, Hiroshima University, Hiroshima, Japan (*jando@hiroshima-u.ac.jp)
[2]Dept. of Earth Sciences, Waseda University, Tokyo, Japan
[3]Geodynamic Research Center, Ehime University, Matsuyama, Japan

Antigorite serpentinite is an important rock in order to understand the dynamics of subducting oceanic plates. However, the plasticity of antigorite serpentinite under mantle/crust conditions has not been fully understood so far. Naturally deformed rocks preserve probably any information about deformation process including its mechanism. Here we observed microstructures of naturally deformed serpentinite with optical and transmission microscopes (TEM) to study its deformation mechanism.

The sample is antigorite grains composed of serpentinite which exposes along the Sashu Fault in the Saganoseki Peninsula of Oita Prefecture, Japan. This serpentinite contains minor magnetite and Cr-spinel in addition to antigorite grains. The grain size of most antigorite is ca. 10 to 50 μm. These antigorite grains show the undulose extinction and shape preferred orientation defining the foliation and lineation. The "S" and "S-C" fabrics are observed on an optical microscopic scale. Moreover, these antigorite grains show the lattice preferred orientation (LPO) characterized by [010] and [001] density maximums subparallel to lineation and normal to foliation, respectively. All of these microstructures suggest that the sample antigorite grains were deformed by dislocation creep with [010](001) slip system.

TEM observation indicates that several types of lattice defects are developed in the antigorite grains. The most typical microstructures are (001) twins and damaged layers parallel to (001) planes. The mirror plane of the (001) twin is always parallel to (001) plane. The (001) twins make twin lamella throughout samples. The serious damage of (001) planes leads to amorphization of the layers. Moreover, subgrain rotation is observed accompanied with amorphization of (001) planes. All of these defects such as (001) twins, damage and amorphization of (001) planes, and subgrain rotation can be created by slip of (001) planes.

We can also observe “modulation dislocation”, but its density is much smaller than those of the other defects described above. Therefore, these facts on TEM scale microstructures suggest that (001) slip, not dislocation glide is important mechanism for deformation of antigorite serpentinite.

The microstructures on an optical microscopic scale suggest that the sample antigorite grains were deformed by dislocation creep, because the antigorite grains show LPO. However, the microstructures on TEM scale do not support this suggestion and intend that (001) slip is an important for deformation. Here we consider that (001) slip of antigorite creates LPO of antigorite grains in serpentinite.

Chemical composition of sphalerite from Mangazeyskoe deposit (Sakha, Russia)

Anikina, E.* & Bortnikov, N.S.
Institute of Geology of Ore deposits, Petrography, Mineralogy and Geochemistry RAS (IGEM RAS), Moscow, Russia
(*anikina@igem.ru)

Investigations of chemical composition of sphalerite are important for understanding mineral-forming processes. In this work, we have studied distributions of Fe, Mn, and Cd in sphalerites from the Mangazeyskoe deposit located in the Kolyma-Verkhoyansk fold belt. Ore bodies of this deposit occur in Carboniferous and Permian siltstones and sandstones, which are intruded by Endybal stocks and dykes of various compositions. Three mineral-forming stages have been recognized there: 1) gold-rare-metal quartz veins (GRM); 2) cassiterite-sulphide-quartz veins (CS); and 3) silver-polymetallic mineralization (SP).

Four generations of sphalerite were found in ores of the deposit. Sphalerite-1 occurs in mineral aggregates of the GRM stage, sphalerite-2 is associated with the CS, and sphalerite-3,4 was found in the SP.

Electron microprobe analyses revealed the following variation of chemical composition of sphalerite (Fig. 1):

Sphalerite-1: from 1.0 to 4.4 wt.% Fe; from 0.2 to 0.4 wt.% Cd; from 1.0 to 4.4 wt.% Mn.

Sphalerite-2: from 1,0 to 4.4 wt.% Fe; from 0.0 to 1.4 wt.% Cu; from 0.1 to 1.2 wt.% Cd; from 0.0 to 0.4 wt.% Mn.

Sphalerite-3: from 0.0 to 9.73 wt.% Fe; from 0.0 to 4.6 wt.% Cu; from 0.0 to 1.1 wt.% Cd; from 0.0 to 0.1 wt.% In; from 0.0 to 0.1 wt.% Mn.

Sphalerite-4: from 0.0 to 3.4 wt.% Fe; from 0.0 to 2.3 wt.% Cu; from 0.1 to 1.3 wt.% Cd; from 0.0 to 0.1 wt.% In.

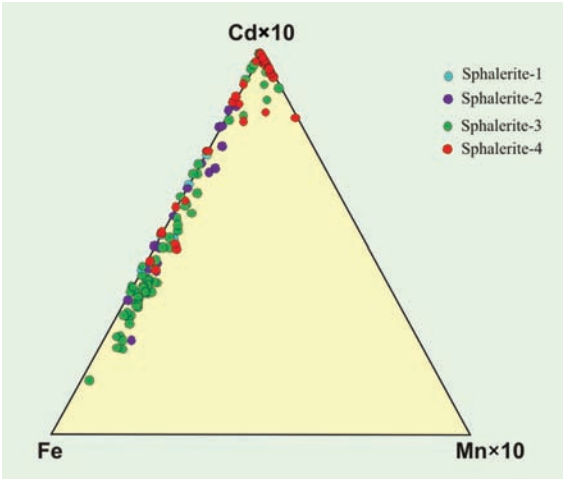

Fig. 1: Fe-Cd-Mn diagram of sphalerite from the Mangazeyskoe deposit.

Groups of points corresponding to sphalerites of different generations overlie one onto another (Fig. 1). It may be explained by the uniform source of fluids. It is probable the change of chemical composition occurs as a result of evolution of mineral system. These data are in disagreement with studies of trace element distributions in sphalerite from typical Pb-Zn deposits [1] that pointed out that sphalerite of different origins can be distinguished in the Fe-(Mn×10)-(Cd×10) diagram.

Isomorphism of Bi-Sb-Pb and Te-Se-S in Bi-bearing minerals in deposits of North-East Asia (Russia)

Anikina, E.[1*], Goryachev, N.A.[2] & Gamyanin, G.N.[1]
[1]IGEM RAS, Moscow, Russia ([*]anikina@igen.ru)
[2] NEISRI FEB RAS, Magadan, Russia

Bi mineralization is widely present in Sn, Ag-Pb and Ag-rare-metal deposits of the North-East Asia (NEA). The NEA regional geochemistry is characterized by a high geochemical background of Sb. Owing to this fact, Bi-bearing minerals of these deposits always contain admixtures of Sb, with the Sb concentration increasing from early to late paragenetic associations. Influence of Sb in Pb-Bi parageneses increases at overlay of Ag-Pb mineralization on cassiterite-sulphide (Prognoz deposit) or cassiterite-silicate (Alyaskitovoe) mineralizations. In these deposits, some Ag-Pb-Sb-Bi minerals have been identified: Sb-gustavite (13-17 % Sb), Bi-owyheeite and teremkovite (2-5 % Bi), Bi-ramdohrite (up to 8 % Bi). A nearly complete solid solution between andorite and its Bi-analogue was revealed (Fig. 1). A considerable admixture of Bi in miargyrite (up to 22 wt.%) was detected as well (Fig. 2).

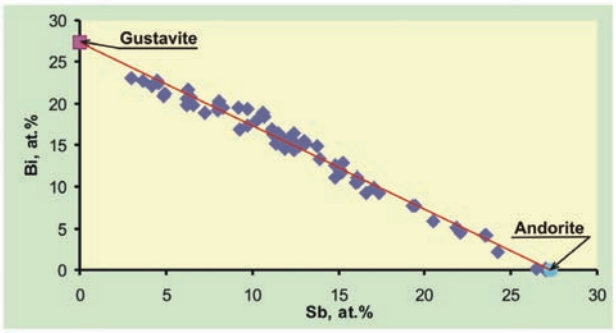

Fig. 1: Plot of andorite-gustavite series microprobe analyses showing relationships between Bi and Sb.

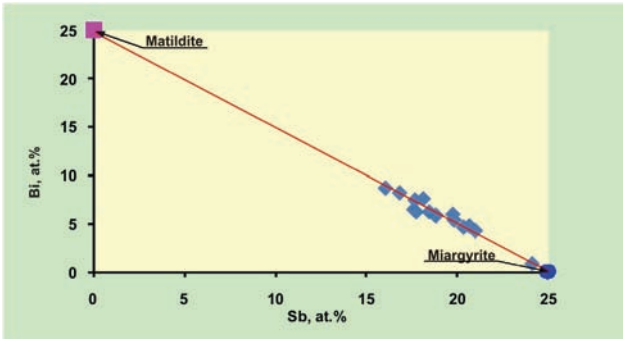

Fig. 2: Plot of miargyrite (with high Bi content) microprobe analyses showing relationships between Sb and Bi.

In Ag-rare-metal deposit, native Bi, sulphides, selenides and sulphotellurides of Bi were identified. One of the interesting features of these minerals is their wide Te-Se-S isomorphic substitutions. In some grains of joseite, Se content varies from 0.9 to 7.6 %. Wide isomorphic substitutions between Se, Se and Te were observed in the bismuthinite-ikunolite-laitakarite series. Silver minerals can be subdivided into sulphide-selenide-telluride and sulphide-bismuth associations.

The wide S-Se-Te and Pb-Sb-Bi isomorphism of studied Bi-bearing minerals is caused by the specificity of ore-forming processes in different Sn, Ag and Ag-Pb deposits of the North-East of Asia.

The Abdasht peridotitic massive is part of the Esphandaghieh ophiolite complex. Constituents of the Abdasht rocks are mostly dunite harzburgite which occasionally convert to lherzolite and wherlite. Chromite deposits occur in 15 mineralized horizons. As constituents of one of the world's ophiolite complexes, Abdasht rocks might be worthwhile sources of PGM, Ni and Co, in addition to Cr. Therefore, various geochemical and ore microscopic studies were conducted to identify sulfide minerals.

The studies reveal the presence of nickel sulfide minerals (especially pentlandite) in the region. These are found in two different parts: (1) in the host rocks of the chromite deposits and (2) in chromite lenses.

PGM occur in very low concentrations (at most 83 ppb in Kamalabad mine), often as inclusions and fine grains in chromite and silicate gangue. Other sulfide minerals such as pyrrhotite, pyrite, millerite, chalcopyrite, chalcocite, nickelpyrite, chalcopentlandite, valleriite etc. were also found. These sulfide minerals (Ni, Co and PGM) do not represent worthwhile resources, and are therefore economically negligible.

Minerals of Jas-Roux (France): an update

Boulliard, J.C.[1*], Morin, G.[1], Bourgoin, V.[2] & Favreau, G.[2]
[1]IMPMC, UPMC, Paris, France
([*]jean-claude.boulliard@impmc.upmc.fr)
[2]Assoc. Jean Wyart (IMPMC) and AFM, ENSMP, Paris, France

Jas-Roux is located in the Parc des Ecrins, Hautes-Alpes, France. It is a hydrothermal stratiform deposit in dolomitc limestones. It appears as several lenses embedded in the Pigeonnier anatexites. These lenses protrude and form small cliffs parallel to the valley. The mineralisation mainly consists of barite, quartz and pyrite. Other minerals reported so far are Zn, Sb, As, Tl, Ag, Hg, Pb sulfides and sulfosalts. Jas-Roux is the type locality of chabourneite, laffitite, routhierite and pierrotite discovered after field researches performed at the end of the 1960's. More recently this deposit has appeared as a good candidate for the study and modelisation of As, Sb, Pb, Tl, Hg diffusion in the soil. Our recent prospects have given rise to the discovery of a dozen of minerals which were not known in this locality so far. Five of them are new in France: dorallcharite, klebelsbergite, millosevichite, szomolnokite and voltaite.

Origin of red colouring in Turonian pelagic limestones from the Vispi Quarry in the Cretaceous of central Italy

Cai Yuanfeng[*], Li Xiang, Hu Xiumian, Chen Xiaoming & Pan Yuguan
State Key Laboratory of Mineral Deposits Research, Dept. of Earth Sciences, Nanjing University, Nanjing, China
([*]caiyf@nju.edu.cn)

Hematite pigmentation has been considered to be the most common and important factor in the formation of the red colour in sediments. Two hypotheses were usually put forward for the origin of the red colour [1]: the first involves the derivation of detrital hematite from lateritic soils while the second involves authigenic precipitation from the weathering of iron-bearing (detrital) minerals such as pyrite, chlorite, biotite, amphibole, pyroxene and olivine. Similar explanations have been suggested for the red pigmentation in limestones but there are some red limestones, such as the Upper Cretaceous Scaglia Rossa limestone from Gubbio in central Italy, in which no hematite is detectable by X-ray diffractometry (XRD). Interpretation of the source of this red colour has been much disputed: the most important and frequently mentioned one is "fine particle size and random distribution".

Mn^{2+}-doped materials have been widely used as optical material to produce different wavelengths of visible light, causing yellow to orange-red, red, dull orange and violet cathodoluminescence in Mn^{2+}-doped calcite. Thermoluminescence occurred at 620 nm, when the Mn^{2+} returned from the excited state back to the ground state. Hence, manganese may be considered another origin of red colour in Mn^{2+}-bearing calcite.

Samples of Turonian red limestones from the Vispi Quarry in central Italy have been examined by XRD, EPMA, ESR, DRS and HRTEM. The ESR, EPMA and XRD results suggested that Mn^{2+} was incorporated into the structure of calcite during the precipitation of the limestones. DRS results suggested the presence of hematite. Under both SEM and EPMA, we use EDS to check the iron signal in the whole section. The observation shows that hematite coexisted with detrital qurtz or layer minerals. However, this type of hematite is very rare and difficult to be found. We selected an area without detrital hematite for futher observation with HRTEM and found that nanometer-size hematite grains were present in red limestones. Grains have neither perfect crystal shapes nor regular or straight boundaries. However, it is most important that they have a typical 0.271 nm diffraction line in selected-area electron diffraction (SAED) patterns and weak iron but no sulphur signal in energy-dispersive X-ray spectra. The hematite grains were present in two forms: one type is present in the interstices of calcite grains, and another is a film-like wrapping substance in which the calcite crystals are buried. Hence, these observations suggest that amorphous nanosize hematite grains and the Mn^{2+}-bearing calcite endowed the limestone with a red colour as the major pigmentation, and the Mn^{2+}-bearing calcite gave it a pink tinge. This study may suggest that the nanosize hematite grain and the Mn^{2+}-bearing calcite granted the red colour of CORBs. Two forms of hematite grains play major roles in the development of colour. These results may suggest that the bottom sea water was oxidized when red limestone precipitated.

Sulfate mineralization at the geyser near Pinchollo, South Peru

Ciesielczuk, J.[1*], Żaba, J.[1], Bzowska, G.[1], Gaidzik, K.[1], Głogowska, M.[2] & Rygał, J.[3]
[1]University of Silesia, Sosnowiec, Poland
([*]justyna.ciesielczuk@us.edu.pl)
[2]Central Mining Institute, Katowice, Poland
[3]The University of Science and Technology, Kraków, Poland

Surface, sulfate mineralization precipitated from thermal water in the vicinity of a geyser located above village Pinchollo, at the foot of Hualca Hualca volcano (6025 m a.s.l.) in the Western Cordillera of Southern Peru were studied. Recent volcanism and thermal activity in Southern Peru is connected with subduction zone as a result of underthrusting of Nazca Plate under the Southamerican Plate. The geyser is one of many thermal activity manifestations in Arequipa department, where a belt of recent stratovolcanoes of Central Volcanic Zone of the Andes coincides with lava fields and small scoria cones of Andahua volcanics. The area is built of crystalline Arequipa Massif, overlain by thick suite of folded Mesozoic sedimentary formations, intruded by Late Mesozoic-Paleogene granitoids and then by Oligocene-Miocene volcanics of Tacaza Group, Plio-Pleistocene Barroso stratovolcanoes (some of them still active), and Pleistocene-Holocene Andahua Group. Seismic activity and fault tectonics is very strong. The area abounds in thermal springs, contains few geysers, and several Neogene epithermal gold-silver deposits are present. Therefore long established Cenozoic geothermal system exists there.

Thermal water present in the Chivay area is mainly chloride. It has a neutral pH and is enriched in Li, Sr, and B. Water erupted in geyser was boiling, but as it is located at the altitude of 4353 m a.s.l. its temperature could be 70-80°C. Temperature of the reservoir is 110-120°C. In the vicinity of Pinchollo three geysers are known, but presently only one of them appears active. Two others situated lower turned to be hot springs, one ceased during an earthquake in 2001.

Minerals of different habits and yellow, orange and white colours have precipitated on the soil and dry plants close to the geyser (location 1) and in a distance of ca 100 m east of the geyser (location 2). Collected samples were dried for one week. Chemical composition and habit of the minerals were investigated using scanning microscope coupled with EDS and phase composition was checked by XRD. All are sulphates.

The chemical composition of all sulfate minerals is simple, consisting only of Al, Fe, S, O and K, Mg, Ca, N. But phase composition is strongly complicated proving with no doubts the presence of the following minerals: alunogene, copiapite, coquimbite, tschermigite, jarosite - ammoniojarosite, gypsum, alunite, apjohnite - pickeringite - halotrichite , boussingaultite, mohrite, rozenite, voltaite - voltaite-(Mg) and mascagnite, picromerite.

Quartz and clay minerals as kaolinite or illite/mica are residual belonging to the soil composition.

Above mentioned set of minerals is very similar to these formed on the burning coal dumps in Poland, where the host rocks are silicoclastic suite of clays, mudstones, sandstones and subordinate carbonatic rocks as siderites, dolomites and limestones.

Fluorine-rich vesuvianite from Borborema province, Brazil

Čobić, A.[1*], Mikulčić Pavlaković, S.[2], Zebec, V.[2], Wegner, R.[3] & Bermanec, V.[1]
[1]Institute of Mineralogy and Petrology, Faculty of Science, University of Zagreb, Croatia ([*]ancobic@geol.pmf.hr)
[2]Croatian Natural History Museum, Zagreb, Croatia
[3]Dept. de Min. e Geol, Centro de Ciências e Tecnologia, Universidade Federal de Campina Grande, Brazil

Investigated crystals were collected from a skarn deposit with molybdenite and F-apophyllite in paragenesis in Sítio São Gonçalo, Santa Luzia, Borborema Province, state of Paraiba, Brazil (coordinates: S 06º54.916´ W 036º50.478´). During this investigation, calcite, pyrite, zircon and molybdenite were noticed. Crushing of samples releases H_2S. There is a record of vesuvianite crystals from this province in literature [1].

Crystals are well developed, but occur as fragments in breccia and are often zoned. Several habits can be distinguished: shorter prismatic where {001} is the dominant form and are lavender-grey in colour; elongated with smaller {001} which are ipe yellow. The habits of purple–orange crystals are between the shorter prismatic and elongated habits. Colourless or almost colourless crystals are minute and covered with calcite crystals. They are probably the latest.

Goniometric measurements on 8 samples exhibit following 30 forms: {001} and {110} as dominant forms, {100}, {450}, {320}, {210}, {310}, {410}, {510}, {102}, {203}, {101}, {201}, {1.1.10}, {113}, {111}, {443}, {221}, {331}, {10.10.3}, {551}, {313}, {414}, {312}, {211}, {311}, {511}, {223}, {421} and {955} which appears very rarely on vesuvianite crystals. Axis ratio calculations yield a:c = 1:0.5373 which is very similar to ratio given by Goldschmidt (a:c=1:0.5376; [2]).

X-ray powder diffraction data of investigated samples show following unit cell parameters: for lavender-grey - a = 15.512(2) Å, c = 11.786(3) Å, V = 2835.8(7) $Å^3$; for ipe yellow - a = 15.598(1) Å, c = 11.784(2) Å, V = 2833.9(5) $Å^3$. Annealing at 1025°C results in decomposition to gehlenite and wollastonite type structures with the remnants of vesuvianite structure. Due to annealing the following loss of water occurs: for lavender-grey 2.39 wt. %; for ipe yellow 3.09 wt. %;

Microprobe analysis performed on a lavender-grey sample, calculated on the basis of Ca+Na = 19.00 apfu, yield following formula:

$(Ca_{18.86}Na_{0.14})_{\Sigma 19.00}(Al_{10.30}Mg_{1.23}Fe_{1.34}Ti_{0.16}Mn_{0.04})_{\Sigma 13.08}[SiO_4]_{10}[Si_2O_7]_4(OH_{4.75}F_{3.38}O_{3.10})_{\Sigma 11.23}$.

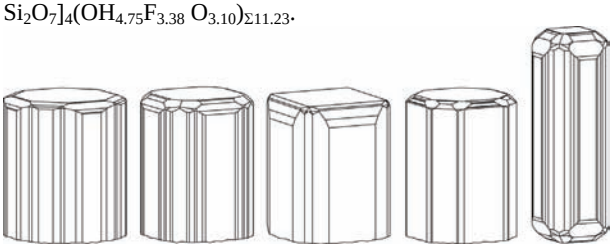

Fig. 1: Morphology of measured vesuvianite crystals.

According to Britvin et al. [3], a mineral can be classified as a fluorvesuvianite if containing F> 4.5 apfu. Thus, this sample is a fluorine-rich vesuvianite.

Morphology investigation of brazilianite from different localities

Čobić, A.[1*], Zebec, V.[2], Scholz, R.[3] & Bermanec, V.[1]
[1]Faculty of Science, Institute of Mineralogy and Petrology, Zagreb, Croatia ([*]ancobic@geol.pmf.hr)
[2]Croatian Natural History Museum, Zagreb, Croatia
[3] Universidade do Estado de Minas Gerais - Faculdade de Engenharia, João Monlevade – MG, Brazil

On the morphology of brazilianite there hasn't been published many papers since its discovery [1]. From the importance of crystallogenetic study and possible differences between material from different localities arises need for a study of brazilianite crystals.

Two circle goniometric measurements were performed on 34 single crystals of brazilianite from different localities in Brazil. 26 measured crystals originate from Telírio claim, Linopolis, Divino das Laranjeiras, one from Divino das Laranjerias province (exact mine not determined), three from São Geraldo do Baixio district and four from Araçuai region.

All brazilianite crystals are well developed, but were probably attached to matrix on one end of [100] so in almost all crystals that side is missing. Crystals colour ranges from yellow, through yellowish-greenish to green, while some crystals are colourless. All forms in [001] zone are striated parallel to [001]. Forms that occur on every measured brazilianite crystal are {010} and {110} and they are striated. Other forms that are very common are: {011}, {$\bar{1}$11}, {211} and {$\bar{1}$01}. Four forms, not measured before, appear on investigated crystals. These are: {143}, {520}, {322} and a form with {hkl} indices. Indices for the {hkl} form could not be exactly determined due to restrictions in precision of stereographic/gnomic projection. The face is very gently inclined and close to {001}.

There is a record of several habits of brazilianite crystals in literature [1, 2]. Several new habits can be distinguished after these measurements (fig. 1).

Two new habits, together with four new forms are recognized during this morphological investigation of brazilianite crystals.

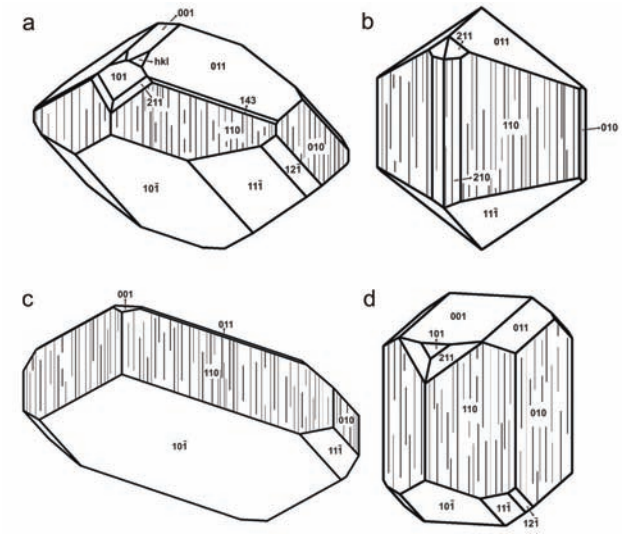

Fig. 1: Different habits of brazilianite crystals.

Unusual minerals of tin in explosive breccias of the Churpunn'ya deposit (East Yakutia, Russia)

Gamyanin, G.[1*], Anikina, E.[1], Kholmogorov, A.[2] & Popova, S.[2]
[1]IGEM RAS, Moscow, Russia ([*]ggn@igem.ru)
[2]IDPMG SB RAS, Yakutsk, Russia

Churpunn'ya deposit is located in the northern part of Eastern Yakutia. It belongs to cassiterite-silica-sulphidic deposits and is related to complex vulcano-plutonic area. Crater facies (J_3) of paleovolcano is intruded by dacite dykes (K_2). Vein bodies and mineralized zones cross dacites and are composed of two stages: cassiterite-quartz-tourmaline and quartz-pyrrhotite-chalcopyrite-sphalerite with admixture of Sn-Pb-Sb sulphosalts. One of the most remarkable features of the deposit is a wide spread of explosive breccias at the early stage and intra-ore explosions at the late stage of its formation. Intra-ore explosions are interesting by its wide variety of Sn minerals. There are small fragments of minerals of an early stage and new-formed mineral in the cementing black ultrafine-grained porous mass of Sn-Fe-oxide-silicate composition (Fig. 1, points 6, 7; table 1). Fragments consist of rhomb-like crystals of ilmenite (Fig. 1, point 4; table 1), Sn-titanomagnetite (Fig. 1, point 5), TiO_2 - the zone lamellar isolations forming polygonal structures. The central part of lamellae correspond to ilmenite composition with admixture of Cr and Sn (up to 2-3 %), whereas their external part contains Sn-bearing (to 8 %) titanomagnetite with admixture of Si (to 5 %). Dendrites of Sn-Fe-Ti-Si-oxide composition and numerous microspheroids (from <1 to 20 μm) are irregularly distributed in the cementing mass. Microspheroids consist of Sn-Sb (Sn–40-56 wt.%; Sb–41-56 wt.%), Sn-Sb-Pb (Sn–44-58 wt.%; Sb–26-48 wt.%; Pb–6-16 wt.%), Sn-Cu-Sb-Ni (Sn–24-56 wt.%; Cu–23-32 wt.%; Sb–8-42 wt.%; Ni–5-10 wt.%) intermetallides and sulphostannates (Sn–56-65 wt.%; Pb–18-25 wt.%; S–18-20 wt.%). The composition of microspheroids is generally similar to that of sulphostannates and intermetallides of sulphide ores, but with prevalence of metals.

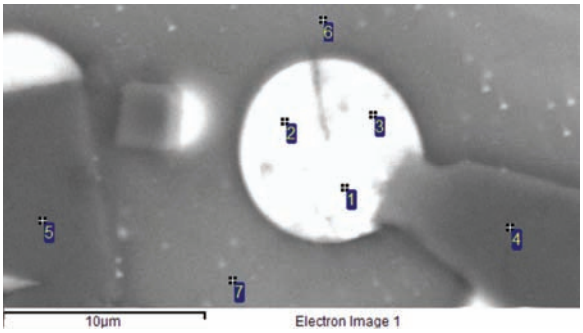

Fig 1: Mineral intergrowths of explosive ores.

Table 1: Microprobe analyses of minerals of explosive ore (№ analyses correspond to those in fig.1)

№	O	Si	Ti	Mn	Fe	Pb	Sb	Sn	S	Sum
1						16,7		63,2	19,6	99,5
2						7,1	48,6	43,9		99,6
3						16,4	26,1	58,4		100,9
4	39,2		36,5	1,9	18,8			1,9		98,3
5	26,5		11,6	1,4	56,2			4,3		100,0
6	34,9	16,3			16,7			31,6		99,5
7	32,8	15,8	1,5		12,6			36,0		98,7

The observed specificity of ore textures and variety of Sn minerals are the result by deposit formation in near-surface conditions under thick effusive cover and the enrichment of fluid by gaseous components.

Composition of arsenopyrite from giant ore deposits of Northeastern Asia

Gamyanin, G.N.[1*] & Goryachev, N.A.[2]
[1]Institute of Geology of Ore Deposits, Petrography, Mineralogy, and Geochemistry, Russian Academy of Sciences, Moscow, Russia ([*]ggn@igem.ru)
[2]Northeastern Interdisciplinary Scientific Research Institute, Far East Branch of Russian Academy of Sciences, Magadan, Russia

Arsenopyrite is the main ore mineral for all giant ore deposits of the North East Asia (Au – Mayskoye, Natalka, Nezhdaninskoye; Sn – Deputatskoye and Ag – Prognoz). The comparison of compositions of arsenopyrite from these deposits indicated that the mineral is formed as three common generations: Ars-1 forms meta crystals in altered rocks; Ars-2 is represented by coarse grains in quartz veins; small grains and crystals of Ars-3 are formed by latest (Sb or Ag-Pb) regeneration-type mineralization. Microprobe and atom-absorbtion analyses provide chemical differences between these generations of arsenopyrite (Table 1).

Table 1: Composition of arsenopyrite generations

Deposit type	Ars 1	Ars 2	Ars 3
Au	S/As-1,095-1,064 Au-20-10000ppm Sb= 50-150 ppm	S/As-1,0611,044 Au - <<200 ppm Sb - 40-300 ppm	S/As-1,020-1,009 Au-<< 50 ppm Sb-200-1500 ppm
Sn	S/As-0,925-0.961 Sb-20-70 ppm Bi-30-400 ppm Ag-100-300ppm Au-5-50 ppm	S/As-0,970-1,030 Sb-100-500 ppm Bi-1-100 ppm Ag- 200-700ppm Au-0.5-5 ppm	S/As=1,040-1,080 Sb-0,3-2,8% Bi-1-20 ppm Ag->1000ppm Au-5-10 ppm
Ag	S/As-0,890-0,930 Sb-0-2% Co-0,1-1,6% Ni-0,1-2% Ag-60-200 ppm Au-0,1-0,3 ppm	S/As-0,975-1,028 Sb-0,5-3% Co-up to 2% Ni-up to 3% Ag-300-600 ppm Au-0.5-1 ppm	S/As-1,025-1,050 Sb- 2-8% Co-0.8-2.9% Ni-2-9% Ag-500-4000 ppm Au-1,5-5 ppm

For composition of arsenopyrite from gold deposits, the data given in Table 1 show a decrease in the S/As ratio and the Au content from Ars-1 to Ars-3 accompanied by the increase of the Sb content. Prismatic crystals of Ars-1 are strongly enriched by Au. The composition of arsenopyrites from tin deposit Deputatskoye shows an opposite trend. Here tendency is to increase S/As ratio and Sb and Ag content from Ars-1 (from tin-bearing greisens) via Ars-2 (from cassiterite-sulphide ores) to Ars-3 (from latest Ag stage) accompanied by the decrease of the Bi content. The Au content in these arsenopyrites is variable. Ars-1 from this deposit has a high content of Co (up to 1%) and Ni (up to 0.3%). The S/As ratio in Ars-2 is very low. For the Ag deposit of Prognoz, we investigated three stages of ore formation: (1) Au-Bi, (2) Sn-sulphide, and (3) Ag-Pb ores. The data of Table 1 demonstrate a tendency of increasing the S/As ratio and Co, Ni, Sb, Au, and Ag contents from Ars-1 to Ars-3. Ars-1 associates with nickeline and gersdorffite. Small prismatic crystals of Ars-3 have zones enriched in Co (up to 8%), Ni (up to 11%), and Sb (up to 15%).

In general, composition of arsenopyrite from different giant ore deposits depends upon mineralogy and geochemistry of ores as well as upon the ore genesis.

Rhönite and associate minerals in a basaltic pillow lava from the Basque-Cantabrian Basin (Vizcaya, Spain)

Gil-Crespo, P.P.[1*], Pesquera, A.[1] & Torres-Ruiz, J.[2]
[1]Depto. de Mineralogía y Petrología, Universidad del País Vasco, Bilbao, Spain ([*]pedro.gil@ehu.es).
[2]Depto. de Mineralogía y Petrología, Universidad de Granada, Spain

Rhönite is a relatively rare mineral that is isostructural with aenigmanite. It occurs in a basaltic pillow lava from the Basque-Cantabrian Basin (Vizcaya, Spain), with kaersutite, Ti-augite, plagioclase and ilmenite as main components. The rhönite-bearing basaltic pillow lava is a laminar body of variable thickness (2 to 20 m thick), which appears interbedded between upper Albian-lower Cenomanian "flysch" sediments. It shows a porphyritic texture in which centimetric phenocrysts (up to 7 cm) of ferromagnesian minerals can be observed.

Plagioclase phenocrysts are coarse grained (<1,5 cm), frequently displaying a normal, oscillatory to patchy zoning with a composition that ranges from ~70 to 90%An. Resorbed plagioclase phenocrysts with sieve and dusty textures are common. Ti-augite phenocrysts have a variable grain size and the largest phenocrysts may reach up to 5 cm in length. They show a prismatic euhedral to subhedral habit, purplish brown, pale brown to yellowish green coloured in thin section, and a complex optical zoning (oscillatory, continuous to patchy zoning). Kaersutite phenocrysts (up to 7 cm in length) show a prismatic subhedral habit to rounded shapes with a strong pleochroism, from reddish brown to yellow brown colour. Ilmenite occurs as (i) subhedral to rounded crystals (<5mm) associated to ferromagnesian minerals, (ii) acicular ilmenite; and (iii) small rounded grains that form part of the groundmass. Subhedral to subrounded apatite is a common accessory mineral. Pyrite and amigdales up to 1 cm filled by chlorite and calcite can be also observed.

Rhönite has been observed in some samples from the central part of the lava, typically associated to the amphibol. It constitutes an accessory mineral, very fine grained (<300 μm), with a prismatic subhedral to skeletal habit, and a dark-reddish brown to black colour. The microprobe analysis of 17 rhönite grains reveals the following compositional variations: SiO_2, 22.30-24.10; TiO_2, 11.56-12.94; Al_2O_3, 15.84-17.01; FeO_t, 19.49-22.07; MnO, 0.11-0.28; MgO, 12.68-14.09; CaO, 11.13-12.28; Na_2O, 0.73-0.89; K_2O, 0.0-0.27. Based on textural relationships, it is believed to be formed as a reaction product after kaersutite, probably under P-T conditions of < 0.5 Kbar, 1090-1120ºC, and an oxygen fugacity lower than the FMQ buffer.

New mineralogical data and genesis of limnosilicites from the Kremnica graben, Central Slovakia

Gregor, M.[1*], Koděra, P.[2], Lexa, J.[3] & Fallick, A.E.[4]
[1]Geological Inst., Comenius University, Bratislava, Slovakia ([*]geolgregor@yahoo.com)
[2]Dept. of Geology of Mineral Deposits, Comenius University, Bratislava, Slovakia
[3]Geological Inst., Slovak Academy of Sciences, Bratislava, Slovakia
[4]Scottish Universities Environmental Research Centre, East Kilbride, UK

Kremnica volcanotectonic graben in the Central Slovakia Volcanic Field hosts several localities with silica-rich rocks, deposited mainly in limnic/lacustrine environment hosted by altered rhyolite tuffs. This area is located S of the Kremnica low-sulfidation Au-Ag deposit, situated at the E side of a local horst. Silicites are often interlayered with bentonite (smectite) deposits and result from episodical inflow of groundwater enriched in silica due to decomposition of volcanic glass.

Limnosilicites are massive, laminated or occasionally brecciated rocks of variable colour, changing from white or reddish-brown to black. Colour variations depend on the content of organic matter and Fe-oxides/hydroxides. XRD and IR analyses showed that *white limnosicilites* are composed exclusively of quartz with index of crystallinity [1,3] ranging from 1 to 8. Their etched surface revealed the presence of quartz pseudomorphs after opal-CT lepispheres. White silicites originated in environment with flowing water as indicated by alignment of sillicified fossil flora. XRD data of dark limnosilicites exhibit diffraction peaks of quartz and peaks corresponding to opal-C or cristobalite (4.11 and 2.50 Å). Diminishing of the 4.11 Å peak after orthophosphoric digestion [2] and increase in FWHM values after refiring at 1050°C [3] confirmed the presence of opal-C. IR spectra showed vibration bands characteristic for amorphous silica, while quartz bands were absent. Crystallinity index of quartz from *dark silicites* is low (<<1), and is interpreted to depend on the content of carbon and Fe oxides/hydroxides that retard recrystallization of amorphous silica to quartz. The presence of organic matter probably results from origin in boggy anoxic environment with standing water. Infrequent *brecciated limnosilicites* have opal-AG matrix. Rarely, limnosilicites are overlain by layers of pure opal-CT.

Oxygen isotope composition of opal-AG and opal-CT bearing samples showed lower $\delta^{18}O$ values (22-29 ‰) compared to opal-C bearing and quartz only samples (14-24 ‰). Systematic increase in $\delta^{18}O$ values of silicites from N to S was observed, while individual localities showed just a limited variation of data. Clear correlation of $\delta^{18}O$ values of silicites and smectites indicates the influence of a similar factor responsible for change in $\delta^{18}O$ composition, which was most likely the change in temperature. This is also supported by correlation of smectite $\delta^{18}O$ composition with smectite crystal size [4]. Temperatures of crystallisation of silicites 80°C in N part to 30°C in S and SE parts were calculated based on equilibrium isotope fractionation between silicites and water [5]. Changes in temperature resulted from paleoflow of heated groundwaters and/or recrystallisation during subsequent shallow burial.

Alluvial minerals from Crişul Negru hydrographic basin (Bihor, Romania)

Hadnagy, A.
Romanian Geological Institute, Cluj-Napoca Mineralogical Branch, Cluj Napoca, Romania (hadnagyarpad@clicknet.ro)

Alluvial deposits are potential sources for recovering certain deficient mineral resources. They could be cheaply mined and easily separated. Thus the complex study of recent alluvia, done on aleatory basis so far, especially the re-evaluation of heavy mineral contents is a must for modern economic geology.

Crişul Negru River hydrographic basin is almost completely located in Bihor County, Apuseni Mts., Romania. The basin basement was intensely studied by previous authors; it shows very different petrographic features resembling a geological mosaic, mainly consisting of acid and neutral igneous rocks (granites, granodiorites, pegmatites, rhyolites, andesites etc.) commonly bearing Ti- and Zr- accessory minerals. These premises justify a re-evaluation for some rare alluvial heavy minerals not used so far.

In order to investigate the qualitative and quantitative (percentage and areal distribution) characteristics of all the possible alluvial mineral resources, the sediment discharge by recent alluvia has been thoroughly separated and studied by using modern equipment: automatic sieving machine, electromagnetic sorting device, electron scanning microscope (SEM), three-stimulus colorimeter, high precision analytical balance; satellite infra-red photographs complemented the study. Special attention has been paid to the structural and textural environment of these heavy minerals in order to present useful metallogenetic data for future investigations. The study has also concerned the mechanic aureoles boundaries of the already-known various lithostratigraphic formations and metallogenetic areas, as well as the delimitation of subordinate heavy mineral areas resulting from hydro-gravitational sorting. The morpho- and hydrodynamic relations inferred from the structural and textural features of the studied alluvia informed on several novel sedimentogenetic characteristics.

The mineralogical study of the 20,000 grain classes and subclasses led to the identification of several rich mineral parageneses which connected well to the known accessory mineral assemblages in the basement rocks. The morphologic study proved different morphoscopic features and very fine crystal shapes, which together with the graphic representations and the photographs provide scientific reference material to be used for future micromineralogic studies of similar minerals. The most relevant heavy mineral concentrate (sample nr. 812) yield 9 kg/m³ ilmenite, 1 g/m³ "leucoxene", 6 kg/m³ hematite, 0.2 kg/m³ rutile, and 0.01 kg/m³ zircon.

The theoretical value of this work consists in the indirect definition of accessory mineral parageneses related to the different rock types of the basement, by the micromineralogic study of monolithic alluvia. By using light reflection capacity of sands resulting from very diverse genetic processes, the role of colour parameters has been stated. The study aimed discriminating between magnetic and non-magnetic metallic spherules according to their origin (cosmic, volcanic and industrial) based on their chemical composition and morphoscopic features (by SEM). About 100 mineral species and varieties were added to the mineralogical topography of Romania, and some minerals were described for the first time in alluvia (nontronite, clinochlore, scheelite, bismuthinite, molybdenite, magnetite replacing fossils etc.). The "leucoxenisation" grade marks the relative age of the rocks. The major distribution source areas are presented. A new scientific view on the bauxite genesis in the Pădurea Craiului (Apuseni Mts.) is offered.

Tasmanian crocoite occurrence and water chemistry – implications for environmental metal contamination

Ii, Hiroyuki[1*], Taniguchi, Masanobu[1] & Sherwood, J.[2]
[1]Faculty of Systems Engineering, Wakayama University, Wakayama, Japan ([*]hiro@sys.wakayama-u.ac.jp)
[2]School of Life and Environmental Sciences, Deakin University, Australia

Crocoite ($PbCrO_4$) is a very rare mineral but abundant in the Dundas area of western Tasmania, Australia. Cr^{3+} is stable in most natural environments and so in most of minerals containing Cr it exists in this form. However, Cr in crocoite exists as Cr^{6+}. Pb and Cr are relatively common metals in the natural environment. However, compounds containing both Pb and Cr are very rare in natural environments. Artificially, Cr^{6+} is easily produced by oxidizing Cr^{3+} under high temperature conditions and it is useful as an oxidizing agent. Therefore, Cr^{6+} is very often used in chemical factories or chemical laboratories. And also, Pb is widely used for battery and historically as pipes for drinking water, in petrol and in paints. Because of this, artificial Cr and Pb contamination for soil and water can be an environmental problem. Therefore it is useful to trace the origins of the Cr and Pb of crocoite under natural conditions in order to better understand migration of Cr and Pb under artificial metal contamination. For this reason, the occurrence condition of crocoite and its associated water chemistry in the Dundas area was studied. Ultrabasic rock contains Cr minerals and sometimes Cr^{6+} is found in groundwater and spring water in the ultrabasic rock. In the Dundas area, Cr ion concentrations were low ranging from 0.004 to 0.01 ppm. However, Cr ion concentration of spring water in serpentinite containing stichtite $Mg_6Cr_2(CO_3)(OH)_{16}\cdot 4(H_2O)$ is 0.13 ppm. Under high pH condition, Cr^{6+} is produced from Cr_2O_3 or Cr^{3+} and Cr^{6+} does not need high Eh conditions. Serpentinite contains Mg hydroxide minerals and so spring water shows high pH. Pb, Zn and Ni ion concentrations of spring, river and crocoite mine adit water were 0.001 to 0.07 ppm, 0.006 to 4 ppm and 0.1 to 0.8 ppm respectively. Crocoite was observed at three old silver mines - the Adelaide, Red Lead and Dundas extended mines. Silver was produced from hydrothermal galena veins in serpentinite. At the Adelaide mine, a 100m deep shaft remains but is filled with water to the river level. Crocoite occurred at the old adit wall and in porous highly weathered rock along the vein above the river level. Because of the strongly weathered zone, original Pb minerals were not observed around the adit. On the other hand, compact silicified rock sometimes contains the Pb carbonate mineral, cerussite. At the Red Lead mine, the ore area was open cut. Crocoite occurred along highly weathered silicified rock or clay veins in the highly weathered rock. Again the original Pb mineral was not observed. In both mines crocoite was observed along weathered veins. At the Dundas extended mine, original and secondary Pb minerals were observed. Crocoite was observed at the adit wall however most crocoite was accompanied by Pb minerals along the galena vein. The original Pb mineral, galena, remains in the vein. Anglesite ($PbSO_4$) occurs around galena. White normal cerussite was observed beside anglesite and galena. Yellow Cr bearing cerussite was observed outside of anglesite and white cerussite. Crocoite was observed outside of galena, anglesite, and white and yellow cerussites. From these observations and the water chemistry, Cr^{6+} of crocoite is thought to be derived from serpentinite containing Cr^{3+} minerals such as stichtite by weathering. Under high pH condition, Cr^{3+} is oxidized to Cr^{6+}. Cr^{6+} is thought to migrate into galena veins via groundwater. Crocoite forms where and Pb and Cr ions co-occur through weathering processes. Therefore, the Cr ion is thought to migrate more easily in groundwater than the Pb ion.

Occurrence of crandallite series minerals in Variscan granitoid rocks in Poland

Kajdas, B.[*], Jerzykowska, I. & Michalik, M.
Institute of Geological Sciences, Jagiellonian University, Krakow, Poland ([*]bartlomiej.kajdas@uj.edu.pl)

Crandallite series minerals belong to APS minerals (aluminium phosphates and sulphates from the alunite supergroup). The general formula of the series is $AB_3(XO_4)_2(OH)_6$ (A – Ca, Sr, REE, Pb, Ba; B – Al, Fe^{3+}; X - P, As, S, Si).

Crandallite series minerals were noted during studies of samples from two Variscan granite massifs in Poland. Samples of the Karkonosze granite (Kowary Średnie) represent highly grusified rock. Samples of the High Tatra granite (Waksmundzki Wierch Mt) were collected as small rock fragments from soil profile. Minerals identification is based on chemical composition determined using SEM-EDS method.

At both localities crandallite series minerals were found in almost completely sericitized K-feldspars as 5-10µm skeletal crystals. In the Karkonosze granite examined minerals are square-shaped in cross-sections. They occur in clusters along fractures and cleavage planes of feldspar. Single pseudohexagonal in cross-section crystals of crandallite series minerals are present in the High Tatra granite. In some feldspars these crystals are replaced by iron oxides containing REE.

SEM-EDS results indicate that chemical composition of crandallite series minerals is close to florencite-(Ce) and goyazite (Table 1).

Table 1: Average chemical composition of crandallite series minerals obtained from EDS analysis (wt%)

	(1)	(2)	(3)
P_2O_5	26.15	30.29	22.37
SO_3	0.10	3.97	9.51
SiO_2	9.97	2.19	9.33
As_2O_5	4.25	n.d.	n.d.
Al_2O_3	32.98	35.47	34.54
Fe_2O_3	0.36	3.17	2.54
La_2O_3	7.20	4.70	1.75
Ce_2O_3	14.27	12.78	3.98
Pr_2O_3	0.27	n.d.	n.d.
Nd_2O_3	2.30	n.d.	0.11
Sm_2O_3	n.d.	1.15	1.37
Gd_2O_3	0.09	n.d.	n.d.
MgO	0.76	0.30	0.49
CaO	0.07	0.36	1.01
SrO	n.d.	4.09	12.11
Na_2O	n.d.	n.d.	0.25
K_2O	1.06	0.18	0.70

Florencite-(Ce) from the Karkonosze granite is characterized by the presence of small amount of arsenic in X position (about 4 wt% of As_2O_5). Florencite-(Ce) crystals from the Tatra Mts. contain Sr in A position (about 4 wt% of SrO) and S in X position (about 4 wt% of SO_3). Goyazite is REE bearing. Presence of SiO_2 in all minerals can be related partly to small crystal size and mixed X-ray signal.

Origin of the crandallite group minerals can be related to weathering or low-temperature hydrothermal processes. Taking to account that crandallite series minerals have not been described in hydrothermally altered or weathered rock samples from both granitic massifs we can assume that specific chemical environment is needed for their formation.

Indium mineralization in the Au-Mo(W)-porphyry Bugdaya deposit, Eastern Transbaikalia, Russia

Kiseleva, G.D.*, Kovalenker, V.A. & Mokhov, A.V.
Institute of Ore Geology, Petrography, Mineralogy, and Geochemistry, RAS, Moscow, Russia (*kis60@rambler.ru)

Indium mineralization consisting of rather exotic mineral species dzhalindite, $In(OH)_3$, was found in Au metal veins cross-cutting Mo(W)-porphyry stockwork at the 50 m depth below earth surface [1]. It occurs only in chalcedony, which cements Fe-rich and In-Cd-bearing sphalerite fragments. Most of the sphalerite fragments are rimmed by CuS-Cu_2S minerals, sometimes with greeenockite, and late galena forming the rims on covellite and greeenockite. Dzhalindite forms euhedral cubic or cubo-octahedral crystals in the zoned chalcedony. Some of the crystals have a spheroidal center and outer parts of rather complicated structure (Fig. 1). In many cases, external zones of crystals are inclined by 45° relative to the internal parts. Some crystals bear evidence of intermediate partial dissolution. Size of the crystals varies from 30 to 94 μm with the most frequent size of 60-70 μm.

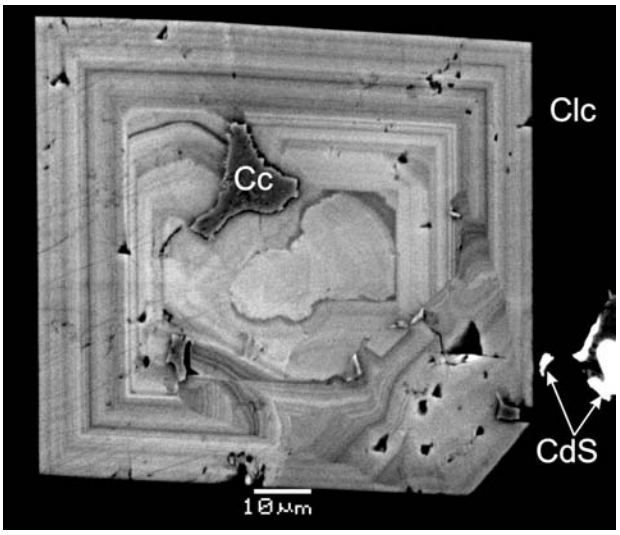

Fig. 1: BSE image of dzhalindite crystal with complicated internal structure. Cc – chalcocite, Clc – chalcedony, CdS – greenockite.

Dzhalindite is transparent or semitransparent, colorless, yellowish, pinkish-yellowish to light brown. All crystals of dzhalindite have oscillatory zoning clearly seen in the BSE images (Fig. 1). The zoning (and color intensity) is caused by the variations of Fe (0.61 – 3.6 wt.%) and In (63.27-78.5 wt.%) content. The lighter internal parts of crystals are most pure $In(OH)_3$ with a higher In-content. Some analyses also show additional components as follows (wt.%): W (1.29-1.5), Sn (4.77), Te (0.67-1.22), Cd (0.83-1.03). Dzhalindite contains inclusions of covellite-chalcocite relics and, very rarely, microspheroidal inclusions of low fineness electrum. Dzhalindite-bearing chalcedony contains native Ag (sometimes with stromeyerite relics), Ag-amalgams, stolzite, Pb oxide, goethite, greenockite, and covellite-chalcocite relics. This assemblage can indicate supergene origin of dzhalindite as the result of dissolution of In-bearing sphalerite and precipitation $In(OH)_3$ from Si-colloidal solution.

Anisotropic garnet from the Yamansu deposit, Xinjiang, China

Kobayashi, S.[1*], Fujisawa, A.[1], Miyawaki, R.[2] & Kaneda, H.[3]
[1]Dept. of Applied Science, Okayama University of Science, Okayama, Japan (*kobayashi@das.ous.ac.jp)
[2]Dept. of Geology and Paleontology, National Museum of Nature and Science, Tokyo, Japan
[3]Dept. of Environmental Science, Toho University, Funabashi, Japan

Anisotropic garnet was found in skarn ores occurring in the Yamansu orthomagmatic deposit, located along a fault in the back arc basin of the Carboniferous, east part of Xinjiang, China. Constituent ore minerals in the skarn ores are chalcocite, chalcopyrite, bornite, magnetite, and pyrite. Gangue minerals are composed mainly of garnet, diopside, actinolite, and calcite. The anisotropic garnet sample was polished to be examined by a petrographic microscope. The garnet has been analyzed for major elements using EPMA, and checked for water content by infrared (IR) absorption spectra. Lattice parameters of the garnet were examined using a micro beam X-ray diffractometer (PSPC-MDG) with a total diffraction collimator of 30 μm in diameter and a single crystal diffractometer.

Optical birefringence of one of the anisotropic garnets (Fig. 1) was 0.002, which was calculated from optical retardation and the thickness. The chemical composition of the garnet showed that the garnet belongs to the grossular-andradite series regardless of the presence of a small amount of Cr, Fe^{2+}, Mn, Ti, Mg shown as chemically ($Gro_{32}An_{61}Uv_1Alm_5Sp_1$ - $Gro_{43}And_{51}$ $Uv_0Alm_5Sp_1$). No chemical zoning observed in a single garnet. IR spectrum of the garnet showed no absorption band by OH stretching vibration. The d_{420}, d_{444} and d_{400} values of the garnet were determined by PSPC-MDG and compared with these of the grossular – andradite series garnets hydrothermally synthesized at temperatures between 536 and 652°C under a pressure of 100 MPa for 5 to 23 days. The d_{400}, d_{420} and d_{444} values of the anisotropic garnets have been plotted on a curved line joining each d value of the synthesized grossular and andradite, respectively. Some of the values were not plotted along the estimated curved line. Moreover, we'd like to discuss the crystal structure of anisotropic garnet with the comparison of other natural optically anisotropic garnets.

REE arsenates in rare-metal greisens from the Sn-W deposit Verkhnee (Priamyrie, Far East, Russia)

Korostelev, P.G.[1], Gorelikova, N.V.[2*], Semenyak, B.I.[1], Karabtzov, A.A.[1], Orekhov, A.A.[1] & Safronov, P.P.[1]
[1]Far East Geological Institute, RAS, Vladivostok, Russia
[2]Institute of Geology of Ore Deposits (IGEM), RAS, Moscow, Russia ([*]ngor@igem.ru)

REE arsenates and phosphoarsenates of variable composition have been found at the chimney body of Sn-W quartz-fluorite-topaz greisens from the Verkhnee deposit embedded in K_2 rhyolites. REE arsenates are associated with brown zones of zoned green fluorite crystals as replacement products of monazite and xenotime. They form small grains and grain agreggates of 0.1-0.3 mm in size. The mineral replacing monazite has a composition of gasparite-Ce [1], whereas one replacing xenotime is similar to chernovite [2].

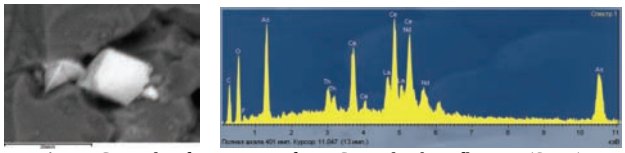

Fig. 1: Crystals of arsenates of La, Ce, Nd, Th in fluorite (SEM).

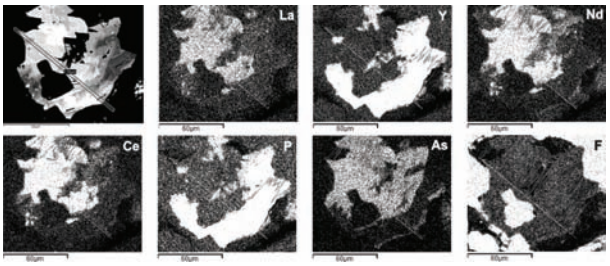

Fig. 2: The replacement of monazite and xenotime by REE arsenates (EMPA).

Electron-microprobe analyses in different points of monazite and xenotime grains provided the following composition (in wt.%): Y 9.58-15.09, Ce 3.17-22.82, La 8.53, Nd 1.19-6.95, Sm 0.95-3.88, Gd 1.25-4.85, Dy 3.33-4.99, Yb 0.92-1.76, Th 0.57-37.87, As 9.87-23.15, P 0.55-3.52, Ca 1.09-2.41, O 16.05-19.09, F 0.98-6.39.

In addition to REE arsenates, phosphoarsenates of Y, REE, Th and a britholite-like mineral have been observed in marginal zones of monazite.

REE arsenates and phosphoarsenates formed at the high redox-potential under conditions of the S deficiency and a higher alkalinity. At these conditions, As exists as As^{4+} and shows more covalent properties than in sulphides and sulphosalts, which promotes replacement of P by As in REE minerals. Owing to its variable valence, As reflects redox conditions of the mineral formation [3].

Rare Mg-hydrocarbonates in mineral assemblage of fissures in serpentinite at Hrubšice, Moldanubian zone, western Moravia

Kovář, O.[1], Losos, Z.[1*], Houzar, S.[2] & Zeman, J.[1]
[1]Institute of Geological Sciences, Masaryk University, Brno, Czech Republic ([*]losos@sci.muni.cz)
[2]Dept. of Mineralogy and Petrography, Moravian Museum, Brno, Czech Republic

The unique low-temperature Mg- (Mg-Fe) hydrocarbonate mineralization was found in the Hrubšice serpentinite, Moravian Moldanubicum. It is linked to the fissure system in serpentinite in the active quarry „U Pustého mlýna“ and it consists of rare minerals (hydromagnesite, artinite, brugnatellite, coalingite), followed by aragonite, brucite, dolomite and calcite. Artinite [1], brugnatellite and coalingite are mineral phases found for the first time in Czech Republic.

Hydrocarbonate mineralization occurs as small veins few mm thick or druses in the fissures in serpentinite. Thicker small veins provided outstanding examples of artinite and partly also magnesite. Remaining described minerals were found only locally in microscopic size. From geochemical viewpoint the minerals belong to the Mg-CO_2-H_2O system, locally with Ca-, Fe- a Mn-, and two latter elements are present only in the oldest mineralization stage. In the system, Al is completely missing.

Based on the carbonate assemblage study, three temporal crystallization stages have been recognized: (1) the oldest stage comprising higher Fe- (Mn-) activity: brugnatellite, coalingite and Fe-bearing brucite, i.e. minerals with high Fe content and locally also with slightly increased Mn content occur. (2) Younger stage is represented by hydromagnesite. Simultaneously, there are separate occurrences of chemically pure artinite in fissures, rarely present with hydromagnesite. There is a rare common occurrence of artinite with hydromagnesite, when younger hydromagnesite grows on artinite. Similarly hydromagnesite is surrounding older Mg-Fe-hydrocarbonates (brugnatellite, coalingite). (3) The youngest fill of fissures is formed by calcite and druses of prismatic aragonite crystals. Even younger, but only with respect to hydromagnesite, is huntite, which probably forms pseudomorphoses after hydromagnesite [2].

The mineralization of described Mg-hydrocarbonates probably precipitated from low temperature solutions rich in Mg^{2+}, at pH ~ 9, low activity of CO_2 and at temperatures less than 44°C. The presence of brugnatellite and coalingite with associated Fe-hydrooxide (i.e. phase comprising Fe^{3+}) indicates at least locally oxidizing conditions during the precipitation of the phases. Source of Mg and of Fe were the processes of serpentinite alteration by aqueous solutions of local circulation.

From genetic viewpoint, the spatial distribution of Mg-carbonates in the Hrubšice serpentinite body is remarkable. Described Mg-, Mg-Fe-hydrocarbonates and huntite represent a typomorph association in fissures only in the southern part of the body. Their genesis may be related to the manifestation of young or even sub-recent re-activation of faults, which was documented at Biskoupky close to the study site [3].

Acknowedgements: The work was supported by grant projects MSM 0021622412 and MK 00009486201.

Dissolution of NaCl crystals studied by X-ray diffraction, reflection and absorption methods

Kryazhev, A.A.[1*] & Petrakov, A.P.[2]
[1]Institute of Geology Komi SC UD of RAS, Syktyvkar, Russia (*reflect@rambler.ru)
[2]Syktyvkar State University, Syktyvkar, Russia

Single-crystal X-ray diffraction method (Bragg-Brentano geometry) was used to study NaCl crystals after splitting and dissolution in distilled water. The (100) reflection was accompanied by several additional peaks arising due to disoriented block microstructure of the crystal studied.

X-ray reflectometry is a useful tool to study physical and geometrical properties of the near-surface region of a crystal in solution with a high accuracy. Using this method, quality of NaCl crystal faces after splitting, as well as short and long time processes of their changes in solution have been estimated. Dynamics of roughness changes of fresh NaCl surface during dissolution in the distilled water was characterized.

NaCl aqueous solution was investigated by X-ray absorption and phase contrast methods. The absorption calibration curve for NaCl solution was obtained. The X-ray phase contrast method [1] provides high resolution visualization of the internal structure of low absorbing substances with a flat density gradient. This method can also be used for the study of processes that induce changes in refraction indices. As a result, changes in density and concentration of NaCl solution near the dissolving crystal were obtained (Fig. 1).

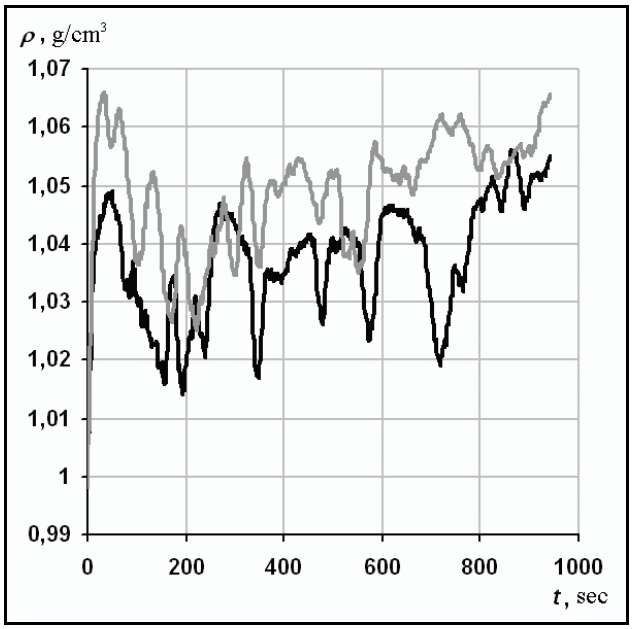

Fig. 1: Solution density change near the crystals NaCl. ▬ – for the crystal with weight m1 = 0.105g, ▬ – m2 = 0.160g.

Acknowledgements: The work has been completed with the partial support of RFBR (grant № 08-05-00346a) and Program of BES RAS SB (09-C-5-1022).

Copper-amalgams from the Rudabánya base metal mineralization, NE Hungary

Kupi, L.[1*], Szakáll, S.[1], Zajzon, N.[1], Kristály, F.[1] & Fehér, B.[2]
[1]Institute of Mineralogy and Geology, University of Miskolc, Hungary (*laszlokupi@gmail.com)
[2]Herman Ottó Museum, Miskolc, Hungary

The Rudabánya metasomatic iron ore formation lies in a 25 km long, NNE-SSW trending range of uplifted and sheared Mesozoic sediments. This regional strike-slip fault zone worked as an upleading zone for fluids. The main mass of the mineralization is composed by siderite with two phases of base metal enrichment (copper and zinc-lead, which differ both in time and space) with barite in the edges of the carbonate bodies. The extensive secondary enrichment zone has been formed after the uplift of the area.

The oxidized zone was overprinted by a low-temperature, epithermal system in the SW parts, with weak silicification. This Sb-As-Hg-enriched fluid saturated the silicified gossan, forming a multi-origin association of elements. In this environment a unique paragenesis has been formed [1].

Copper-amalgams were observed by X-ray diffraction and electron microprobe, supported by reflection optical microscopy. The presence of belendorffite is proven by using a Gandolfi X-ray camera. The Gandolfi-camera results show a good match with the belendorfitte structure of Bernhardt & Schmetzer [2]. Bragg-Brentano geometry measurements indicate the combination of multiple polytypes, with strong preferred orientation, but deconvolution of peaks was possible. The X-ray diffraction data from Bernhardt & Schmetzer [2] and Cipriani & Mazzetti [3] was used to identify single peaks.

The results suggest a belendorffite-dominated composition, with varying kolymite contribution. The Cu-Hg alloy with ~ 1:1 atomic ratio is a combination of the hexagonal or pseudocubic and cubic polymorphs. It forms isometric crystals up to 1 mm in cavities of cuprite and native copper, or coats irregular aggregates of copper (Fig. 1)

Fig. 1: Native copper is margined by belendorffite in cuprite 1N 250x (Andrássy I. mine district, Rudabánya)

The structural behaviour of Cr-spinels from the Rum Layered Suite, NW Scotland

Lenaz, D.[1*], O'Driscoll, B.[2] & Princivalle, F.[1]
[1]Dept. of Geosciences, University of Trieste, Trieste, Italy
([*]lenaz@units.it)
[2]School of Physical and Geographical Sciences, Keele University, Keele, United Kingdom

The Rum Layered Suite, NW Scotland, intruded at 60.53 ± 0.08 Ma during Paleogene opening of the North Atlantic and is widely considered to be a classic example of a layered mafic intrusion formed by open-system magmatic differentiation. The Eastern Layered Intrusion of the Rum Layered Suite comprises 16 coupled feldspathic peridotite-troctolite (± olivine gabbro) cyclic units and outcrops over ca. 25 km^2. Cr-spinel seams occur at the junctions of some of the major cyclic units. At certain unit boundaries, so-called "subsidiary" Cr-spinel seams also occur. The here studied Cr-spinels, analysed by means of X-ray single crystal diffraction and electron microprobe, are from the anorthosite, the subsidiary and main seams, the troctolite and the peridotite.

According to [1], Cr-spinel compositions in the Eastern Layered Intrusion can be divided into two distinct groups: one comprised Fe- and Cr-rich spinels occurring in the anorthosite and troctolite, the other Mg- and Al-rich Cr-spinels from the subsidiary and main seams. This fact is clearly reflected also in the structural data of the analysed spinels. Both cell edges (a_0) and the oxygen positional parameter (*u)* are related to the chemistry of the spinels, so that a_0 values for spinels in anorthosites and troctolites range between 8.3215 (5) and 8.3582 (4) Å, while those from the seams are in the range 8.2126 (1) – 8.2569 (2) Å. The most important feature is that, as far as the *u* values are concerned, three, instead of two, groups have been recognised here. In fact, the Cr-spinel in the anorthosite ranges from 0.2584 to 0.2607, those in the troctolite are between 0.2618 and 0.2625, those in the seam from 0.2629 to 0.2632. The cell edge and *u* values calculated for Cr-spinel in anorthosites are very important; they reflect a high Fe^{3+} composition quite similar to those of synthetic spinels belonging to the series $MgCr_2O_4$ - $MgFe_2O_4$ [2]. Due to the impossibility of performing Mössbauer analyses on these disseminated spinels, it is noteworthy that single-crystal X-ray diffraction, coupled with the electron microprobe analyses can provide a clear indication of an high Fe^{3+} content.

Fe^{3+}/Fe_{tot} ratio in the mantle: a micro-Mössbauer study of chromites included in diamond and kimberlites

Lenaz, D.[1*], Skogby, H.[2], Logvinova, A.M.[3], Princivalle, F.[1] & Sobolev, N.V.[3]
[1]Dept. of Geosciences, University of Trieste, Italy
([*]lenaz@units.it)
[2]Dept. of Mineralogy, Swedish Museum of Natural History, Stochkolm, Sweden
[3]Inst. of Geology and Mineralogy, Russian Academy of Sciences, Siberian Branch, Novosibirsk, Russian Federation

Oxides with the spinel structure AB_2O_4 occur as main or accessory minerals in many different rocks of the Earth, from the upper mantle to the crust. The wide ranges of composition and mineral assemblages of spinels allow them to be employed as petrogenetic indicators. Being sensitive to temperature, pressure, oxygen fugacity, bulk rock and fluid composition, intra- and inter-crystalline equilibria in spinel are extremely useful for constructing mineral geothermometers and geobarometers. In such a context, problems with the correct evaluation of Fe^{2+}/Fe_{tot} ratio can lead to important mistakes in calculated temperatures, pressures and oxygen fugacities.

The oxidation state of the upper mantle and its evolution with time are among the most important problems facing geologists. Oxygen fugacity (f_{O_2}) is a fundamental but little known intensive variable in mantle processes. It influences the P/T position of a mantle solidus and the composition of mantle-derived melts and fluids, and constrains mantle-core equilibria and a number of geophysical properties of the mantle. An important source of information on oxidation states is the ferric/ferrous iron ratio in mantle spinels. Since the magnetite component is low in mantle spinels, normal analytical errors translate into considerable f_{O_2} uncertainties. Recently, the most accurate evaluation of ferric/ferrous ratio have been achieved by using different spectroscopic methodologies (single crystal X-ray diffraction, electron microprobe analyses, Mössbauer spectroscopy) and comparing their results. Because spinel usually occurs as small grains, Mössbauer cannot be widely applied because it requires a relatively large sample size. Given that, in the same sample analysed by conventional Mössbauer there could be a large number of spinels with different degrees of oxidation/alteration leading to possible errors in the interpretation of the results.

The diamond deposits of Siberia (Russia) compose the Yakutian kimberlite province, located in the northwestern region of the Siberian craton. About 1000 kimberlite bodies of a wide range of emplacement ages from Early Paleozoic to Late Mesozoic are known within several kimberlite fields. In this study single crystals of chromites previously analysed by means of single crystal X-ray diffraction and electron microprobe [1] occurring in the kimberlites of the Mir and Internatsionalnaya mines, in the Obnazhennaya barren pipe and included in a diamond from the Udachnaya mine have been analysed by Micro-Mössbauer in order to avoid possible errors deriving from different oxidation/alteration degrees of multiple grains.

The Fe^{3+}/Fe_{tot} ratios obtained from the Mössbauer spectra are in fair agreement with X-ray diffraction data for some samples, but show higher Fe^{3+} values for other samples, which may indicate a minor deviation from stoichiometry.

Probing the geological environments and occurrences of quartz crystals in south-west Central Mountain Range, Taiwan

Li Yu-Ho[1], Chen Huei-Fen[1*] & Fang Jian-Neng[2]
[1]Institute of Applied Geosciences, National Taiwan Ocean University, Keelung, Taiwan ([*]diopside0412@yahoo.com.tw)
[2]Dept. of Collection Management, National Taiwan Museum, Taipei, Taiwan

This study investigates the regional geological environments in which well-developed quartz crystals can be found and the formation mechanisms of quartz in the Central Mountain Range (CMR), Pingtung, Southern Taiwan. We discovered three morphological types of quartz crystals: (a) prismatic quartz (Fig. 1a), (b) faden quartz (Fig. 1b), and (c) doubly terminated quartz (Fig. 1c). We listed observed occurrences, crystal morphology, micro-observation of inclusions, and micro-Raman spectroscopy of intergrowth minerals to probe formation mechanisms and thermobaric ranges of this quartz.

According to the geological survey and locations data faden quartz occurs in the older anchizone to low epithermal environments (Lushan Formation), doubly terminated quartz is mainly found in the high diagenetic zone (Mudan Formation), while prismatic quartz grows in this whole region and often intergrows with the other two types. The faden quartz grows from near-plastic deformation cracks under higher temperature and higher pressure conditions at 2 to 5 km depth. Its preferred-orientation crystals bear thread-like inclusions, which indicate the direction of the extension crack. Moreover, it can intergrow with rutile and chlorite. The doubly terminated quartz grows in brittle fractures from sandstone joints. Its host rocks proceeded from an uplift history to the shallow tectonic region. An obvious character is that the doubly terminated quartz has large fluid inclusions of variable sizes. Its crystals did not attach to host rocks, because they grew from autonucleation under fluid oversaturation passing through decreasing temperature/pressure. The two types of quartz can show fissure development due to the host rock uplifting at different depths in the region.

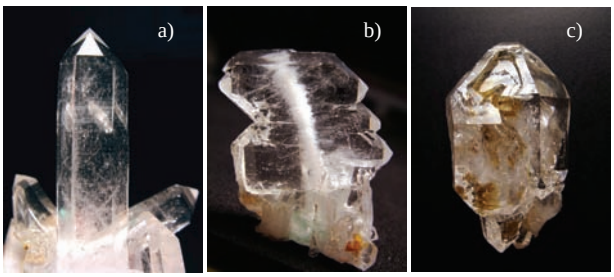

Fig. 1: a) Prismatic quartz; b) faden quartz; c) doubly terminated quartz.

Nanostructures of manganese oxides in ferromanganese nodules

Lysyuk, G.
Institute of Geology, UB RAS, Syktyvkar, Russia
(glysiuk@geo.komisc.ru)

Manganese oxides, widespread and of great practical importance, are formed and transformed in natural environments due to the active role of microorganisms.

In our study, all of the previous observations of the biogenic origin of ferromanganese nodules (FMNs) were confirmed by scanning electron microscopy (SEM). Numerous relics of planktonic organisms often replaced by Mn oxide as coating films were identified in the inner zones of FMNs. X-ray amorphous Mn oxides are widespread in FMNs. As follows from the SEM examination, these phases are mineralized glycocalyx. Experiments on high-temperature transformations allowed identifying this phase as todorokite, and SEM images indicate that todorokite was formed under the influence of bacterial activity. A cyanobacterial mat detected in the interlayer space of nodules is an additional evidence for the participation of bacteria in nodule growth and the formation of finely dispersed Mn minerals. The chemical composition of this cyanobacterial mat is as follows (wt.%): 48.35 MnO, 6.23 Fe_2O_3, 8.67 MgO, 5.05 Al_2O_3, 4.45 SiO_2, 3.63 NiO, 2.30 Na_2O, 2.19 CuO, 1.31 CaO and 0.68 K_2O.

The SEM examination of the inner zones of FMNs allowed detection of numerous biofilms in the interlayer space of nodules. These biofilms are composed of fusiform, rod-shaped, and coccoid bacteria and their filamentary cover. The bacterial mass is composed of (wt.%) 28.34 MnO, 17.14 Fe_2O_3, 7.11 SiO_2, 2.41 CaO, 7.90 TiO_2, 1.74 Na_2O, 1.73 Al_2O_3, 1.30 MgO, 1.25 P_2O_5, 1.25 SO_3, 0.68 CoO, 0.54 CuO, 0.53 NiO and 0.50 K_2O. Thus, the chemical composition of cyanobacteria and bacterial mass of biofilms corresponds to Mn oxides. A great variety of bacterial forms were found on the nodule surface, testifying to their participation in the mineral formation on the ocean bottom.

Numerous findings of finely dispersed native metals confirm the great contribution of the biogenic factor to the formation of FMNs. Sulfide minerals in nodules (pyrite, chalcopyrite, pyrrhotite, troilite, covellite, and bornite) are usually associated with organic remains and were formed in the reducing environment created by bacterial activity. The occurrence of Ni minerals (taenite, bunsenite, niccolite, and violarite) in FMNs is related to biochemical processes as well.

Inclusions of native metals were found in FMNs and Mn-bearing zones of weathering. Numerous copper red and brass yellow metal lamellae, flakes, and dendrites in FMNs were identified by a microprobe as native copper and intermetallic compounds of Cu and Zn (brass yellow grains). Fe-Cu compounds and pure Fe are less abundant. In addition, sporadic grains of native Al and Zn were found. The occurrence of native metals can be explained by segregations of organic matter that served as microscopic domains with highly reducing conditions.

The association spurrite – perovskite in the inner exoskarn zone from Cornet Hill (Metaliferi Mountains, Romania)

Marincea, Ş.[1*], Dumitraş, D.G.[1] & Fransolet, A.M.[2]
[1]Geological Institute of Romania, Bucharest, Romania
([*]marincea@igr.ro)
[2]Laboratoire de Minéralogie, Université de Liège, Belgium

The high-temperature skarn occurrence from Cornet Hill (Metaliferi Mountains, Romania), located approximately 20 km west of Brad, and 40 km northwest of Deva, is known as one of the rare occurrences of spurrite and tilleyite worldwide. The skarn contains essentially spurrite, tilleyite and gehlenite and develops at the contact of a monzodiorite - quartz monzonite body, of Upper Cretaceous age, with Tithonic - Kimmeridgian reef limestones of the Căpâlnaş-Techereu unit. The skarn from Cornet Hill is clearly zoned, the zoning being, from the outer to the inner part of the metasomatic area: calcite (marble) / tilleyite / spurrite / wollastonite + gehlenite + vesuvianite / wollastonite + grossular / quartz monzonite.

Spurrite from Cornet Hill concentrates in the outer endoskarn zone, and practically defines a monomineralic zone where it forms 90-95% of the rock volume. A minute study shows, however, that the typical assemblage is spurrite + perovskite, with minor proportions of tilleyite, wollastonite, gehlenite, titanian andradite and hydroylellestadite. The spurrite-bearing skarn is characterized by a massive appearance with medium-grained crystals of grayish blue to pale gray spurrite that exceed generally 5 mm in their largest dimension, without preferred orientation. Some of the larger patches of spurrite are, however, cross cut by microveins containing scawtite, plombièrite, tobermorite, calcite and secondary aragonite. The optical constants of a representative sample are α = 1.637(2), β(calc.) = 1.675(2), γ = 1.680(3) and 2V = 39°. The measured density of the same sample [D = 3.02(2) g/cm^3] agrees perfectly with the calculated density (D_x = 3.022 g/cm^3). The cell parameters, obtained as mean of 6 different sets of individual values obtained by least-squares refinement of X-ray powder data are: a = 10.493(15) Å, b = 6.716(9) Å, c = 14.179(16) Å and β = 101.36(4)°. The chemical composition, obtained as average of 23 electron-microprobe spot analyses on different samples is (in wt% oxides): SiO_2 = 26.84, TiO_2 = 0.03, Al_2O_3 = 0.01, FeO = 0.03, MgO = 0.05, CaO = 63.11, Na_2O = 0.07, K_2O = 0.01, CO_2 (calculated) = 9.83. The chemical-structural formula, calculated on the basis of 11 oxygen atoms, is: $Ca_{5.010}Mg_{0.002}Mn_{0.003}Fe^{2+}_{0.002}Ti_{0.002}Na_{0.011}K_{0.001}(Si_{1.990}Al_{0.001})O_{8.015}(CO_3)_{0.995}$.

Granular inclusions of perovskite in the spurrite mass are common in most of the samples, and are particularly abundant in the close vicinity of the gehlenite-bearing endoskarn. The grain sizes commonly vary between 0.01 and 0.05 mm. The physical constants of a selected sample are α = 2.302(2), β(calc.) = 2.341(2), γ = 2.383(2), D_x = 4.049 g/cm^3, D = 4.04(1) g/cm^3. The average composition taken as mean of 15 point analyses on various crystals is (in wt.% oxides): SiO_2 = 0.36, TiO_2 = 57.25, Al_2O_3 = 0.28, FeO = 1.19, MnO = 0.02, CaO = 40.23, Na_2O = 0.02, K_2O = 0.01 and leads to the chemical-structural formula: $(Ca_{0.983}Fe^{2+}_{0.023}Mg_{0.002}Na_{0.001})(Ti_{0.982}Si_{0.008}Al_{0.008})O_3$, approaching the stoichiometry.

The unit-cell parameters, obtained by least-squares refinement of the X-ray powder dataset obtained for a spurrite-included perovskite separate are: a = 5.382(3) Å, b = 5.437(3) Å, c 7.634(4) Å. The refinement was carried out accepting the orthorhombic symmetry of the mineral, space group Pbnm.

Trace elements in anorthite megacrysts from West Japan volcanic belt

Matsui, T.[1*], Arakawa, Y.[2] & Kimata, M.[2]
[1]Faculty of Education, Kagoshima University, Kagoshima, Japan ([*]matsui@edu.kagoshima-u.ac.jp)
[2]Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan

Anorthite megacrysts from eight volcanic regions (Aso, Aira, Kaimon-dake, Satsuma-Iou-jima, Kuchierabu-jima, Kuchino-shima, Suwanose-jima, Akuseki-jima) of the West Japan volcanic belt were analyzed by inductively coupled plasma analysis (ICPA) for concentrations of Mg, K, P, Ba, Be, Co, Cr, Cu, Dy, Eu, La, Li, Mn, Mo, Ni, Pb, Sc, Sn, Sr, Ti, V, W, Y, Zn, and Zr. The anorthite megacrysts, reaching a maximum size of approximately 2 cm in diameter, are mainly found as phenocrysts in the andesitic lava series, but are also present in basalts and as crystal bombs in basaltic scorias from a number of these volcanic regions. These megacrysts show no or only slight optical zoning, and electron microprobe studies show that these megacrysts are chemically homogeneous and unzoned [1]. Anorthite content of the megacrysts is approximately 90-94 mol %, although the content varies slightly in each volcanic region [1]. Similar anorthite megacrysts are found in the East Japan volcanic belt [2] and have been mineralogically and geochemically characterized, with a focus on their genesis and migration of subduction components (e.g., [3]; [4]; [5]; [6]).

The anorthite megacrysts from the East Japan volcanic belt occur in Neogene and Quaternary basaltic rocks, and their host rocks are grouped into two types: tholeiite and high-Al basalt [2]. In contrast, most Quaternary volcanism in Kyushu and Ryukyu Islands is classified into calc-alkaline rock series [7]. The $^{87}Sr/^{86}Sr$ ratio of the anorthite megacrysts is somewhat lower than that of their host rocks which suggests that the anorthite megacrysts did not crystallized from the surrounding host magmas [8].

Trace element partition coefficients between the anorthite megacrysts and their host rocks differ slightly in several specimens. The measured large-ion lithophile element content exhibits a gradual increase in concentration toward the rear arc and appears to be related to the $^{87}Sr/^{86}Sr$ ratio of the anorthite megacrysts, which shows a systematic decrease from south to north in accordance with the Trench Volcano Gap. Since the megacrysts have virtually constant anorthite content, and accordingly, megacryst/melt partitioning is expected to be identical, the observed variation in the megacryst/host-rock partition coefficients indicates that some of the anorthite megacrysts are xenocrysts

It follows from the present data that the environment was favorable for anorthite megacrystallization within the magmatism under the island arc, regardless of differences in the host magma. After megacrystallization, these anorthites were incorporated as xenocrysts into a different magma in which strontium was not isotopically equilibrated. It seems reasonable to conclude that regional variations in tectonic settings of subduction zones resulted in differences in host magma between the anorthite megacrysts.

Gartrellite and other arsenates from Likas-kő, Velence Hills (Hungary)

Menyhárt, A.* & Szakáll, S.
Dept. of Mineralogy and Petrology, University of Miskolc, Hungary (*adrienn711@gmail.com)

At Likas-kő, Meleg Hill, Velence Hills, at the tectonic contact of the granite and contact schist a siliceous zone was formed. This siliceous zone contains enargite mineralization, which produced secondary arsenate minerals, like beudantite, cornubite, cornwallite, conichalcite. A greenish-yellow earthy aggregate is assumed to be gartrellite. Its ideal formula can be expressed as $PbCuFe(AsO_4)_2(OH,H_2O)_2$.

We performed electron microprobe spot analyses on several samples (greenish-yellow globular aggregates and greenish-yellow aggregates of small plates) which gave Pb, Cu, Fe, (Al)-arsenate compositions. The chemistry of 2 samples (seen on the pictures) in normalized weight percentage – average of 4 (sample 1) and 2 (sample 2) spot analyses – is shown in Table 1.

Table 1: Average composition of samples 1 and 2

	(1) wt%	(2) wt%
As_2O_5	44.42	41.84
PbO	28.99	26.94
CuO	16.85	20.52
Fe_2O_3	6.65	8.79
Al_2O_3	2.92	1.91

These analyses show more As_2O_5 and less PbO than the type material [1]. The total amount of cations thus does not correspond to the amount of As_2O_5.

Inside the aggregate of small plates (Fig. 1a) there is a Cu-arsenate mineral (cornubite; darker phase on Fig. 1a), which formed earlier than gartrellite. In contrast, on Fig. 1b gartrellite is surrounded by a Cu-arsenate (cornubite), and this is connected to malachite (the dark grey phase on the right side of Fig. 1b). Ba-pharmacosiderite also surrounds gartrellite. On another sample gartrellite is intergrown with a (Ca,Cu)-arsenate (probably conichalcite).

The X-ray powder diffraction pattern shows the reflections (d_{meas} and intensity) of gartrellite at 2.948 (100), 3.299 (83), 2.899 (81), 3.202 (73), 3.177 (61), 2.509 (66), 4.461 (37).

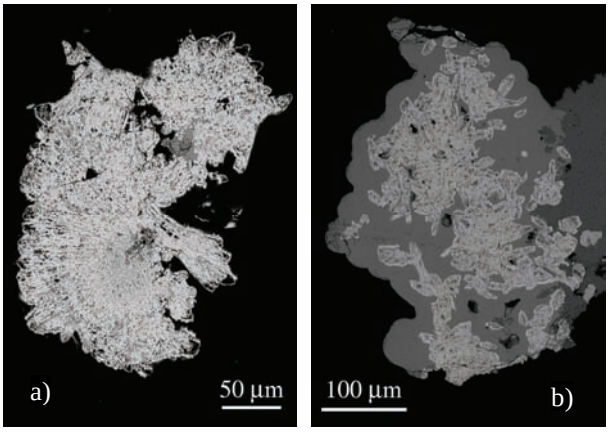

Fig. 1: a) SEM BSE image of sample (1); b) SEM BSE image of sample (2).

Mineralogical research of opals in Slovakia

Mesiarkinová, M.[1*]& Ozdín, D.[2]
[1]SOLIPHA – Laboratory of X-Ray Diffraction, Dept. of Mineralogy and Petrology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovak Republic (*mesiarkinova@fns.uniba.sk)
[2]Dept. of Mineralogy and Petrology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovak Republic

A lot of historical occurrences of opal exist in Slovakia. We identified samples from some of them, determined their structural ordering, chemical composition as well as the role of Fe in the structure of SiO_2 phases with several analytical methods (EMPA, Powder XRD, Mössbauer methods and DTA). Most of opals occur in volcanic tuffs mainly of andesitic composition. A part of opals, especially silicified woods, occurs in Neogene (Baden-Sarmat) sedimentary rocks. Opals on the localities Ľubietová-Jamešná and Tri Vody are formed on the contact of Triassic carbonates and Neogene andesites. As suggested by the study of opals on the locality Ľubietová – Jamešná and Tri Vody, samples originally regarded as opals are formed of grey to brown quartz with content of iron up to 0.25 at% and Fe oxides with content of Si up to 19.91 at% [1]. On the base of XRD and Mössbauer spectroscopy, Fe is trivalent and may be incorporated in minerals goethite and probably hisingerite. Textures of silicites/opalites are very complicated. Brecciated textures are composed of several types of matrix and veinlets (Fig. 1). We observed two distinct sequences of SiO_2 phases formed from fluids filling the voids in goethitic quartz,: 1 – forming of higher-temperature void fillings begin with the crystallization of jasper-like SiO_2 phase with banded texture and crystallization process finished with crystallic quartz; 2 – lower-temperature void fillings comprise following SiO_2 phases (from outer zone to inner zone): chalcedony (microcrystalline) → opal-CT (with banded texture) → opal-AN (collomorph hyalite).

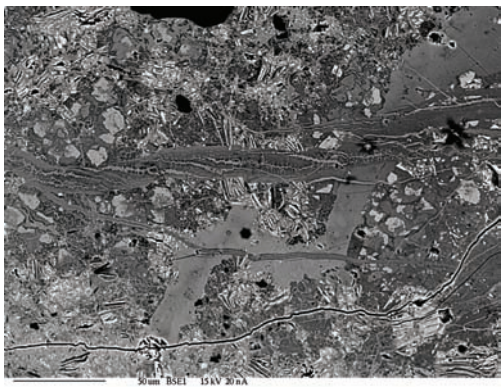

Fig. 1: Complicated brecciate texture of Fe-rich silicate (loc. Ľubietová).

Our XRD and EMPA research on silicified woods from several localities in Slovakia, previously described as wood opals, indicates that they are represented by: 1 - silicified or petrified trunks formed by α-quartz [2]; 2 - wood opals composed mostly of opal-CT and rarely of opal-AN (hyalite). Fossilized residues of plants and microbes in SiO_2 phases contain quartz and opal-CT according to XRD study.

Reinvestigation of "dognácskaite"

Papp, G.[1*] & Stanley, C.J.[2]
[1]Dept. of Mineralogy & Petrology, Hungarian Natural History Museum, Budapest, Hungary ([*]pappmin@ludens.elte.hu)
[2]Dept. of Mineralogy, The Natural History Museum, London, United Kingdom

"Dognácskaite" (hereinafter we omit parentheses for simplicity) is an invalid mineral species described originally in 1884 by Krenner [1], for a detailed research history see [2]. It is usually regarded as "a mixture of various sulfides" [3] but major reference works disagree about its exact mineral composition. This research was aimed at clarifying this open question.

Five specimens labelled dognácskaite from Dognecea (Caraş-Severin County, Banat, Romania) were studied by ore microscopy, SEM, EPMA, and XRPD methods during a systematic reinvestigation project of inadequately known minerals first described from the Carpathian region. One of the studied specimens is probably that used for the original description by József Krenner. Every specimen proved to be a mixture with a similar mineral composition and texture. The main component of dognácskaite is bismuthinite rimmed by wittichenite (containing strings of native bismuth), the latter is again rimmed by copper sulfides (mainly djurleite with some covellite). Emplectite can also be found occasionally in the larger voids of bismuthinite. Magnetite (sometimes martitized), chalcopyrite, bornite (replacing chalcopyrite), rare sphalerite and tetradymite form inclusions in bismuthinite or in the rims surrounding it. Goethite, calcite, bismuth ochre and other unspecified fine-grained alteration products are abundant in the voids. Data from earlier studies can easily be explained on the basis of this mineral assemblage, suggesting that every dognácskaite specimen is a mixture of this kind. The samples may correspond to a (pyrite-)magnetite-chalcopyrite skarn ore replaced by a post-skarn hydrothermal bismuthinite ore, later affected by supergene copper enrichment then by oxidation processes.

The exact locality of dognácskaite within the Ocna de Fier–Dognecea ore field cannot be determined but, based on an old museum label, one of the specimens studied was collected in the mine "Petri-Pauli" (or "Péter-Pál"), now "Petru şi Pavel" on Mt. Danilii. This fact implies that at least some of the specimens came from an area that is now included in the Ocna de Fier ore field (at the time of description it belonged to the Dognecea [in Hungarian Dognácska] ore field)

Preliminary data of oxidation kinetics of $Fe^{2+}Cr_2O_4$ synthetic spinel

Parisi, F., Lenaz, D.[*] & Princivalle, F.
Dept. of Geosciences, University of Trieste, Italy
([*]lenaz@units.it)

The spinel structure is based on a nearly ideal cubic close-packed array of oxygen atoms with tetrahedral (T) and octahedral (M) cavities. In common 2-3 spinels, one eighth of the T sites and one half of the M sites are occupied by heterovalent cations A and B in the ratio AB_2O_4. In general, spinels do not show this idealized configuration, with A cations in T sites and B cations in M sites. Commonly there exists octahedral-tetrahedral disorder of A and B cations depending on thermal history. Consequently, the crystal-chemistry of spinels is described by the general formula $^{IV}(A_{1-i}B_i)^{VI}(A_iB_{2-i})O_4$, where "i" refers to the inversion parameter. With increasing temperature, disorder takes place, i.e. A and B cations undergo increasing intersite exchange over the three cation sites per formula unit. Modifications of T-O and M-O bond distances to accommodate various chemical compositions and/or cation distributions determine variations in the oxygen positional parameter u and the cell edge a_0.

The aim of this study is the investigation of oxidation mechanism in $Fe^{2+}Cr_2O_4$ spinels previously synthesized using a flux-growth method and analyzed by single-crystal X-ray diffraction, electron microprobe, and optical absorption-, infrared-, and Mössbauer spectroscopies [1]. These analyses showed that iron occurs almost exclusively as $^{IV}Fe^{2+}$ while Cr is present as a trivalent cation in the octahedral site. It is to notice that the large excess octahedral crystal field stabilisation energy of Cr^{3+} should ensure that Cr-bearing spinels have an almost completely normal cation distribution [2]. Given that the M site is completely filled by Cr, and that Cr should not be oxidized in spinels, we would expect that heating affects only the iron cation present in the T site. Consequently, the only possible effect is the oxidation of Fe^{2+} to Fe^{3+} and the formation of vacancies following the mechanism proposed by [3].For our purposes the crystals were put in a thin-walled quartz tube and heated in a vertical tube furnace at 600, 700 and 800°C. Heating runs were performed at room pressure in air. Run temperatures were accurately measured and controlled by means of a calibrated Pt/Pt-Rh thermocouple located near the sample; the uncertainty is estimated to be about ± 5°C.

Preliminary results showed that after 30 days, the heatings at 600°C show very few changes with cell edge moving from 8.3754 (1) to 8.3745 (3) Å. Spinel heated at 700°C, after 13 days, show cell edge moving from 8.3761 (1) to 8.3737 (1) Å, and that heated at 800°C (2 days) from 8.3759 (1) to 8.3641 (2). It is to notice that $Fe^{2+}Cr_2O_4$ spinel heated at 600°C, where an exchange between the two sites was observed, showed after the same heating time a change in the cell edge from 8.1396 (1) to 8.0989 (6) Å [4], so that the presence of Cr, fully occupying the M site, may prevent large variations in the cell parameter.

Antiphase boundaries found in sillimanite phenocrysts in Tosu rhyolite (Japan)

Shimobayashi, N.
Dept. of Geology and Mineralogy, Graduate School of Science, Kyoto University, Kyoto, Japan (shimo@kueps.kyoto-u.ac.jp)

Al_2SiO_5 polymorphs (andalusite, sillimanite and kyanite) are of a great significance for mineralogists and petrologists because of their value as indicators of the pressures and temperatures of the rocks containing them. Of these three, sillimanite has Al-Si disorder because it contains both Al and Si in tetrahedral coordination. [1] suggested that the *dP*/*dT* slope of the kyanite-sillimanite equilibrium is affected by Al-Si disorder in the sillimanite. [2] implied the Al-Si disordering transformation in sillimanite at high temperature. The Al-Si disorder would result in a space group change from *Pbnm* to *Pbam*. However, the high-temerature form of sillimanite has not been established because the breakdown reaction sillimanite → mullite + SiO_2 and incongruent melting occur at high temperatures.

TEM investigation of sillimanite in Tosu rhyolite was carried out in the present study. Tosu rhyolite, characterized by containing a plenty of sillimanite phenocrysts (over 10% in modal per cent), is distributed only at a small hill (relative height: 5 m) in the western part of Tosu City, Kyushu, Japan. The sillimanite phenocrysts are perfectly euhedral and show a long prismatic shape (0.5 to 1.5 mm in length). No chemical zoning can be seen although their chemical compositions, $(Al_{2.01}Fe^{3+}_{0.02})_{\sum 2.03}Si_{0.98}O_5$ in average, are slightly Si-deficient from the ideal stoichiometric composition. Neither reaction rims surrounding them nor erosion texture can be observed. The sillimanite phenocrysts are assumed to crystallize directly from the magma at high temperature [3].

The present sillimanite specimens gave sharp *l*=odd reflections in electron diffraction patterns, the fact of which indicates that they have the Al-Si ordered *Pbnm* structure. However, features resembling APB's can be found in dark-field images only used with *l*=odd reflections (Fig. 1). The fact that these features cannot be seen in dark-field images with *l*=even reflections suggests that the displacement vector should be ***R***=1/2[001]. APB's in the natural sillimanite in absence of mullite are first found in the present study although [4] observed APB's in sillimanite porphyroblast of the Bergell tonalite, which coexists minute domains of mullite. As pointed out by [6], APDs with stacking vector of 1/2[001] would be expected to appear during an ordering transformation from *Pbam* to *Pbnm* in sillimanite. Therefore, the present observation of the APB's may suggest the natural occurrence of the high-temperature disordered sillimanite (*Pbam*).

Morphological varieties of cannonite from Nagybörzsöny (Hungary)

Szakáll, S.[1*], Fehér, B.[2], Kristály, F.[1] & Bigi, S.[3]
[1]Dept. of Mineralogy and Petrology, University of Miskolc, Hungary ([*]askszs@uni-miskolc.hu)
[2]Dept. of Mineralogy, Herman Ottó Museum, Miskolc, Hungary
[3]Dept. of Earth Sciences, University of Modena and Reggio Emilia, Modena, Italy

Nagybörzsöny is a Bi-Cu-As-(Au-Ag) meso-epithermal ore deposit in the Börzsöny Mts. (Hungary). The characteristic Bi minerals are bismuthinite, native bismuth and the members of cosalite-lillianite series. There are some secondary minerals in the cavities of bismuth ores. Among them the most widespread is cannonite – a rare monoclinic $Bi_2O(OH)_2(SO_4)$ phase. In close association with cannonite, native sulphur, gypsum, an unknown Bi-bearing mineral, and a non-crystalline Fe-Bi arsenate were identified.

In Nagybörzsöny four morphological types of cannonite were observed: 1) thick tabular crystals up to 20-30 μm in diameter; 2) lath-like crystals up to 50-60 μm in length (Fig. 1); 3) short prismatic crystals up to 100-120 μm in length; 4) globular aggregates consisting of lamellae up to 250-300 μm in diameter (Fig. 2).

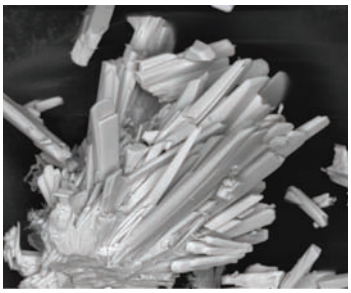

Fig. 1: Lath-like cannonite crystals (type 2) (width of the picture 120 μm).

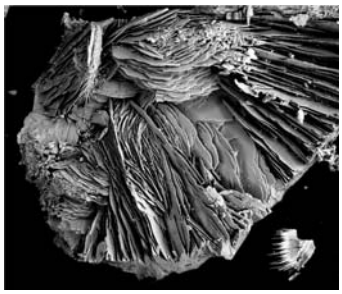

Fig. 2: Globular aggregate consisting of lamellae (type 4) (width of the picture 150 μm).

All the studied materials have been identified by X-ray powder diffraction. Cannonite is monoclinic with space group $P2_1/c$. The refined unit-cell parameters for type 2: a = 7.731(4) Å, b = 13.890(8) Å, c = 5.702(3) Å, β = 109.20(5)° are based on 32 reflections in the X-ray powder pattern obtained using a 114.6-mm Gandolfi camera. It has a cell volume of 578.2(4) $Å^3$ with Z = 4. Calculated density is 6.213 g/cm^3.

We performed some spot analyses on these materials by electron microprobe:

Average of 9 spot analyses for type 2: Bi_2O_3 78.97, Fe_2O_3 0.03, SO_3 15,42, H_2O (calc.) 3.26, Total 97.68 wt%. It corresponds to $Bi_{1.88}O(S_{1,06}O_4)(OH)_2$.

Average of 7 spot analyses for type 4: Bi_2O_3 78.96, Fe_2O_3 0.05, SO_3 15,36, H_2O (calc.) 3.25, Total 97.62 wt%. It corresponds to $Bi_{1.88}O(S_{1,06}O_4)(OH)_2$.

Low-temperature samarskite modification: structural relationship between pre-metamict and recrystallised structure

Tomašić, N.[1*], Bermanec, V.[1], Gajović, A.[2] & Čobić, A.[1]
[1]Institute of Mineralogy and Petrology, Faculty of Science, University of Zagreb, Croatia ([*]ntomasic@geol.pmf.hr)
[2]Ruđer Bošković Institute, Zagreb, Croatia

Previous investigations on samarskite proposed two structural modifications: low-temperature samarskite, being observed at temperatures up to 550°C, and high-temperature samarskite, which occurs at temperatures above 950°C [1]. A sample of samarskite-(Y) from Ampangabe, Madagascar, was investigated to trace relics of the original structure in metamict matrix and to relate them to the sample recrystallised in air at temperatures around 500°C.

Investigations performed by high-resolution electron microscopy (HRTEM) revealed occurrence of regions containing relics of pre-metamict structure. These relics were surrounded by amorphised mineral matrix (Fig. 1). Selected area electron diffraction (SAED) of these regions reveals an orthorhombic unit cell having following unit cell parameters: a = 5.66 (4) Å, b = 4.97 (2) Å, c = 5.28 (6) Å, V = 149 (2) Å^3.

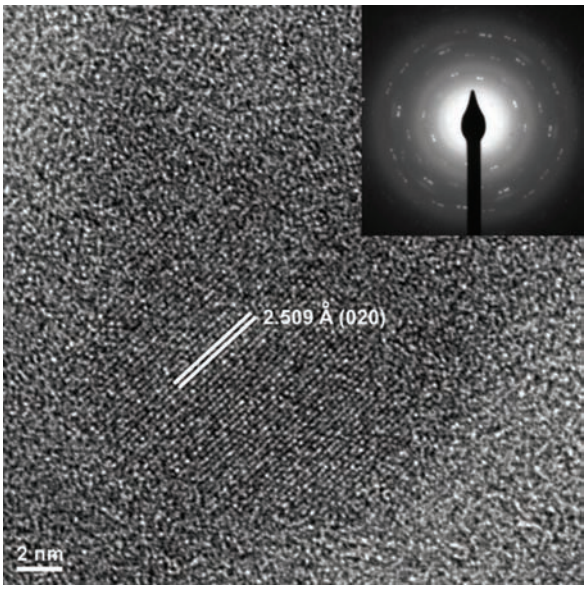

Fig. 1: HRTEM and SAED image (inset) of the thermally untreated samarskite-(Y) from Ampangabe, Madagascar.

X-ray diffraction (XRD) pattern of the thermally untreated sample is typical for heavily metamictised minerals. Four low-intensity diffraction maxima were observed that could be attributed to the low-temperature samarskite modification. X-ray diffraction pattern of the sample annealed at 500°C revealed mostly recrystallised low-temperature samarskite with an orthorhombic unit cell: a = 5.58 (2) Å, b = 4.92 (2) Å, c = 5.19 (2) Å, V = 142.3 (7) Å^3.

A comparison of HRTEM and XRD data indicates a structural relation of the preserved pre-metamict structure and the recrystallised mineral at 500 °C. This can be used as a prerequisite in a structure solution for samarskite samples.

Tennantite-tetrahedrite minerals from the Madan Pb-Zn deposits, Bulgaria

Vassileva, R. D.[*] & Atanassova, R.
Geological Institute, Bulgarian Academy of Sciences, Sofia Bulgaria ([*]rosivas@geology.bas.bg)

The minerals from the tennantite-tetrahedrite series are characteristic, though in subordinate quantities in the veins of the Madan Pb-Zn deposits, Central Rhodopes. Fahlore minerals are indicative for increased Sb and As in the late ore precipitating fluids. The behavior of these minerals in the hydrothermal deposits and mining sites could help in resolving some environmental issues.

Tennantite-tetrahedrites are formed in the late phases of the main quartz-sulphide stage with galena, sphalerite, pyrite and chalcopyrite. Representative samples are studied from the deposits of Petrovitsa, Gradishte and Strashimir. These minerals occur: 1) as single crystals and their aggregates overgrowing galena, pyrite and chalcopyrite. The tetrahedral crystals (1-3 mm) are shaped by *o* {111}, *d* {110}, *a* {100} and *n* {211}; 2) in close association with chalcopyrite and sphalerite, presented mainly as crusts, resembling the polyhedral sulphide crystals (Fig. 1). Oriented overgrowth of tetrahedrite on chalcopyrite (due to the similar structural motifs) and on galena with parallel mutual orientation (Gal (100) [100] // Td (001) [110]) occurs.

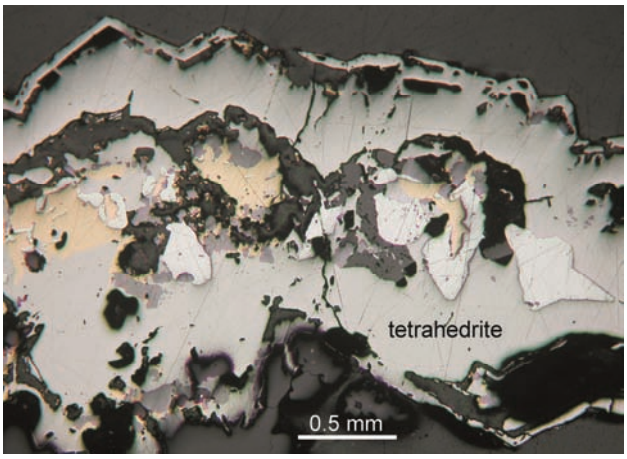

Fig. 1: Mineral relationships of tetrahedrite with main sulphides from the Petrovitsa deposit, reflected light.

The well-known variations in the chemical composition of tennantite-tetrahedrites (Cu-Ag, Zn-Fe and Sb-As) and trace-element distribution are determined by EPMA, ICP-AES, LA-ICP-MS. A considerable increase in the Zn-content in most samples is registered (up to 7.08 wt. %), and insignificant Fe-content (always less than 0.80 wt. %). Silver reaches 1.40 wt. % in several tetrahedrites. Some amount of Mn, Hg, Bi, Se, and Cd traces are revealed as well. The mean crystallochemical formulae calculated on the basis of 29 apfu are:

Petrovitsa $(Cu_{9.72}Zn_{1.73}Ag_{0.18}Fe_{0.15})_{11.78}(Sb_{3.69}As_{0.99})_{4.68}S_{12.54}$
Gradishte $(Cu_{9.58}Zn_{1.57}Fe_{0.19})_{11.34}(Sb_{0.90}As_{3.74})_{4.64}S_{13.02}$
Strashimir $(Cu_{10.35}Zn_{1.46}Fe_{0.59})_{12.40}(Sb_{2.33}As_{1.72})_{4.05}S_{12.55}$.

All studied minerals belong to the zincian members of the tennantite-tertrahedrite group.

The increased Zn-content reflects in the unit cell parameter *a* 10.37(8) Å of Petrovitsa tetrahedrite, determined by data from XRD. The chemical variations in tennantite-tetrahedrite minerals correspond to the geochemical specialization of the Madan Pb-Zn deposits.

Johannsenite-rhodonite replacement in the base metal deposits, Central Rhodopes, Bulgaria

Vassileva, R.D.
Geological Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria (rosivas@geology.bas.bg)

Pyroxenoids are major constituent of the retrograde stage of alteration of manganoan skarns [1] in the replacement ore bodies in the Central Rhodopean Pb-Zn deposits (Madan, Laki districts and Enyovche deposit), South Bulgaria. The radiate and sperulitic aggregates of the primary skarn clinopyroxenes belong to the Mn-enriched members of hedenbergite-johannsenite series.

Extensively distributed, though subordinate, rhodonite is among the wide spread alteration products after johannsenite. In Madan deposits it occurs as: 1) oriented epitactic and topotactic overgrowths and replacements after the pyroxene crystals; or 2) massive, 1-2 cm narrow zone along the pyroxene-marble replacement front, without any orientation to the primary pyroxene, and considered as reprecipitated after partial natural dissolution of the earlier pyroxene.

The complete reaction of alteration from johannsenite to rhodonite according to [2] occurs stepwise. The intermediate products are found to have increased Ca content in their structure, in studied case 9-10, reaching up to 12 wt.% CaO, corresponding to ~1/5 of octahedral sites in rhodonite structure. The pyroxenoids show structural orientation to the direction of pyroxene chains $[110]_{px}$// $[100]_{rdn}$ at 52°. Products of johannsenite-rhodonite reaction are observed as: i) small crystals epitaxically overgrowing the pyroxene prismatic faces or forming nests together with calcite (Fig. 1a); ii) as interstitial radial grains in the pyroxene aggregates; iii) as fine-lamellar intergrowths, observed also by [3], replacing topotaxically the johannsenite prismatic crystals (Fig. 1b). The replacement takes place initially along the grain boundaries, and later - thoroughly, forming radiating rhodonite pseudomorphs after johannsenite. The reaction mechanisms include: 1) topotactic solid-state replacement with cation re-arrangement and inheritance of the O-stacking; 2) epitactic overgrowth of rhodonite crystals with reconstructive reprecipitation of material on preliminary oriented nuclei. The mutual orientation in both cases is equal. Substantial transfer and reprecipitation of material in second case is connected with more liberated open space after dissolution.

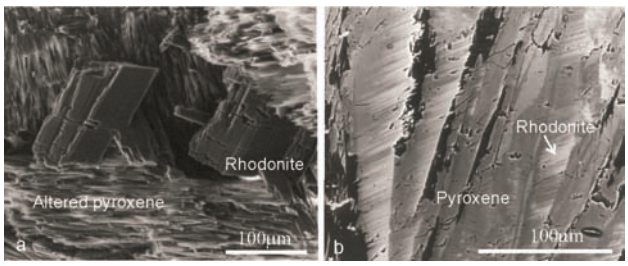

Fig. 1: Epitactic (a) and topotactic (b) replacement of johanssenite from rhodonite.

Acknowledgements: The study is supported by 2009-2010 Scholarship by World Federation of Scientists and SCOPES IZ73Z0-128089 project of the Swiss Science Fund.

Zirconolite family minerals in the alumina-rich fenites of the Khibiny alkaline complex (Kola Peninsula, Russia)

Yakovleva, O.S.* & Pekov, I.V.
Geological Faculty, Moscow State University, Moscow, Russia (*ya_olik@mail.ru)

Zirconolite, ideally $CaZrTi_2O_7$, known in several natural modifications (2*M*, 3*O*, 3*T*), is common accessory mineral in the fenites formed after xenoliths of alumina-rich rocks in the Khibiny alkaliny complex, Kola Peninsula, Russia. Zirconolite occurs there in the rocks mainly composed by alkali feldspars, typically with nepheline. Other common associated minerals are hercynite, ilmenite and zircon. Corundum, sodalite, rutile, biotite, crichtonite, sekaninaite, Ti-rich magnetite, freudenbergite, dawsonite, fayalite, baddeleyite, srilankite, *etc*. are also found there. Zirconolite forms equant or elongate crystals (up to 0.5 mm) and rims around zircon and baddeleyite grains. Zirconolite-like minerals with prevalence of *REE* (with Ce-, Nd- or Y-maximum) or Na over Ca in the large-cation site are also typical in the alumina-rich fenites at Khibiny. These minerals and zirconolite form continuous solid-solution system and can be united in the zirconolite family. The major schemes of substitutions in this family are: $2Ti^{4+} \rightarrow Nb^{5+} + Fe^{3+}$; $2Ca^{2+} \rightarrow REE^{3+} + Na^{+}$; $Ca^{2+} + (Th,U)^{4+} \rightarrow 2REE^{3+}$; $Ca^{2+} + Ti^{4+} \rightarrow REE^{3+} + Fe^{3+}$. Other possible schemes are: $Ca^{2+} + O^{2-} \rightarrow Na^{+} + (OH)^{-}$; $Zr^{4+} + Ti^{4+} \rightarrow Nb^{5+} + Fe^{3+}$; $2Ca^{2+} \rightarrow (Th,U)^{4+} + {}^{0}$. Typical feature of all zirconolite-like minerals is strong affinity to Nd (all analyses show Nd > La). Having also significant affinity to Ca, they are typically the only concentrators of this element in some kinds of the alumina-rich fenites at Khibiny. Thus, appearance of zirconolite analogues with prevalence of *REE* or Na over Ca indicates strong deficiency of Ca in the mineral-forming systems. In some rocks, zirconolite replaces zircon. Such evolution of mineral form of Zr, from silicate to oxide, shows decrease of silica activity during the formation of the Khibiny alumina-rich fenites. Generally, presence of *REE*- or Na-analogues of zirconolite can be considered as an indicator of both low silica activity and deficiency of Ca in natural alkaline systems.

Is the study of crystal morphology really old-fashioned?

Zebec, V.[1], Bermanec, V.[2*] & Čobić, A.[2]
[1]Croatian Natural History Museum, Zagreb, Croatia
[2]Faculty of Science, Institute of Mineralogy and Petrology, University of Zagreb, Croatia ([*]vberman@public.carnet.hr)

In 1998, at the 17th General Meeting of IMA in Toronto, one of the goals was to encourage further studies of crystal morphology and its relation to growth conditions, as a part of mineralogical investigations in the 21st century.

What is the purpose of these morphological studies?

This kind of investigation has irreplaceable value for a better understanding of crystals and crystal growth. The explanation of this is presented by some examples.

1. By investigating morphology, one can study morphogenesis. For example, studies of barite and calcite from Krapinske toplice thermal spring in Hrvatsko Zagorje, Croatia, where six generations of barite (Fig. 1) were investigated in order to determine crystal genesis [1].

2. Oriented coalescence is practically impossible to study in any other way but via morphological studies. Several oriented coalescences are described on minerals from Stari Trg - Trepča mine, Kosovo [2-4].

3. Parallel-perspective drawings of crystals in addition with growth prints on crystal faces make possible the orientation of crystals. Very good examples of this are measurements of epidote crystals from Smilevski dol near Dunje in Macedonia [5].

4. Using morphological measurements one should be in a position to acquire axis ratio which is the basic information about a crystal [5].

Rhodonite group mineral from Morro da Mina mine, Conselheiro Lafaiete, Minas Gerais, Brazil

Žigovečki Gobac, Ž.[1*], Scholz, R.[2] & Bermanec, V.[1]
[1]Inst. of Mineralogy and Petrology, Faculty of Science, University of Zagreb, Croatia ([*]zeljkaz@geol.pmf.hr)
[2]Faculty of Engineering, University of Minas Gerais State, João Monlevade, Brazil

Deep pink to red, transparent tabular crystals of gem quality were collected at Morro da Mina mine, located in the city of Conselheiro Lafaiete, 115 km south from Belo Horizonte, the capital city of Minas Gerais state, Brazil.

The manganese deposits of Morro da Mina are hosted in a metavolcanosedimentary sequence of Archean age, cutted by granodioritic bodies. The regional and contact metamorphism and a sequence of hydrothermal events produced a complex mineralogy, including Mn-bearing minerals rhodonite, pyroxmangite, spessartite and others [4].

According to similar physical properties, the sample was erroneously assumed to be rhodonite. Subsequent X-ray powder diffraction analysis (using CuKα radiation) identified the sample as a mineral belonging to the p-p (pectolite-pyroxene) isostructural series of pyroxenoides, most probably natronambulite.

Crystal structure of investigated minerals belonging to p-p isostructural series of pyroxenoides [5], including nambulite, natronambulite, marsturite and lithiomarsturite, although similar, differs from those of rhodonite [3], which belongs to the w-p (wollastonite-pyroxene) isostructural series. The differences in their structures are reflected in X-ray diffraction pattern (Fig. 1), helping their identification.

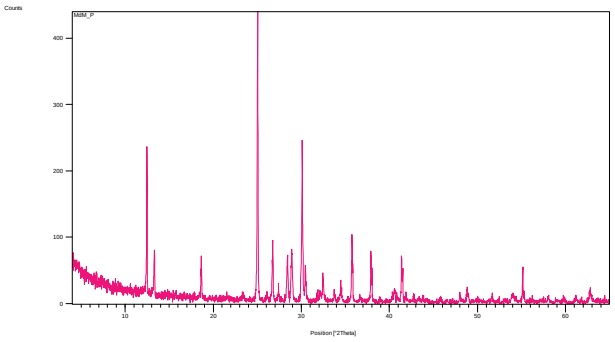

Fig. 1: XRD pattern of the sample from Morro da Mina mine.

Further investigation of chemical composition, particularly possible Na, Li, Ca and Mg presence, will help to distinguish mineral member of p-p isostructural series of pyroxenoides [1].

This is the first report of a mineral belonging to this isostructural series from this locality. So far nambulite and natronambulite have been recorded in various localities, including Japan [1,7], Namibia [6] and India [2], all in the metamorphosed manganese ore deposits.

Structural complexities of natural and synthetic perovskites

Mitchell, R.H.
Dept. of Geology, Lakehead University, Thunder Bay, Ontario, Canada (rmitchel@lakeheadu.ca)

The structural hierachy of perovskite group compounds as derived from group theory and experimental data is briefly described together with the classification of naturally occurring perovskite-structured oxide, fluoride, hydroxide, and silicate minerals. Aspects of the structure and compositional variation of the quaternary solid solution series perovskite-loparite-lueshite-tausonite are described.

The crystal structures $(CaTiO_3)_{50}(SrTiO_3)_{50}$ and Sr_2CrTaO_6 are described to illustrate some of the experimental problems in the determination of simple perovskite structures by X-ray and neutron diffraction.

Neutron and X-ray diffraction data are presented for the system $CaTiO_3$ - $Ca_4Nb_4O_{14}$ to illustrate how Nb is incorporated into latrappite [(Ca,Na)(Nb,Fe,Ti)O_3]. These data show the limit of solubility of Nb in $CaTiO_3$ is 16 wt.% Nb_2O_5 and that increasing amounts of Nb result in the formation of layered perovskites belonging to the $A_nB_nO_{3n+2}$ series with the general formula $Ca_n(Ti_{n-x}Nb_x)O_{3n+0.5x}$. These adopt the space groups $Cmc2_1$, $Pnn2$, and $Pbn2_1$ for the n = 6, 5, and 4 compounds, respectively.

The structure of lueshite [(Na,Ca)(Nb, Ti)O_3] is shown not to be identical to that of synthetic $NaNbO_3$. Single crystal XRD data suggests that lueshite adopts the space group *Pbmn* at room temperature. However, these data are not corroborated by powder XRD (Rietveld) or high resolution time-of-flight neutron diffraction (GSAS). Lueshite, in common with synthetic $NaNbO_3$ undergoes a series of structural phase transtions from *Pm*3*m* through I4/*mcm* to *Cmcm* from high to low termperature. However, the room temperature structure of lueshite remains ambiguous, due to pinning of the higher temperature *Cmcm* structure and/or failure of even high resolution neutron diffraction to resolve possible orthorhombic or monoclinic structures.

Perovskite and post-perovskite in Earth's lower mantle

Hirose, K.*, Sinmyo, R. & Ohta, K.
Dept. of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan (*kei@geo.titch.ac.jp)

A phase transition from $MgSiO_3$ perovskite to post-perovskite occurs above ~120 GPa at 2500 K corresponding to about 2600 km depth from the surface, which has significant implications for the nature and dynamics in the lowermost mantle. Post-perovskite has a layer stacking crystal structure with density higher than that of perovskite by about 1%. The changes in elastic properties and the large Clapeyron slope, about four times larger than those of upper mantle phase changes, explains the abrupt shear wave velocity jump at the D" seismic discontinuity and its rich topography. In addition, thermal and electrical conductivities, viscosity, and diffusivity can all vary greatly across the perovskite to post-perovskite phase transition. We report our recent measurements of such transport properties at high pressure in a diamond-anvil cell. These lower mantle transport properties are fundamental to heat transport and thermal evolution, electromagnetic core-mantle coupling, chemical heterogeneity and dynamical properties of the deep mantle.

The valence state and spin state of iron can be also different between perovskite and post-perovskite. Al-bearing (Mg,Fe)SiO_3 perovskite is known to include substantial amount of Fe^{3+}. Our recent electron energy-loss near-edge structure (ELNES) spectroscopy measurements demonstrate that the $Fe^{3+}/\Sigma Fe$ ratio in Al-bearing post-perovskite depends on the oxygen fugacity but does not increase with increasing Al content, which is in remarkable contrast to the case of perovskite. This suggests that upon perovskite to post-perovskite phase transition, Fe^{3+} in perovskite and coexisting metallic iron recombine to form Fe^{2+}. Since Fe^{2+} partitions preferentially into (Mg,Fe)O ferropericlase, post-perovskite should be depleted in iron compared to perovskite. This is consistent with our previous report on crystal chemistry change in a pyrolitic mantle across the post-perovskite phase transition [1]. Such a marked change in the valence state of iron and resultant redistribution of iron has broad implications for the seismic and transport properties in the lowermost mantle. The phase transition from perovskite to Fe-depleted post-perovskite can occur in relatively narrow pressure range of about 5 GPa [2], although seismology suggests even sharper seismic discontinuity.

Iron in mantle silicate perovskite

Shim, S.-H.[1*], Grocholski, B.[1], Catalli, K.[1], Sturhahn, W.[2] & Prakapenka, V.[3]
[1]Massachusetts Institute of Technology, Cambridge, USA
([*]sangshim@mit.edu)
[2]Argonne National Laboratory, Argonne, IL, USA
[3]University of Chicago, USA

Magnesium silicate in the perovskite structure may be the most abundant mineral in the Earth as it represents 70% of the most voluminous layer, the lower mantle. Therefore, its properties are fundamental to understand the physical and chemical processes in the lower mantle.

Iron is the most dominant transition metal cation in mantle silicate perovskite (Pv) and undergoes changes in the spin and valence states at the pressure-temperature conditions relevant to the lower mantle [1,2]. However, the effects of its different spin and valence states on the properties of Pv have not been well understood.

We have synthesized Pv samples with iron dominantly in Fe^{2+}, all iron in Fe^{3+}, and iron in Fe^{3+} combined with Al^{3+} in the diamond-anvil cell at 50 GPa and 2000 K, in order to isolate the effects of different valence states [3-7]. We also synthesized Pv with realistic amounts of Fe and Al for the lower mantle under the appropriate redox condition for the region, in order to measure the content of Fe^{3+} [4,7]. The valence and spin states were measured using Mössbauer spectroscopy (Sector 3 of Advanced Photon Source, USA) and their effects on the crystal structure of Pv were measured using X-ray diffraction (GSECARS of Advanced Photon Source) up to 100 GPa. The measurements were conducted under quasi-hydrostatic stress conditions.

We found that Fe^{2+} remains high spin to at least 70 GPa. We observed the high quadrupole-splitting site that was previously assigned to the intermediate spin state [8,9]. Because a similar value was also found in garnet at 1 bar, we favor an interpretation of the high quadrupole-splitting site as high spin Fe^{2+}. Fe^{2+} decreases the distortion in the unit cell of Pv and expands the unit cell throughout the lower mantle. However, Fe^{2+} does not change the compressibility of Pv.

We found that Fe^{3+} undergoes a high-spin to low-spin transition at 0-55 GPa in an Al-free system [5] and 70-80 GPa in an Al-bearing system [6]. The spin transition is likely limited to Fe^{3+} in the octahedral site of Pv. In both Al-free and Al-bearing systems, Fe^{3+} increases the compressibility of Pv. In the Al-free system, Fe^{3+} expands the unit cell of Pv throughout the lower mantle. In the Al-bearing system, Fe^{3+} collapses the volume to that of Mg-end member Pv. The Al dependence is likely due to Al-Fe^{3+} site mixing.

Under reducing oxygen fugacity and quasi-hydrostatic stress conditions, we found that iron is dominantly in Fe^{2+} in aluminous Pv at pressures of the deep lower mantle. This is in sharp contrast with an earlier low-pressure study that reported as much as 60% of iron is Fe^{3+} [2]. Our new results may have important implications for the oxygen fugacity and transport properties of the lower mantle.

[4]GSECARS, University of Chicago, Argonne, USA
[5]European Synchrotron Radiation Facility, Grenoble, France

The remarkable ability of the perovskite structure to accommodate widely varying sizes of cations and anions through angular distortions and a strong tolerance for non-stoichiometry leads to a wealth of interesting and useful properties, as well as the capability to incorporate more than half of the elements of the periodic table. In the dominant chemical system of the Earth's mantle, MgO-SiO_2-Al_2O_3-FeO-Fe_2O_3, the perovskite structure is the most stable host over a wide range of pressure and temperature conditions, constituting up to 80% of the lower mantle. The ability of iron to adopt multiple valences and spin states can drastically change the physical and chemical properties of lower mantle perovskite from those of the endmember composition $MgSiO_3$, which can have significant implications for the modelling of lower mantle properties and dynamics. Iron occurs as both Fe^{2+} and Fe^{3+}, where the latter is expected to predominate in lower mantle perovskite compositions due to the stabilising influence of Al^{3+} on Fe^{3+} [1], even under reducing conditions. Spin transitions are possible in both Fe^{2+} and Fe^{3+}, and a number of controversial results have been reported, including the discovery of the unusual intermediate spin state of Fe^{2+} (four paired and two unpaired 3*d* electrons), which appears to be stable over pressure and temperature conditions covering the bulk of the lower mantle [2,3].

In order to resolve existing controversies and to assess the implications of different valence states and spin transitions in silicate perovskite on the properties of the lower mantle, it is necessary to conduct *in situ* studies on relevant perovskite compositions at high pressure and high temperature conditions. Nuclear resonance methods offer a unique opportunity for studying both the electronic and dynamic properties of iron compounds, and include laboratory-based methods such as Mössbauer spectroscopy, and synchrotron-based methods such as nuclear forward scattering (NFS) which allows the measurement of hyperfine parameters complementary to Mössbauer spectroscopy, and nuclear inelastic scattering (NIS) which allows the determination of elastic wave velocities for direct comparison with bulk geophysical data.

We will report recent results using a new approach to conduct nuclear resonance experiments in the diamond anvil cell with a portable laser heating system. These results include the measurement of elastic wave velocities in iron-bearing silicate perovskite using NIS, coupled with NFS to determine spin populations. We will discuss our results in the context of other studies on iron-bearing silicate perovskite using complementary methods, and explore their implications for the structure and properties of the lower mantle.

Stability of mantle silicate in Super-earths: insights from a high-pressure study of neighborite

Grocholski, B.[1*], Shim, S.-H.[1] & Prakapenka, V.[2]
[1]Massachusetts Institute of Technology, Cambridge, USA
([*]brent_g@mit.edu)
[2]University of Chicago, USA

The Clapeyron slope of a phase transition has important implications on the thermal evolution of planets. For instance, in the Earth a negative Clapeyron slope of the ringwoodite to perovskite + ferropericlase boundary at 660-km depth behaves as a permeable barrier for thermal mantle flow [1]. Newly discovered Super-earth type extrasolar planets have brought up questions about their mantle structure and the stability of magnesium silicates at the extreme high pressures in these objects.

Computer simulations by [2] indicate a breakdown of $MgSiO_3$ into MgO + SiO_2 at a pressure achieved in the interior of 10 earth-mass Super-earths (~1000 GPa). They predict a strongly negative Clapeyron slope that would make the boundary impermeable for thermal mantle flow, allowing for an oxide-rich stratified deep mantle.

Our current static compression techniques are not capable of reaching the relevant pressure conditions of Super-earth to assess the stability of the silicate phase. However, we can investigate analog materials, which undergo the same sequence of phase transitions as mantle silicates but at much lower pressures. Umemoto et al. (2006) [3] predicted that mineral neighborite $NaMgF_3$ ($MgSiO_3$ analog) dissociates into NaF (MgO analog) and MgF_2 (SiO_2 analog) at 40 GPa which is readily obtained using the diamond cell. Neighborite has orthorhombic perovskite structure and undergoes a transition to post-perovskite (at 15-20 GPa), similar to mantle silicate perovskite.

We have conducted in situ X-ray diffraction measurements on neighborite and MgF_2 in the laser-heated diamond-anvil cell at the GSECARS sector of Advanced Photon Source. The samples were loaded with an Ar medium, which provides thermal insulation and quasi-hydrostatic stress conditions. We do not observe the breakdown of $NaMgF_3$ up to 70 GPa and 2500 K, much higher than the predicted breakdown pressure. Diffraction patterns can be indexed as a combination of the perovskite and post-perovskite structures with some residual NaF from the starting material. Notably, we did not observe any diffraction intensity at the angle where the most intense diffraction line from MgF_2 would appear. The absence of the 100% line of MgF_2 is unambiguous evidence for the stability of $NaMgF_3$ against decomposition at pressures at least up to 70 GPa.

In the computational simulations, the primary driving force for the breakdown is a large decrease in volume at a phase transition in SiO_2 and MgF_2 from the pyrite-type to cotunnite-type. We find a new phase of MgF_2 whose stability field exists between these two structures. This new phase appears to be one (or more) of the several possible distorted pyrite types with seven-fold coordination. SiO_2 likely has a similar high pressure phase, expanding the stability field of $MgSiO_3$ to pressures in excess of those found in the rocky mantle fraction of Super-earths.

Our experimental results suggest that mantle silicates are stable to the highest pressures found in rocky planets of all sizes. The implication of this finding is that the mantles of Super-earths may not have phase boundary which would behave as a barrier for the mantle convection.

New empirical constraints on the capability of perovskite to sequester and fractionate trace elements

Chakhmouradian, A.R.[1*], Kamenetsky, V.[2], Reguir, E.P.[1], Zaitsev, A.N.[3], Golovin, A.V.[4] & Sharygin, V.V.[4]
[1]Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada ([*]chakhmou@cc.umanitoba.ca)
[2]School of Earth Sciences, University of Tasmania, Hobart, Australia
[3]Dept. of Mineralogy, St. Petersburg State University, St. Petersburg, Russia
[4]V.S. Sobolev Inst. of Geology and Mineralogy, Russian Academy of Sciences (Siberian Branch), Novosibirsk, Russia

Although perovskite sensu stricto ($CaTiO_3$) is universally recognized as one of the principal repositories for a variety of incompatible elements in undersaturated rocks and is widely used in isotopic chronological and provenance studies, we still know very little about the partitioning of trace elements between this mineral and magmas, or even about the extent of substitution of Ca and Ti by cations of different valence [1,2]. The well-characterized structural parameters of perovskite and zoning patterns observed in natural samples are not consistent with some of the partitioning data available for this mineral in the literature. In this work, we examined the extent of compositional variation in perovskite from several different types of igneous rock (including kimberlites, carbonatites, ijolites, clinopyroxenites, olivinite, melilitolite and katungite) using electron-microprobe analysis and laser-ablation ICP-MS. In contrast to the published work, our data show that the Rb and Ba contents in this mineral do not exceed 1.5 and 120 ppm, respectively, whereas Cs was not detected in any of the samples (i.e. << 1 ppm). With respect to their calculated partition coefficients, the examined trace elements can be grouped into four categories: strongly incompatible with $^{Prv/L}D$ << 0.1 (Zn, Ba, Rb, Cs); moderately incompatible with $^{Prv/L}D$ = 0.1-0.5 (Mn, Al, Cr); moderately compatible (Sr, Sc, V, Fe) and strongly compatible with $^{Prv/L}D$ > 10 (Y, REE, Th, U, Zr, Hf, Nb, Ta). In agreement with the published data [1,2], light lanthanides (with a peak at Nd) are much more compatible than heavy REE or Y. There is surprisingly little variation in Y/Ho ratio, which is consistently subchondritic (11.5-18.5) in both primary perovskite and that equilibrated with subsolidus fluids. These data indicate that the so-called non-CHARAC partitioning of Y and Ho is not restricted to fluid-rich systems [3] and may result from fractionation of perovskite (and possibly other minerals) in magmatic systems. The composition of perovskite from primitive mantle-derived rocks also indicates that it is a very effective vehicle of Zr-Hf, Th-U and Nb-Ta decoupling. However, some samples from carbonatites and ijolites show anomalously low Th/U ratios (< 3), possibly resulting from preferential partitioning of Th into an as yet unidentified phase or phases.

Megawite $CaSnO_3$ – a new mineral of the perovskite group

Galuskin, E.V.[1*], Galuskina, I.O.[1], Gazeev, V.M.[2], Dzierżanowski, P.[3], Prusik, K.[4], Pertsev, N.N.[2], Zadov, A.E.[5] & Gurbanov, A.G.[2]

[3]Inst. of Geochemistry, Mineralogy and Petrology, University of Warsaw, Poland

[4]Inst. of Materials Science, University of Silesia, Katowice Poland

[5]OOO Science-Research Center NEOCHEM, Moscow, Russia

Megawite [a = 5.56, b = 5.71, c = 7.94 Å, *Pbnm*) with end-member formula $CaSnO_3$ was discovered in an altered carbonate xenolith in the Upper Chegem caldera, Kabardino-Balkaria, Northern Caucasus, Russia [1]. Associated minerals are spurrite, reinhardbraunsite, rondorfite, wadalite, srebrodolskite, lakargiite, perovskite, kimzeyite, periclase, fluor- and hydroxylellestadite, while secondary minerals are brucite, ettringite-group minerals, afwillite, hydrocalumite and hydrogrossular. The formation of megawite is connected to high-temperature contact metamorphism of carbonate xenoliths within diatreme-facies ignimbrites of Pliocene age (2.8 Ma) under larnite-facies conditions (temperatures > 800ºC and low pressures). Megawite is usually represented by a Zr-bearing variety and commonly occurs together with lakargiite, $CaZrO_3$ [2] (Fig. 1). Investigation of the megawite-lakargiite natural solid solution suggests the existence of a continuous series from pure lakargiite to megawite with 60 mol.% $CaSnO_3$ end-member. High contents of Ti (up to 17 wt.% TiO_2) and U (up to 10 wt.% UO_3), characteristic of lakargiite, are not noted for megawite. Raman spectra of lakargiite and megawite are similar, so for identification of these minerals it is necessary to measure their composition (Fig. 1).

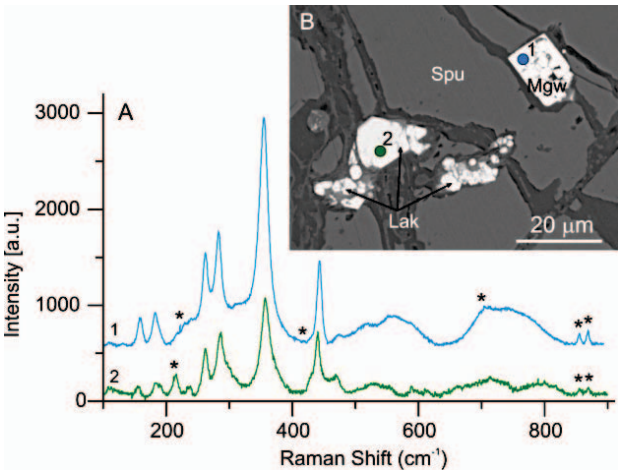

Fig. 1: A: Raman spectra of Zr-rich megawite (1) and Sn-rich lakargiite (2); B: Sn-rich lakargiite (Lak) and Zr-rich megawite (Mgw) in spurrite (Spu). Points of microprobe analyses are shown [1- $Ca(Sn_{0.58}Zr_{0.34}Ti_{0.07}Fe^{3+}_{0.01})_{\Sigma1}O_3$; 2 - $Ca(Zr_{0.68}Sn_{0.28}Ti_{0.02}Fe^{3+}_{0.02})_{\Sigma1}O_{2.99}$] and the Raman spectra were obtained at the same points (* - impurity of spurrite).

The name megawite honors the crystallographer Dr. Helen Dick Megaw (1907–2002), who pioneered the structural studies of perovskites [3].

The perovskite-brownmillerite series: perspectives for temperature estimation in Ca-rich pyrometamorphic rocks

Sharygin, V.V.

V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (sharygin@uiggm.nsc.ru)

Synthetic compounds from the $CaTiO_3$-$Ca(Fe,Al)_2O_5$ series have been extensively studied since 1960-70s, and several polymorphs of perovskite $CaTi_{1-x}Fe_xO_{3-x/2}$ ($0 \le x \le 0.5$), two polymorphs of $Ca_2(Fe_{1-x}Al_x)_2O_5$ ($0 \le x \le 0.67$), $Ca_4Ti_2Fe_2O_{11}$, $Ca_3TiFe_2O_8$ and $Ca_5TiFe_2Al_2O_{13}$ have been recognized [1-4]. Natural analogues of all these phases, sometimes enriched in Al and Si, have already been discovered. If pure perovskite is a common mineral in diverse rocks from skarns to kimberlites, the occurrence of other Fe-Ti-phases is limited to Ca-rich pyrometamorhic rocks (larnite rocks, melilite-bearing paralavas and hornfels in combustion metamorphic complexes; metacarbonate xenoliths in alkali basalts; skarn-like rocks in siliceous volcanics) [5-8]. It is not always possible to reliably constrain the crystallization temperature of these rocks on the basis of their mineralogy. For example, larnite rocks of the Hatrurim Formation (Dead Sea region) are considered as high-temperature products of solid-state reactions during combustion metamorphism, and their mineral associations are stable in a wide temperature range (900-1200°C).

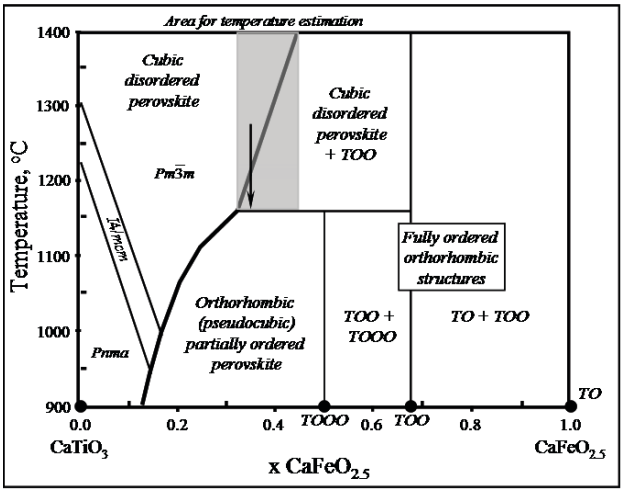

Fig. 1: Phase diagram for the system $CaTiO_3$–$CaFeO_{2.5}$ after [4-5]. TO - $Ca_2Fe_2O_5$; TOO - $Ca_3TiFe_2O_8$; TOOO - $Ca_4Ti_2Fe_2O_{11}$. Arrow shows a possible cooling trend for the Fe-perovskite + $Ca_3Ti(Fe,Al)_2O_8$ association in the Hatrurim Basin larnite rocks.

Analysis of the phase diagram $CaTiO_3$–$CaFe_2O_5$ shows that the coexistence of Fe-perovskite and $Ca_3TiFe_2O_8$ may be used for temperature estimation, whereas the brownmillerite - $Ca_3TiFe_2O_8$ pair is non-informative for temperature evaluation (Fig. 1). According to this phase diagram, the Fe-perovskite - $Ca_3Ti(Fe,Al)_2O_8$ association implies the minimum formation temperature for some Hatrurim larnite rocks as 1170-1200°C [5]. This paragenesis can serve as a new thermometer for metacarbonate rocks of the high-temperature region of the spurrite-merwinite facies.

Non-stoichiometry in perovskites: the role of "surplus" oxygen

Chakhmouradian, A.R.[1*] & Mitchell, R.H.[2]
[1]Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada ([*]chakhmou@cc.umanitoba.ca)
[2]Dept. of Geology, Lakehead University, Thunder Bay, Ontario, Canada

Oxide minerals commonly contain an excess amount of high-charged cations that is not compensated by any coupled substitutions in the cation sites and can only be explained by the uptake of additional oxygen [1,2]. Among minerals, one of the most extreme cases of this type of substitution is Nb-rich perovskite and latrappite (Ca,Na)(Nb,Ti,Fe)O_3, where "surplus" Nb cannot be accounted for by the substitutions $NaNb(CaTi)_{-1}$ or $NbFe^{3+}(Ti)_{-2}$ and is conventionally assigned to the hypothetical end-member $Ca_4Nb_4O_{14}$ (CN). Unlike perovskite, this compound has a layered structure, which can be interpreted as a stacking of perovskite-like slabs four NbO_6 octahedra thick and related to one another by ½[011] crystallographic shears [3,4]. The inter-slab spacings allow for the accommodation of more oxygen atoms in $Ca_4Nb_4O_{14}$ relative to perovskite ($4 \times CaTiO_3 = Ca_4Ti_4O_{12}$). We investigated limits of solubility between the $CaTiO_3$ (CT) and $Ca_4Nb_4O_{14}$ (CN) end-members using synthetic samples obtained by sintering of bulk compositions containing 20, 40, 60, 80 and 100 mol% CN (CN-20...100), i.e. fitting the general formula $Ca_n(Ti^{4+}_{n-x}Nb^{5+}_x)O_{3n+0.5x}$. The synthesis products were characterized by scanning and transmission electron microscopy, electron-microprobe analysis and X-ray powder diffraction combined with full-profile structure refinements. The limit of Nb uptake by perovskite is ca. 16 wt.% Nb_2O_5 (or 17% of the total occupancy of the B site). Charge neutrality of the Nb-doped compositions is maintained through the accommodation of "surplus" oxygen along non-periodic shear planes, and formation of minor vacancies in the Ca site. $Ca_{0.99}(Ti_{0.87}Nb_{0.13})O_{3.06}$ is isostructural with, but has a larger cell than, CT: *Pbnm*, *a* 5.3922(4), *b* 5.4552(4), *c* 7.6619(5) Å. In addition to the Nb-doped perovskite, samples CN-20-60 contain an increasing proportion of $Ca_6Ti_2Nb_4O_{20}$ (n = 6, x = 4). This phase is orthorhombic, *Cmcm* or *Cmc*2_1, *a* 3.844(1), *b* 37.573(8), *c* 5.478(2) Å; its structure is similar to that of $Ca_4Nb_4O_{14}$, but consists of perovskite-like slabs six $(Nb,Ti)O_6$ octahedra thick. Sample CN-80 consists entirely of $Ca_5TiNb_4O_{17}$ (n = 5, x = 4). This phase is orthorhombic, *Pmnn* or *P*2*nn*, *a* 3.843(2), *b* 32.020(11), *c* 5.485(2) Å, and consists of slabs five octahedra thick. Sample CN-100 corresponds to $Ca_4Nb_4O_{14}$ (n = 4, x = 4) well characterized in the literature [3,4]. In summary, a subsolidus assemblage of Nb-doped perovskite with $Ca_6Ti_2Nb_4O_{20}$ is stable over a wide compositional range, and is replaced at high Nb contents by layered perovskite-like structures with x = 4 and progressively decreasing n. Our data show that the incorporation of limited amounts of high-charged cations in oxide minerals can be effectively compensated by anionic non-stoichiometry.

Perovskite from the Proterozoic Tiksheozero carbonatite (Russia): age and genesis

Lepekhina, E.N.[1*], Antonov, A.V.[1], Belyatsky, B.V.[2] & Sergeev, S.A.[1]
[1]Centre of Isotopic Research, VSEGEI, St.-Petersburg, Russia ([*]Elena_Lepekhina@vsegei.ru)
[2]VNIIOkeangeologia, St.-Petersburg, Russia

The Tiksheozero carbonatite complex located near the NE continental margin of the Karelian Craton within Archean TTG gneisses is a typical ring complex where carbonatites are associated with intrusions of ultramafic and alkaline rocks: olivinites, pyroxenites, theralites, jacupirangites, ijolites and nepheline syenites. Carbonatites occur as large bodies more than several hundred meters wide and up to 3 km long. The main carbonatite associations are: calcite, apatite, tetraferriphlogopite, magnetite and amphibole (high-T association); ankerite, dolomite, amphibole and apatite (low-T association) [1].

There were many attempts to determine the age of the complex by various radiometric techniques, but the results were not satisfactory [1]. We have also attempted to constrain the time of carbonatite intrusion by U-Pb dating of zircon and baddeleyite. The obtained data confirm the Proterozoic age of the carbonatites, but the internal structure of the zircon crystals unequivocally demonstrates metasomatic recrystallization of metamict areas of the crystals, which probably took place much later during the Caledonian orogeny.

It is well known that perovskite is a ubiquitous mineral in alkaline-ultramafic rocks and carbonatites [2]. This mineral is used as a geochronometer, which in contrast to zircon cannot be xenogenous and, hence, allows the time of emplacement to be determined precisely. Perovskite separated from a drill-core sample of Tiksheozero carbonatite is represented by anhedral crystals typically 100-500 μm in size with composition close to $CaTiO_3$ and limited variations in Fe, Na, Sr, Ce and Nd (0.6-1.7 and ≤ 1.2, 0.9, 3.7 and 1.6 wt.% respective oxides). Most of the grains contain inclusions of rock-forming and accessory minerals (calcite, dolomite, mica, diopside, apatite, ilmenite, pyrrhotite), as well as plucked inclusions. Sixteen perovskite grains were analyzed with a SIMS SHRIMP-II for U-Pb isotope abundances using Tazheran perovskite as a standard (465 ± 15 Ma). The obtained spread in isotope compositions was sufficient for regression best-fitting of the analytical data with a common-lead $^{207}Pb/^{206}Pb$ ratio of 0.836. The calculated age of the Tiksheozero perovskite is 381 ± 10 Ma (MSWD = 0.63).

The obtained age contradicts the generally accepted Proterozoic age for the Tiksheozero complex, but agrees well with the age of zircon recrystallization during a hypothetical metasomatic overprint event [1]. We speculate that the studied perovskite is not a primary magmatic phase and that its formation is related to the processes of recrystallization and metasomatic reworking of the carbonatites. A similar origin has been proposed for some of the perovskite from the Devonian alkaline-ultramafic/carbonatite complexes in the Karelia-Kola region [3]. Moreover, there are well-known examples of metasomatic perovskite in skarns at the contact with alkaline and mafic intrusions such as the Shishim Mountains in the Urals and Tazheran complex in Siberia [2]. We propose that the metasomatic event responsible for the perovskite formation in the Tiksheozero carbonatites is connected with the widespread alkaline magmatism in the region, which was triggered by mantle-plume activity at 360-380 Ma [4].

Major and trace elements in perovskite from a micaceous kimberlite nodule, Udachnaya-East pipe, Siberia

Sharygin, V.V.[1*] & Kamenetsky, V.S.[2]
[1]V.S.Sobolev Inst. of Geology and Mineralogy SB RAS, Novosibirsk, Russia ([*]sharygin@uiggm.nsc.ru)
[2]School of Earth Sciences, University of Tasmania, Hobart, Australia

A unique nodule of micaceous kimberlite (6 cm in size) has been found in unaltered kimberlite of the Udachnaya-East pipe. This cognate nodule contains large olivine xenocrysts (3-7 mm) in a medium-grained matrix consisting of olivine, phlogopite, zoned spinel and perovskite. Mg-rich ilmenite, monticellite, djerfisherite, sodalite, calcite, shortite, chlorides, apatite and Mg-silicate (humite or serpentine) occur as minor or accessory phases. The contact between the nodule and its host kimberlite is sharp and does not show any reaction relations. The micaceous kimberlite differs from the host rock in containing higher modal abundances of phlogopite, spinel and perovskite and in the scarcity of carbonates, sulfides and chlorides.

Perovskite forms euhedral crystals (up to 150 μm), some of which show normal zoning (bright core, dark rim) in reflected light and BSE images. The zoning is more common in perovskite near the contact with the host kimberlite. The core-to-rim variations in discrete crystals with simple zoning involve a decrease in $LREE_2O_3$ (from 4-5 to 2-2.5), ThO_2 (from 0.5-1.6 to 0) and sometimes Nb_2O_5 (from 1.5-2 to 0.7-1 wt.%). Perovskite from the central part of the nodule exhibits fine oscillatory zoning and does not contain a Th-rich interior. Oscillatory-zoned crystals show only subtle variations in Ca, Ti, LREE and Nb, although there is general tendency in a slightly decreasing LREE and Nb levels from the core rimward. Perovskite from the micaceous kimberlite does not differ in major- and trace-element contents from perovskite in the host kimberlite. In both cases, perovskite approaches the ideal composition ($CaTiO_3$), and the total contribution from all other end-members ($Na_{0.5}Ce_{0.5}TiO_3$, $NaNbO_3$, $CeFeO_3$, $Th_{0.5}TiO_3$) does not exceed 8 mole %. Such composition is typical of perovskite from kimberlites worldwide [1]. LA-ICP-MS data for perovskite from the nodule and host kimberlites confirm EMPA data with regard to the distribution of REE, Th and Nb, and indicate a decrease in Ta (from 2700 to 700), Cr (from 300-400 to 30-50), Pb (from 200 to 10 ppm) toward the rim at approximately constant values of Zr (450-1100), U (200-300), Y (200-300) and Hf (20-40 ppm).

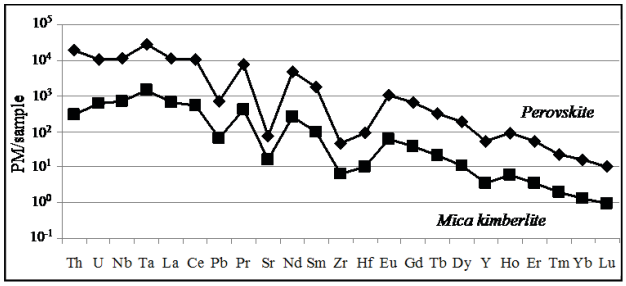

Fig. 1: Spider diagram for perovskite and mica kimberlite nodule from the Udachnaya-East pipe, LA-ICP-MS and ICP-MS average data.

Comparison of the ICP-MS data for perovskite and host micaceous kimberlite shows that perovskite is the principal carrier of the incompatible trace elements in the nodule (Fig. 1). The same pattern of perovskite-rock element distribution is observed in the host kimberlite.

Pyrophanite after perovskite from serpentinite at Perkupa, northern Hungary

Zajzon, N.[1*], Kristály, F.[1], Szakáll, S.[1], Fehér, B.[2], Váczi, T.[3] & Pekker, P.[3]
[1]Inst. of Mineralogy and Geology, University of Miskolc, Hungary ([*]nzajzon@uni-miskolc.hu)
[2]Herman Ottó Museum, Miskolc, Hungary
[3]Inst. for Nanotechnology, Bay Zoltán Foundation for Applied Research, Miskolc, Hungary

The Perkupa serpentinite, a member of the Bódva Valley Ophiolite Formation, was formed from dunite or pyroxenite under regional metamorphism. The first occurrence of pyrophanite in serpentinite in the Carpathian region is documented here.

Pyrophanite occurs as brownish-maroon-coloured euhedral crystals 10–200 μm in size in the serpentinite. Pleochroism is not visible. Internal reflections are common and strong. Commonly, a well-defined, semi-transparent, dark central zone and a pinkish, more opaque rim can be recognized (Fig. 1A). These zones are visible in BSE images as well. The chemical composition is $Mn_{0.96}Fe_{0.04}TiO_3$ (WDX analysis). Some crystals contain perovskite inclusions (Fig. 1B). The perovskite cores are close to the ideal formula and contain only 0.01 apfu Fe. The identity of this mineral as pyrophanite was confirmed by Gandolfi X-ray diffraction and Raman spectroscopy (Fig. 2).

Occasionally, large white inclusions were found in the pyrophanite. On the basis of optical, Raman and electron–microscopic examination, they are interpreted to consist of two phases: anatase and calcite. Dolomite (Ca, Mg > Mn) inclusions were also found.

Perovskite is a common constituent of this type of ultrabasites, but it becomes instable under CO_2-rich secondary processes, and gives way to TiO_2 polymorphs, calcite and titanite. Pyrophanite can form by reaction of the perovskite with Mn-bearing hydrothermal fluids. Manganese is an important component of fluids involved in ocean- floor metamorphism. Pyrophanite crystals described here are pseudomorphs after perovskite, sometimes retaining a remnant perovskite core (Fig. 1B). Chemical alteration of some of these remnants explains the formation of the white calcite-anatase inclusions.

Partial alteration of monazite and xenotime during mineral-fluid interaction: implications for geochronology

Harlov, D.E.[1*], Williams, M.[2], Jercinovic, M.[2], Budzyn, B.[3] & Hetherington, C.[2]
[1]GeoForschungsZentrum Potsdam, Germany ([*]dharlov@gfz-potsdam.de)

[3]Inst. of Geological Sciences, Polish Academy of Sciences, Kraków Research Centre, Kraków, Poland

Monazite and xenotime can give significant information about a rock during its initial formation and subsequent geological evolution. This information takes the form of both geochronology (e.g. crystallization age and/or the age of various metamorphic events) and geochemistry (P-T-X constraints, fluid monitors, etc.). In metamorphic rocks, monazite and xenotime may either grow as the net product of a series of mineral reactions or be inherited from igneous and/or sedimentary precursors. Any Th in the system normally is strongly partitioned into the monazite as the monoclinic huttonite [$ThSiO_4$] and/or cheralite [$CaTh(PO_4)_2$] components via the coupled substitution reactions $Th^{4+} + Si^{4+} = REE^{3+} + P^{5+}$ and $Th^{4+} + Ca^{2+} = 2\ REE^{3+}$, respectively. To a lesser extent, Th can also be partitioned into xenotime as the tetragonal thorite [$ThSiO_4$] component via the coupled substitution $Th^{4+} + Si^{4+} = REE^{3+} + P^{5+}$. In contrast, xenotime commonly takes more U than monazite via the coupled substitution $U^{4+} + Si^{4+} = REE^{3+} + P^{5+}$. Once formed, monazite and xenotime can be partially or totally altered with respect to the Th, U, and (Y+REE) distribution and content. During alteration, Th or U is gained or lost in variable amounts such that irregular patches, extending from the rim into the grain interior, with sharp compositional boundaries, either depleted or enriched in Th and/or U are developed in the body of the original monazite or xenotime grain due to the presence of locally mobile Th, U, Si, Ca, P, and (Y+REE) in a grain boundary/pore fluid that is reactive with regard to monazite or xenotime.

A series of experiments have been performed in sealed Au capsules at amphibolite-facies to granulite-facies temperatures and pressures (600–900°C and 500–1000 MPa) in the piston-cylinder (CaF_2 setup, cylindrical graphite oven) and hydrothermal autoclave utilizing a natural monazite (20 mg) relatively homogeneous with respect to Th (7–8 wt% ThO_2) and a natural xenotime (20 mg) with a Th and U content below the EMP detection limit. Fluids (20–25 mg) used included 2N NaOH, 2N KOH, and $Na_2Si_2O_5 + H_2O$. Silicon was added as quartz (5 mg) or $Na_2Si_2O_5$. In the monazite experiments the source of Th was the monazite itself whereas in the xenotime experiments UO_2 or ThO_2 were added. In each experiment, the monazite or xenotime reacted with the fluid via a coupled dissolution-reprecipitation process [1] such that patches of variable enrichment or depletion in the Th or U with sharp compositional boundaries occurred, resulting in textures similar to that seen in nature. The metasomatised regions represent a pseudomorphic, partial replacement of the original monazite or xenotime with new Th- or U-enriched or -depleted monazite or xenotime. In a subset of the experiments Pb was totally removed. These experiments support the hypothesis that similar patches observed in natural monazite or xenotime could be the result of fluid-induced alteration via coupled dissolution-reprecipitation. If so, such altered regions would yield information concerning the nature of the fluid responsible for their formation as well as allow for the dating of single or multiple metasomatic events assuming that all pre-existing radiogenic Pb is removed during alteration.

Multiple phases of monazite growth in the South Bohemian HP-HT granulites: a chance to constrain the entire timing of metamorphic evolution from subduction to exhumation by Th-U-Pb geochronometry?

Finger, F.[1*], Dunkley, D.[2] & Knop, E.[1]
[1]Dept. of Materials Engineering and Physics, University of Salzburg, Austria ([*]friedrich.finger@sbg.ac.at)
[2]National Inst. of Polar Research, Tokyo, Japan

High-pressure, high-temperature felsic granulites are important tectonic elements in the Variscan Bohemian Massif. Formed from Early Palaeozoic granitic protoliths [1], the rocks were initially metamorphosed in a Variscan subduction setting, probably passing through an eclogite-facies stage (peak pressure around 3 GPa at 800-900°C)[2] into a HP-HT granulite facies stage (1.6 GPa at ~900-1000°C)[3]. Subsequently, the rocks were rapidly exhumed (near isothermal decompression to ~0.8 GPa), then retrogressed to varying degrees under decreasing temperatures and pressures.

There is a long-standing debate as to whether zircon and monazite U-Pb ages of ~340 Ma, which have been consistently obtained in several studies, record the timing of subduction *versus* exhumation-stage metamorphism (*e.g.*, [4]). It has been suggested that subduction and eclogite-grade metamorphism took place considerably earlier, in the late Devonian (*e.g.*, [5]; see [6] for review and tectonic model).

High-spatial resolution U-Th-Pb dating of monazite may provide more information regarding the timing of multistage metamorphism. A microstructural and crystallochemical study carried out by electron microprobe indicates that several generations of monazite are preserved in the granulites. The youngest monazite (M3) formed during the decompression stage by reaction from REE enriched high-pressure apatite. Granulite-facies monazite (M2) is generally characterized by low yttrium content, due to Y-partitioning into garnet. Garnet occasionally contains inclusions of monazite, some of which preserve yttrium-rich cores. It is possible that this monazite type (M1) formed during prograde metamorphism, and could be used to directly date the subduction stage of orogenesis. In examples studied so far, electron microprobe-based Th-U-Pb dating provided no evidence for a large time gap between the formation of relict monazite and 340 Ma peak *P-T* monazite. This may indicate that the subduction stage immediately preceeded granulite-facies metamorphism. Since a time difference smaller than 10 Ma cannot be reliably resolved by the electron microprobe, further dating is planned on zoned monazite grains by SIMS.

Unusually yttrium rich monazite with 6-14 wt.% Y_2O_3 in a granulite from the Bohemian Massif: implications for monazite-xenotime miscibility gap thermometry

Krenn, E.* & Finger, F.
Dept. of Materials Engineering and Physics, University of Salzburg, Austria (*erwin.krenn@sbg.ac.at)

Accessory monazite with an unusually high xenotime solid solution component of 21-42 mol.% (6.5-14 wt.% Y_2O_3, 6-11 wt.% $HREE_2O_3$) was discovered in a retrogressed Variscan HP-HT granulite from the Dunkelsteiner Granulite Massif (Gföhl unit), Lower Austria. These granulites experienced peak-PT conditions of ~16 kbar/1000°C and a subsequent rapid, near-isothermal uplift, which was followed by a stage of near isobaric cooling at around 5-7 kbar [1,2].

The sample consists of a fine grained (0.1-0.5 mm), statically recrystallized quartz-feldspar-biotite matrix with several up to 3 mm garnet crystals, a few 0.2-1 mm kyanite crystals and accessory sillimanite, rutile, apatite, zircon, monazite and opaques. Garnet often displays marginal alteration to biotite, quartz, some plagioclase, and occasionally sillimanite. Clusters (~1 mm) of fine grained biotite-quartz intergrowths probably represent pseudomorphoses after orthopyroxene.

The Y-rich monazite occurs as small (3-15 µm) crystals at grain boundaries. Apart from their high xenotime component, they contain minor amounts of cheralite (2-10 mol.%) and huttonite (0.4-3 mol %). A chemical Th-U- total Pb age of 340 ± 13 Ma (weighted average) is consistent with the Variscan age of the HP-HT granulite series.

Projection of xenotime values into published monazite-xenotime miscibility gap thermometers [3, 4, 5] give temperatures between 800 and 1200°C. Taking the highest measured X(Y+HREE) value of 0.41, the empirical thermometers of [3] and [4] give temperatures of 1050°C and 1100°C, which are close to previously published temperature estimates for the granulite-facies stage [1,2]. The experimental thermometer of [4] that was calibrated in the pure YPO_4-$CePO_4$ system yields ca. 50-100°C higher temperatures.

The results are geologically important because the Y-rich monazite provides a new and independent argument for the high-T nature of this granulite series.

The Y-rich monazite grew either at HT/HP conditions or during isothermal decompression. The yttrium source could have been probably free xenotime, which reacted out at peak temperatures. During decompression Y+HREEs could have become available from garnet breakdown. The extremely high xenotime component in monazite was attained because only little monazite-substance precipitated during the high-T stage. At this stage, significant proportions of REEs were trapped in apatite as is evidenced by abundant secondary monazite at apatite rims.

Gadolinite and crichtonite group minerals: breakdown products of primary monazite and xenotime in granitic and metamorphic rocks

Uher, P.[1*], Dianiška, I.[2], Bačík, P.[1], Ondrejka, M.[1], Pršek, J.[3] & Zubaj, R.[1]
[1]Dept. of Mineralogy and Petrology, Comenius University, Bratislava, Slovakia (*puher@fns.uniba.sk)
[2]Geo, s.r.o., Rožňava, Slovakia
[3]AGH University of Science and Technology, Kraków, Poland

Monazite and xenotime represent the principal REE-bearing phosphate minerals of common granitic and metamorphic rocks. They usually precipitate as primary accessory phases. Younger post-magmatic, hydrothermal or metamorphic, fluid-rich processes caused their partial to complete breakdown and formation of secondary assemblage usually including apatite (REE-rich), epidote-allanite s.s. and thorite [1,2]. However, recent detailed EMP study reveals more complex and diverse breakdown products after monazite and xenotime in selected Hercynian granitic and metamorphic rocks of the Western Carpathians (Slovakia), including the members of gadolinite and crichtonite group.

Secondary minerals form corona-like overgrowths around primary monazite-(Ce) + xenotime-(Y) assemblage in the S-type granites of the Gemeric Unit. The breakdown products located of the monazite-(Ce) comprise apatite, LREE-rich epidote to allanite-(Ce), thorite and titanite, whereas xenotime-(Y) is overrimed by apatite, epidote, thorite and gadolinite-(Y) to hingganite-(Y) s.s. In addition, late synchysite-(Y), synchysite-(Ce), calcite and rutile occur in outer rim zone around the both primary REE phosphate minerals.

Hingganite-(Y) to Nd-dominant hingganite (members of the gadolinite group) in association with S,Sr-rich secondary monazite-(Ce) (up to 0.3 S and 0.2 Sr apfu) originated after primary metamorphic, Nd-depleted monazite-(Ce) and xenotime-(Y) in banded, magnetite-rich metaquartzitic rocks near Bacúch, Veporic Unit. The secondary hingganite + S,Sr-rich monazite form tiny anhedral grains or overgrowths on the primary monazite-(Ce) crystals along the fracture fillings of the parental rocks.

The members of the crichtonite-group minerals [generally $(Sr,Ca,Ba,Pb,Na,K,La,Ce)(Mn,Fe,Y,U,Zr)(Fe,Mg,Zn)_2(Ti,Fe,V,Nb,Cr)_{18}(O,OH)_{38}$] were described in mylonitized granodiorites to granites of the Western Tatra Mountains. Crichtonite, dessauite-(Y) and loveringite-like phase, in association with rutile, allanite-(Ce) to REE-rich epidote, rarely hydroxylapatite-britholite-(Ce) s.s., calcite, titanite, pseudorutile and yttrocrasite-(Y), form secondary lensoid cleavage-fillings of chlorite pseudomorphs after biotite or irregular veinlets and overgrowths on monazite or apatite. Textural relationships indicate a dissolution and breakdown of primary magmatic monazite-(Ce), apatite, biotite and plagioclase, and reprecipitation of the secondary REE- and Ti-rich minerals.

All the above mentioned examples indicate a partial dissolution and/or breakdown of primary magmatic or metamorphic REE-phosphate phases (monazite, xenotime), and precipitation of complex secondary assemblage, including the REE-bearing minerals of gadolinite and crichtonite group. The process was driven by hydrothermal-metamorphic fluids probably during Alpine overprint of the parental rocks.

U-Pb SHRIMP dating, Hf isotope and trace element investigations on multiple zoned zircons from a South-Bohemian granulite

Friedl, G.[1], Cooke, R.[2], Finger, F.[2*], Gerdes, A.[3], McNaughton, N.J.[4] & Fletcher, I.[4]
[1]Dept. of Geography and Geology, University of Salzburg, Austria ([*]friedrich.finger@sbg.ac.at)

[3]Dept. of Geosciences, University of Frankfurt, Germany
[4]Centre for Global Metallogeny, University of Western Australia, Crawley, Australia

High-pressure-temperature granulites are a conspicuous feature of the Variscan Bohemian Massif. Formed from Early Palaeozoic granitic protoliths [1], the rocks were initially metamorphosed in a Variscan subduction setting, probably passing through an eclogite-facies stage (peak pressure around 3 GPa at 800-900°C)[2] into a HP-HT granulite facies stage (1.6 GPa at ~900-1000°C)[3,4]. Subsequently, the rocks were rapidly exhumed (near isothermal decompression to ~0.8 GPa), then retrogressed to varying degrees under decreasing tem-peratures and pressures [4]. Resolving the exact time-frames of the individual evolution stages preserved in the granulites is a great challenge for geochronologists and a pre-requisite for understanding the tectonic evolution of the Central European Variscides.

Zircons from the south Bohemian granulites have a complex multi-phase internal growth zoning. Apart from abundant remnant cores, considered to be derived from the granitoid protoliths, two chemical distinct outer growth shells have been recognised using BSE imaging. An U-rich shell around the inherited cores with bright BSE-signal is followed by a distal U-poor shell which is dark in BSE. Conventional zircon dating techniques which utilise whole grains, may not resolve potentially small, but distinct age differences between such growth shells. Therefore, the SHRIMP method was applied in an attempt to individually date single stages of zircon growth. The sample used is a typical leucocratic, medium grained and weakly foliated Moldanubian granulite from the Dunkelsteiner Wald granulite massif, S of Krems (Gföhl unit). The peak metamorphic assemblage of garnet + kyanite + ternary feldspar + quartz is remarkably preserved in this sample.

SHRIMP analyses carried out in the protolithic zircon cores produced strongly scattering, although concordant ages. Most fall in the time range between 450 und 400 Ma. We assume that the granitic protolith formed at that time. A concordant Cadomian age of c. 580 Ma has been measured in one core. A further generation of inherited cores records an age of ca. 480-500 Ma. In one case a discordant $^{207}Pb/^{206}Pb$ age of ca. 2.3 Ga was detected.

Analyses in the U-rich growth shells around the cores yielded concordant to subconcordant ages of around 340 Ma. Analyses from the U-poor outermost growth zones give slightly younger ages with a mean average $^{206}Pb/^{238}U$-age of 333 ± 6 Ma (2σ). The results are tentatively interpreted as dating two distinct stages in the metamorphic evolution of the rock. The age of 333 ± 6 Ma (zircon rims) probably dates the exhumation of the granulite to mid crustal levels. The older age may represent granulite facies zircon growth at higher PT-conditions.

Hf isotope data suggest that dissolved zircon material from the granitic protolith functioned as the main source for the Variscan zircons.

Pre-Variscan evolution of the Western Tatra Mts., Poland: new insights from U-Pb zircon dating

Burda, J.[1*] & Klötzli, U.[2]
[1]Faculty of Earth Sciences, University of Silesia, Sosnowiec, Poland ([*]jolanta.burda@.us.edu.pl)
[2]Dept. of Lithospheric Research, University of Vienna, Austria

The crystalline basement of the Tatra Mts. comprises a polygenetic Variscan granitoid intrusion dated at 360–340 Ma [1] and its metamorphic envelope. In the metamorphic complex, mainly represented by paragneisses, orthogneisses and amphibolites (metabasalts), two superimposed units (Upper and Lower) have been distinguished. In the Lower Unit peak metamorphic conditions were estimated at T=550-580°C and P=5-8 kbar, while in the Upper Unit T=690-780°C and P=7.5-10 kbar [2].

The protolith ages and geochemical characteristics of selected orthogneiss samples from these two units were determined, providing new constraints for reconstructing of the Palaeozoic geodynamic evolution of this sector of the Variscan chain.

Orthogneisses from the Lower Unit are mostly banded, fine- to medium-grained rocks while in the Upper Unit varieties with augen structures predominate. They consist of aligned dynamically recrystallised qtz+pl+bio±grt with zircon and apatite as accessory phases. Muscovite is a late post-kinematic. Some primary feldspar relics with recrystallised mantles are preserved within a strongly oriented granoblastic matrix. They are peraluminous (ASI=1.2–1.27) and belong to high-K calc-alkaline suites within a VAG–type tectonic setting.

LA-MC-ICP-MS U-Pb zircon ages from both samples from crystals with oscillatory zoning yield a similar ages of ca. 534 Ma. The Th/U ratios of all analyses range from 0.19 to 0.67 and have values typical of magmatic zircons. This is interpreted to reflect the magmatic crystallization age of similar igneous precursors, in agreement with the geochemical characteristics of these rocks. In zircons from a gneiss from the Upper Unit, a luminescent internal part with well-developed oscillatory zoning is surrounded by weakly luminescent, low contrast rims (Th/U ratios of 0.02-0.08). These yield a well defined weighted mean U-Pb age of 387±14.

In summary, two distinct Early Cambrian and Middle/Upper Devonian tectonothermal events are recognized. The first event represented by the oldest meta-magmatics so far dated in the Western Carpathians could be an expression of rifting and crustal thinning at the northern Gondwana margin. The granodiorites from the Upper Unit experienced a subsequent high-grade metamorphic event, constrained by partial recrystallisation of primary magmatic zircon and growth of new zircon rims at ca. 387 Ma. These could be connected with the formation of crustal-scale nappe structures and generation of collision-related magmatism.

Xenotime–zircon solid solutions in topaz granites of the Saxothuringian Zone

René, M.
Institute of Rock Structure and Mechanics, Academy of Sciences of the Czech Republic, Prague, Czech Republic
(rene@irsm.cas.cz)

Topaz granites form two distinct magmatic suites in the Saxothuringian Zone in the Bohemian Massif. The first suite is formed by high-P (>0.4 wt% P_2O_5), highly evolved S-type granites. High-P topaz granites occur in granite stocks of the western part of the Saxothuringian Zone (Horní Slavkov–Krásno and Ehrenfriedersdorf ore districts). The second topaz granite suite is formed by low-P (<0.4 wt% P_2O_5), aluminous A-type granites. These granites include small granite bodies and stocks with important Sn-W ore deposits (Altenberg and Zinnwald/Cínovec).

Both types of topaz granites are alkali feldspar granites with variable contents of quartz, albite, K-feldspar, Li-mica and topaz. Zircon, Nb-Ta-Ti oxides and uraninite are common accessory minerals. High-P granites host large amounts of apatite, together with monazite and relative scarce xenotime. Apatite is absent in low-P granites, and the low contents of whole-rock phosphorus are reflected by variable amounts of monazite and xenotime and by low phosphorus contents in zircon. However, the distinctly high phosphorus contents in high-P granites are reflected also in feldspar, topaz and zircon. The P_2O_5 concentrations in zircon reach 8.3 wt% (Krásno) and max. 20.2 wt% (Podlesí, [1]).

Both types of topaz granites are characterized by zircon–xenotime intergrowths. Zircon grains very often show strong hydration and fluorination. The highest concentration of H_2O and F are displayed by zircon crystals from the apical part of the low-P granites Cínovec cupola (max. 18.5 wt% H_2O and 1.2–2.4 wt% F). However, the hydration and fluorination of zircon from high-P granites is likewise high. Fluorine reaches max. 2.1 wt.% in zircons from topaz-albite granites of the Horní Slavkov–Krásno ore district and even 3.5 wt.% in zircons from Li-mica dyke granite of the Podlesí granite stock [1]. All these zircons contain moderate Hf concentrations (1.2–9.8 wt% HfO_2) with no considerable differences between the two types of topaz granites. However, zircons from low-P and high-P granites show significant differences in the contents of Y. Zircon from low-P granites displays high concentrations of Y. Zircons from the Cínovec granite cupola contain max. 9.2 wt.% Y_2O_3 [2], whereas Y contents in high-P granites from the Horní Slavkov-Krásno ore district reach only 4 wt.% Y_2O_3.

Xenotime occurs also in both granite types, but highly intimate zircon–xenotime intergrowths are present in low-P granites from the Cínovec cupola. Epitaxial overgrowths of xenotime in zircon were frequently observed in these granites. Xenotime from the low-P granite of the Cínovec cupola displays a considerable enrichment in Th and HREE compared to xenotime from high-P granites of the Horní Slavkov–Krásno ore district. The contents of Zr in xenotime are relatively low, commonly in the range of 0.4 to 1.0 wt% ZrO_2, with no significant difference between xenotimes from low-P and high-P granites. However, xenotimes from low-P granite of the Altenberg and Markersbach granite stocks display a considerable enrichment in Zr (13.0–14.5 wt% ZrO_2, [3]).

Crystal chemistry of zircon from granitic rocks (Japan): genetic implications of HREE, U and Th enrichment

Hoshino, M.[1*], Kimata, M.[2], Nishida, N.[3], Shimizu, M.[2] & Akasaka, T.[4]
[1]Mineral Resources Research Group, Inst. for Geo-Resources and Environment, AIST, Tsukuba, Japan
([*]hoshino-m@aist.go.jp)
[2]Earth Evolution Sciences, Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan
[3]Chemical Analysis Div., Research Facility, Center for Science and Technology, University of Tsukuba, Japan
[4]Center for Tsukuba Advance Research Alliance, University of Tsukuba, Japan

Zircon from granitic rocks from Japan is classified into two major types; based on the minor element content determined by electron microprobe, a heavy rare earth element (HREE)-U-Th-poor (Type I) and a HREE-U-Th-rich (Type 2). Zircons characteristically occurring in common granites of type-1 are relatively poor in HREE including Y and Sc, up to 2.72 wt% $HREE_2O_3$; up to 0.44 wt% ThO_2; up to 2.10 wt% UO_2, while zircons characteristically occurring in granitic pegmatites of type-2 are much richer in HREE including Y and Sc, up to 18.99 wt% $HREE_2O_3$; up to 11.09 wt% UO_2; and up to 6.58 wt% ThO_2.

However, analyses showing a significantly high amount of REE+Y almost certainly represent altered zircon and/or accidental analysis of inclusions [1]. Only crystal structure of zircon free of inclusions and zoning (type-2; Takenouchi granitic pegmatite) was refined to R = 4.3 % and for the first time has been confirmed that zircons of type-2 exist as a single-crystal phase in nature.

High enrichment of HREE, Y, and Sc are preferentially incorporated by xenotime substitution $HREE^{3+} + P^{5+} \leftrightarrow Zr^{4+}+Si^{4+}$ (Fig. 1). Furthermore, incorporation of U and Th into zircon is primarily governed by coupling the thorite substitution with the coffinite one $U^{4+} + Th^{4+} \leftrightarrow 2Zr^{4+}$. Zircon crystals from granites and granite pegmatites, extraordinarily enriched in HREE, U, and Th, are generally anhydrous, which strongly suggested that they were formed at the magmatic stage of granitic rock formation. Enrichments of HREE, U and Th are generally observed in both the zircons from granitic pegmatites and the rims of zircons from granites, and originate in fractionation processes in the last stage of crystallization of granitic magma. The discovery of both type-1 and type-2 zircons occurring in granitic rocks from the magmatic arc in Japan means that the former were formed from the granitic magmas at high temperature while the latter were from the magmas intimately related to the formation of granitic pegmatites at low temperature.

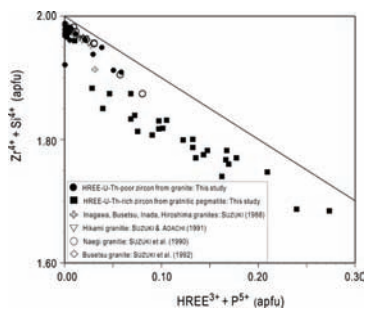

Fig. 1: Compositional correlation between the two types of zircon from granitic pegmatites and granites, in terms of cations per formula unit. There is a negative correlation between $Zr^{4+} + Si^{4+}$ and $HREE^{3+} + P^{5+}$, which deviates from the 1:1 line due to other substitutions.

Titanite as a prospecting tool in the tin granite belt, Nanling Range, South China: a comparison study

Wang RuCheng[*], Xie Lei, Chen Jun, Lu JianJun & Wu JinWei
School of Earth Sciences and Engineering, Nanjing University, Nanjing, China ([*]rcwang@nju.edu.cn)

Titanite is a common accessory silicate in metaluminous granites (I-type or A-type). It was studied in order to assess its potential role for determining the ore potential of tin of granites. The targets include three tin granites (Qitianling, Huashan, Guposhan) related with large Sn deposits and two barren granites (Lianyang, Dadongshan) in the Nanling tin belt, South China. These granites, whatever their tin contents, are metaluminous with ACNK of about 1.1, lithologically (amphibole)-biotite granites and are classified as A-type granites.

In three tin granites, titanite includes at least two distinctive types: one is euhedral, closely associated with perthitic feldspar, quartz and biotite, and is primary and magmatic phase, while the other is anhedral, always associated with chlorite, thus as secondary product of biotite chloritization. Electron-microprobe results reveal subordinate but distinctive contents of Sn, Al and Fe in two types of titanite, suggesting alternative substitutions: $Ti^{4+} = Sn^{4+}$ and $Ti^{4+} + O^{2-} = (Al, Fe)^{3+} + F^{-}$. The primary titanite contains 0.2 to 1.2 wt% SnO_2 (on average about 0.4 to 0.5 wt%), 3.46 to 4.60 wt% Al_2O_3 and 1.79 to 3.75 wt% Fe_2O_3. However, chemical composition of the secondary titanite is simply characterized by elevated concentrations of Al_2O_3 and F up to 9.56 and 2.14 wt% respectively, but lower concentrations of Fe_2O_3, similar to hydrothermal titanite after biotite reported in literature [1,2]. The average content of SnO_2 is 1.49 wt%.

As a comparison, titanite from the barren granites of Dadongshan and Lianyang in the same district was also studied. Primary and secondary categories were identified for titanite according to the morphology and Al-Fe-F concentrations. Very interestingly, the Sn contents of both primary and secondary titanite are clearly lower than those from the tin granites.

Therefore, titanite can be used as an indicator mineral to distinguish tin granites from barren systems, although the whole-rock features are not distinguishable between them.

[1] Eggleton, R.A. & Banfield, J.F. (1985) *Am. Mineral.*, **70**, 902-910. [2] Broska, I. et al. (2007) *Lithos*, **95**, 58-71

Tracing evolution of peraluminous granitoids through contrasting tourmaline types

Balen, D.[1*], Broska, I.[2] & Petrinec, Z.[1]
[1]Faculty of Science, University of Zagreb, Croatia ([*]drbalen@geol.pmf.hr)
[2]Geological Inst., Slovak Academy of Sciences, Bratislava, Slovakia

The peripheral parts of the Cretaceous Moslavačka Gora (Croatia) peraluminous granites host two contrasting tourmaline types (Fig. 1) having separated origin: slightly alkali-deficient nodular schorl to dravite (Fe# 0.43-0.58) and disseminated schorl (Fe# 0.75-0.85). Origin of the nodular tourmaline has been attributed to the interaction of a fluid phase from the residual granitic melt with a fluid derived from the wall rock environment [1], which resulted in increasing the MgO content in the nodular tourmaline compared to the disseminated one. Observed textures suggest that nodular tourmaline crystallized as the last mineral in a quasi-closed system inside host granite.

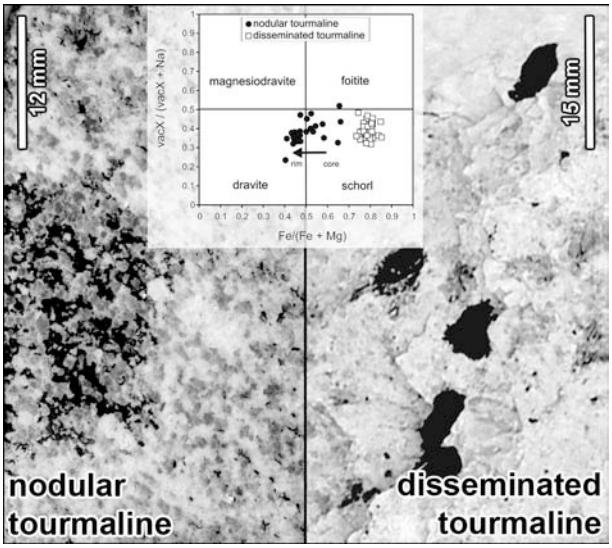

Fig. 1: Anhedral to subhedral nodular (left) and disseminated tourmaline (right); inset show compositional variations for two tourmaline types occurring in the Moslavačka Gora granites.

The peculiar texture and distribution of tourmaline nodules can be most suitably explained through an emplacement setting of the studied granite intrusion. In a situation when magma rapidly reached shallow crustal levels, resulting decompression and cooling lead to the separation of a boron-rich melt in form of distinct volatile-rich bubbles [2] ± crystals. If these bubbles were unable to escape the system owing to impermeable host and wall rock, they cause the formation of tourmaline nodules in almost completely solidified granite. The Moslavačka Gora two-mica granite that hosts tourmaline nodules can thus be regarded as an occurrence of magma that escaped from the plutonic levels and stalled in a low pressure crustal setting (ca. 720 °C, 70 – 270 MPa, H_2O_{melt} up to 4.2 wt. %). Decreasing pressure and related cooling were major factors controlling the melt differentiation, liquid immiscibility, fluid behaviour, partitioning of elements and crystallization path of the two-mica granite.

Disseminated tourmaline from leucogranite host, on the other hand, can be considered as a typical magmatic product and common accessory phase.

The Shilu iron–polymetallic ore deposit on Hainan Island, South China: origin of andradite and chemical dating of metallogenic processes

Bakun-Czubarow, N.[1*], Kusiak, M.A.[1], Xu, D.[2], Wang, Zh.[2], Konecny, P.[3] & Kusy, D.[1]
[1]Inst. of Geological Sciences, Polish Academy of Sciences, Warszawa, Poland ([*]nbajun@twarda.pan.pl)
[2]Guangzhou Inst. of Geochemistry, Chinese Academy of Sciences, Guangzhou, China
[3]Geological Inst. of Dionyz Stur, Bratislava, Slovakia

The Shilu iron-polymetallic ore deposit located in western Hainan Island, South China, occurs within the Meso-Neoproterozoic complex of low-grade metamorphosed volcanoclastic sediments and carbonates. The amphibole itabirites (banded diopside–tremolite rocks), dolomite itabirites and dolostones are the main hosts for iron ores. At the present state of knowledge, the Shilu ore deposit is considered to be a structurally re-worked as well as hydrothermally altered and enriched ore deposit of Banded Iron Formation (BIF) type [1,2].

The aim of the project is dating of the skarnization process caused by hydrothermal activity in this region to understand metallogenic processes in the Shilu ore deposit. We applied *in situ* dating of monazite (using the Th–U–Pb_{tot} isochron method), combined with the study of mineral chemistry of coexisting minerals, characteristic for skarn, hydrothermal stage of metallogeny. For the present research we selected 3 rock samples from the close vicinity of the Beiyi iron mine – one gangue rock: F8–7 – amphibole itabirite and the two garnet–bearing itabirites belonging to iron–poor ores: 0907 and ZSL6–14. In the sample 0907, andradite (Adr) garnet megacryst of 5 mm in diameter recorded distinct zoning (Fig. 1). In this grain the Adr content decreases from the plateau-like core (99.7 mol.% Adr) to rim (71.2 mol.% Adr), while the content of grossular (Grs) increases. Moreover, the garnet grain, almost devoid of solid inclusions in core, contains numerous tiny quartz inclusions in middle zone, and small inclusions of iron oxides are abundant in rim zone. Thus, most likely, the andradite megacryst recorded during crystallization the temperature decrease and distinct changes in composition of fluids.

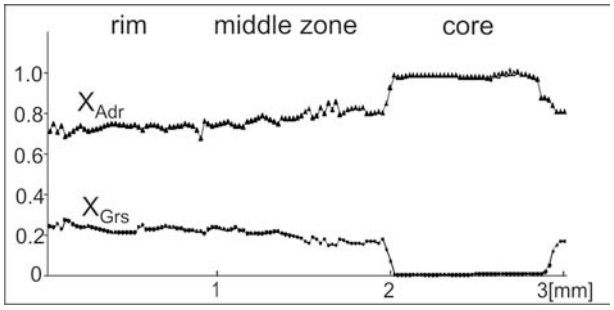

Fig. 1: Zoning profile for the andradite megacryst from the iron-poor ore, sample no 0907.

Monazite grains from the gangue amphibole itabirite yield 564±7 Ma and 442±14 Ma isochron ages, while monazites from garnet–bearing iron–poor ore gave much younger result of 258±7 Ma. In this sample, monazite often occurs as inclusion in garnets. Obtained Permian age could be considered then as the age of skarnization process. Further study is being carried to address metallogenic processes in this complex ore deposit.

Origin of Palaeoproterozoic high-metamorphic metacarbonate rocks (calciphyres) of the Irkut block (Sharyzhylgai Uplift, Siberian Craton)

Urmantseva, L.N.[*] & Turkina, O.M.
Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia ([*]urmantseva@gmail.com)

The Sharyzhalgai Uplift of basement is the southern termination of the Tungusska Province of the Siberian Craton [1]. The Irkut Block metamorphic complex is subdivided into two associations. The metavolcanic association includes the hypersthene-bearing biotite and amphibole-biotite gneisses and two-pyroxene and amphibole-pyroxene basic schists. The second, metasedimentary one, is dominated by garnet-biotite, hypersthene-biotite and cordierite-bearing gneisses. Also this association contains marbles and calciphyres. Archean magmatic protolith of metavolcanic rocks underwent at least two stages of metamorphism during Neoarchean (2.55-2.57 Ga) and Palaeoproterozoic (1.85-1.87 Ga) [2-4]. Metasedimentary rocks are from Palaeoproterozoic stage (1.85-1.97 Ga) [5]. The aim of this study was to define conditions of metacarbonate rocks formation and time of carbonate rock metamorphism.

Garnet-bearing and cordierite-garnet-biotite gneisses of the Irkut block have been formed during granulite metamorphism of sedimentary rocks. Paragneisses' protoliths correspond to terrigenous sediments, ranging from greywacke to shale. Full characteristic is given in [6]. The REE distribution indicates that the terrigenous material of the paragneisses was derived from felsic and mafic provenance. Increase in contents of Fe, Ti, Cr, Ni, Sc and decrease in La/Sc from the garnet-biotite to the cordierite-bearing gneisses reflect growth of the abundance of mafic rocks in the provenance.

Metacarbonate rocks are represented by calciphyres. Using the programm MINLITH [7] the averaged normative mineral composition was determined. The protolithes of calciphyres are represented by three main parts: carbonate (70-90%), clay (3-20%), and debris (5-10%). Calciphyres are presented of dolomite varieties. They have fractionated REE spectra, characterized by $(La/Yb)_n$=59-71 and show strong Eu minimum (Eu/Eu*=0.4-0.5). It can be concluded that such characteristics are due to clay component in carbonate sediments.

Zircons from calciphyres have irregular form without traces of zoning. The analyses of zircons yield an upper intersect of discordia and concordia at 1873±6 Ma (MSWD=1.6). This age corresponds to the time of Palaeoproterozoic granulitic metamorphism within the Irkut block. Metamorphic origin of these zircons is confirmed by REE distribution. Zircons are characterized by low $(La/Yb)_n$=8.5-14.6 and $(Sm/La)_n$=0.4-4.6. They have strong Ce (Ce/Ce*=1.4-1.7) and Eu anomalies (Eu/Eu*=0.4-0.6).

Results of this study indicate that the formation of calciphyres relates with metamorphism of terrigenous-carbonate rocks. Accumulation of carbonates was accompanied by supply of clay material.

Iron oxide minerals in Western Carpathian granitoids in relation to the assimilation processes and granite mapping

Broska, I.[1*], Ondrejka, M.[2], Bónová, K.[3], Petrík, P.[1] & Konečný, P.[4]
[1]Geological Inst., Slovak Academy of Sciences, Bratislava, Slovakia ([*]igor.broska@savba.sk)
[2]Dept. of Mineralogy and Petrology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
[3]Inst. of Geography, Faculty of Sciences, Pavol Jozef Šafárik University, Košice, Slovakia
[4]Dionýz Štúr Inst. of Geology, Bratislava, Slovakia

Fe-oxides, mainly magnetite, belong to the most important mineral phases for the recognition of I-type granitoid suites in the Western Carpathians. Magnetite is generally present as individual grains or clusters, as well as inclusions in accessory and rock-forming minerals. The host granitoids of the Fe-oxides showing the I-type affinity are coarse to medium grained, metaluminous to slightly peraluminous biotite (leuco)tonalites to granodiorites, with minor proportion of muscovite-biotite granites. The bulk rock concentration of magnetite is variable, but usually reaches ca hundreds g/t but can increase to several thousands g/t in some parts of the granitoid body, especially in the areas with occurrences of microgranular mafic enclaves. The increase of magnetite concentration was observed also in the late magmatic differentiates, in leucocratic dikes.

Fe oxides in the Western Carpathian I-type granitoids occur as (1) early-orthomagmatic, pre-mixing titanomagnetite, which breaks down upon cooling, (2) late-magmatic, post-mixing, stochiometrically pure magnetite, which crystallizes from mixed tonalite magma, and (3) low-temperature hydrothermal hematite replacing both earlier magnetite types. The orthomagmatic titanomagnetite is volumetricaly much smaller, pure magnetite dominates. The primary magnetite and Ti-hematite during cooling release titanium by inter-oxide re-equilibration and form ilmenite exsolutions, followed by rutile precipitation. The second late-magmatic stage of Fe-oxide formation, results in the assemblage of pure magnetite, titanite and apatite the magnetite itself having originated from reaction of early titanomagnetite, annite and anortite. The magnetite may be locally transformed to hematite or Ti-hematite.

The mafic enclaves in the West-Carpathians I-type granites have always a high precentage of Fe oxides. They are tonalitic to dioritic in composition, the rock-forming plagioclase having a similar composition to those one in host tonalite. The elevated values of magnetic susceptibility observed in the I-type granitoids in places with abundant mafic microgranular enclaves may be explained by more extensive precipitation of the Fe-Ti oxides or titanomagnetites after mixing with a hotter mafic melt, rich in siderophile elements, or by partial assimilation of trapped and mingled blobs of the basic melts, i.e. enclaves. The increased content of Fe-oxides in aureolas around microgranular mafic enclaves in host I-type granitoids may indicate a higher degree of mixing of Fe components from mafic magma to a crustal acid silicate melt and inheritance of titanomagnetite from the mafic magma. The abundance of magnetite in I-type granites causes the increase of whole rock magnetic susceptibility in host granitoids. The enclaves show natural remanent magnetisation commonly around 16 x 10^{-3},SI units. A typical value discriminating I/S-type Western Carpathian granitoids is 2 x 10^{-4} SI units. The measurement of rock magnetic susceptibility index in the field appears as a useful tool for regional geological mapping of I-type granites and searching of enclave rich regions.

Uranium and thorium distribution in the Double S Zone of the uraniferous Lac Turgeon Intrusive Complex, Quebec, Canada

Beal, K.*, Lentz, D.R. & McFarlane, C.
Dept. of Geology, University of New Brunswick, Fredericton, New Brunswick, Canada (*k.beal@unb.ca)

The Double S Zone is located along the North Shore of the St. Lawrence Seaway, in the Grenville Province of Canada. The zone (along with the neighboring Middle and TJ zones) contain 40.7 million pounds U_3O_8, averaging 0.012% U_3O_8 [1]. The Double S Zone is a sequence of granitic pegmatites with adjacent, coeval, coarse-grained granites-alaskites. Granitic gneiss and quartzite xenoliths are also present. SEM-BSE and SEM-CL imaging followed by EMPA were completed on U- and Th-bearing accessory minerals from the uraniferous Double S zone. Preliminary geochronology on the Double S pegmatite yielded approximately 944 Ma (U-Th-Pb monazite; see [2] for method), approximately 150 Ma younger than the age of peak Grenvillian metamorphism commonly reported. This date is slightly younger than dating by [3] (962 ± 9 Ma by U-Th-Pb in monazite for the pegmatite) and dates reported for the host granite include >980 (U-Pb monazite and uraninite [4]), 961 ± 7 Ma (U-Th-Pb monazite; [3]) and 948 ± 23 Ma (Rb-Sr whole rock isochron; [5]).

The distribution of uraninite and uranothorite are relatively heterogeneous in the pegmatite and granite, but each suite of minerals contains similar average elemental content (compiled with [3]). Uraninite in the granite shows a greater distribution in U/Th, ThO_2, PbO, and CaO impurities (7.5-14.3%, 3.7-9.9%, 5.5-12.0%, and 0.6-6.0%, respectively) than the pegmatite suite. Uranothorite in the pegmatite shows a greater distribution in U/Th, UO_2, and PbO (0.1-0.6%, 4.5-27.8%, and 0.0-2.5%, respectively) than the host granite. Zircon displays xenocrystic cores, oscillatory zonation, and recrystallization along the rims. Zircon in pegmatite samples associated with uraninite and thorite contain higher average REE content and U/Th (3457 ppm and 36.3) compared to 1979 ppm and 8.6 in unmineralized pegmatite. Pegmatite zircons also contain the highest U/Th ratio (average 12.2) compared to the less fractionated leucogranite (average 11.1). Apatite displays blocky, equant crystals and common simple zonation that is indicative of a slow-cooling magma [6]. The apatite contains erratic actinide content, but averaged 0.6% REE in the granite and 0.2% in the pegmatite reflecting the greater distribution of REE-rich phases in the pegmatite. A fergusonite analysis from the pegmatite contained 6.5% REE, 16.5% UO_2, and 2.5% ThO_2 and xenotime crystals contained up to 13.4% REE, 0.5% UO_2, and 0.4% ThO_2. Monazite, compiled with data from [3], contains up to 20.2% ThO_2 and 0.9% UO_2 in the pegmatite with a lower distribution of ThO_2 and UO_2 (up to 16.2% and 0.8%, respectively) in the granite.

Overall, uraninite and uranothorite in the pegmatite and host granite explain the high levels of radioactivity in the Double S zone. Additional radioactivity produced by other actinide-bearing phases contributes to the high background levels.

PGE compositions of magnetite from porphyry Cu-Mo deposits of Siberia and Mongolia

Berzina, A.N.
Institute of Geology and Mineralogy, Novosibirsk, Russia
(anitansk@gmail.com)

This study provides the first platinum group elements (PGE) data in magnetites from some porphyry Cu-Mo deposits in the Central Asian Orogenic Belt (Siberia and Mongolia). Primary magnetites were analyzed for all PGE (Os, Ir, Ru, Rh, Pt and Pd), and Au, as well as Cu and Ni, using ICP-MS. Magnetites show low to intermediate PGE contents ranging from 5 to 60 ppb. For most samples Os and Ir concentrations are less than limits of detection. Ruthenium concentrations range from <1 to 14 ppb, Rh from <1 to 12 ppb, Pt from <1 to 7 ppb, and Pd from <1 to 56 ppb. Palladium concentrations are typically higher than Pt. Positive anomalies of Rh are consistent with the experiments of Capobianco et al. [1] showing high Rh compatibility in magnetite. There is a wide range of Ni, Cu and Au contents in magnetites. The Au content varies from below detection levels (1 ppb) to 240 ppb. Ni content ranges from 1 to 221 ppm, while Cu content ranges from 3 ppb to 384 ppm. Au shows no correlation with other PGEs, indicating that Au was probably redistributed during later hydrothermal activity.

Overall shape of the average magnetite PGE patterns of the deposits studied are relatively similar with variations toward Rh maximum, a Pt drop and a Pd rise (Fig.1). Within each deposit the metals show relatively similar behaviour, except Au. The magnetite mantle-normalized metal distribution between Os and Pd display patterns similar in shape to basalt rocks in other areas (e.g. basaltic rocks from Jiding ophiolite [2]). This suggests that PGE in magnetites are of magmatic origin.

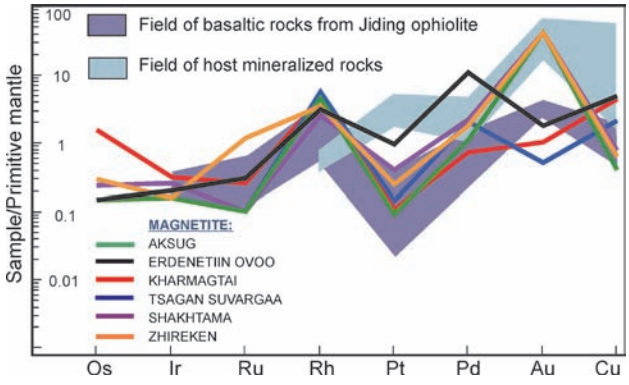

Fig. 1: Mantle-normalized PGE patterns of magnetites and host mineralized rocks from porphyry Cu-Mo deposits of Siberia and Mongolia in comparison with basaltic rocks from Jiding ophiolite [2].

The mineralized rocks hosting magnetite show intermediate PPGE (Rh+Pt+Pd) contents. IPGE (Os+Ir+Ru) concentrations were not determined in mineralized samples. The Cu and Mo content in analyzed samples vary from 45 ppb to 1.7 ppm and from 3 ppb to 550 ppb, respectively. The PGE distribution patterns in the mineralized samples are steep, positively sloped, and different from the irregular distribution patterns in magnetites. Mineralized rocks don't appear to be enriched of Pd over Pt. With the exception of Erdenetiin Ovoo deposit, Pd contents are typically higher in host rocks than in magnetites. It is suggested that PGE distribution in magnetite is inherited from the parent magmatic source. The PGE patterns of sulfide-mineralized samples imply that PGE were redistributed and concentrated during the late stage hydrothermal activity with preferential mobilization of more soluble Pt, Pd and Au.

Zircon U-Pb and Hf isotope constraints from Gandese Paleogene granitoids on the collisional magmatism and tectonic evolution in Tibet

Dong Guochen[*], Mo Xuanxue, Zhao Zhidan & Zhu Dicheng
State Key Laboratory of Geological Processes and Mineral Resources & School of Earth Science and Mineral Resources, China University of Geosciences, Beijing, China
([*]donggc@cugb.edu.cn)

The collision between India-Asia continents preceding the north subduction consumed the Neotethyan Ocean in Cenozoic period and gave rise to the extensive magmatism in southern Tibet, forming a giant magmatic belt in Gangdese and causing of crustal uplift along the collision zone. Based on the research of the Natural Science Foundation (NSFC) project (No.40672044), in this contribution, we selected Hf and U-Pb isotope analyses of in situ zircon from 4 separate cross sections of Cenozoic granites in southern Tibet in order to identify the significant magmatism and magma evolution of whole Gangdese. Igneous zircons from the 4 Gangdese granite sections gave out a discrete magmatic event of 65-40Ma and systemic $\varepsilon_{Hf}(t)$ values between +13.4 and -23, in which the $\varepsilon_{Hf}(t)$ values tended to be increased gradually southwards. The positive $\varepsilon_{Hf}(t)$ values with young Hf model ages of 1200-500Ma are accepted that they were derivate from juvenile crust. The zircons with minus $\varepsilon_{Hf}(t)$ values up to 23 with crustal Hf model ages from ca.1.4 to 2.1 Ga is knowing as an old crust remelting in Cenozoic time. It is likely concluded that the predominantly Early Paleogene intrusive activity was contributed with both juvenile mantle and India Continent, which induced that more mantle masses southwards to Yalo Tsangbo suture zone were introduced to the crust and mixed with the partial melted older crust. Combining these with literature data [1,2], we interpret the Gangdese Paleogene magmatism as an early product of the India-Asia continental collision that started up the mass exchange both mantle and crust and played a long-lasting role in the tectonic evolution of southern Tibet.

Fluid-mediated re-equilibration and self-irradiation of euxenite-zircon assemblage in pegmatites, South Norway

Duran, C.[1], Seydoux-Guillaume, AM.[1], Bingen, B.[1,2], de Parseval, Ph.[1*] & Ingrin, J.[1]
[1]LMTG-UMR 5563 CNRS-Université de Toulouse-OMP-UPS, Toulouse, France ([*]parseval@lmtg.obs-mip.fr)
[2]Geological Survey of Norway,Trondheim, Norway

The Sveconorwegian belt hosts abundant pegmatites in South Norway. Pegmatites are well known for their rare mineral assemblages. They are distributed in several fields, notably the Evje-Iveland field in the Telemarkia terrane and the Froland and Arendal-Kragerø fields in the Bamble terrane. Pegmatites spatially unrelated to granite plutons, intruded during the waning stage of Sveconorwegian high-grade metamorphism as crosscutting dykes to sills, at ca. 1094-1060 Ma in Arendal-Kragerø and ca. 911 Ma in Evje-Iveland.

We sampled several localities to evaluate the respective effect of self-irradiation damage and fluid mediated alteration on the crystal chemical properties of radioactive minerals and their U-Th-Pb geochronological systematics. Particular attention was given to (Y, REE, U, Th)-(Nb, Ta, Ti) oxide minerals. The statistical classification of Ercit [1] allows sorting these minerals in four groups: samarskite, pyrochlore, fergusonite and euxenite-aeschynite. Here we report SEM images and chemical data on euxenite, with special focus on a locality in Iveland, showing a cogenetic assemblage of euxenite, zircon, xenotime and monazite. Euxenite crystals always show altered (A) and unaltered (B) zones (Fig. 1). The first ones appear dark in BSE, highly porous, have a poor resistance to the e-beam during microprobe analyses with low wt% total, and contain 9% UO_2 and 1% ThO_2. FTIR analyses show the presence of O-H stretching (at 3600 cm^{-1}) within these altered zones, in agreement with an alteration by hydrothermal fluids. Sometimes galena crystallized within these altered zones (white crystals in figure 1). In the unaltered domains (bright in BSE - B in Fig. 1), Euxenite contains 11.5% UO_2 and 1.5% ThO_2. Plotting analyses in the Ercit statistical diagram allows denoting alteration paths from euxenite into pyrochlore group; moreover, analyses done within altered rim of euxenite and within healed cracks (dark grey in BSE) correspond to pyrochlore. Finally, self-irradiation (and irradiation coming from neighbored radioactive minerals, e.g. zircon), caused volume increase, and therefore is responsible for cracks formation that allow fluid circulation within fractures, and led to chemical reactions with elements remobilization.

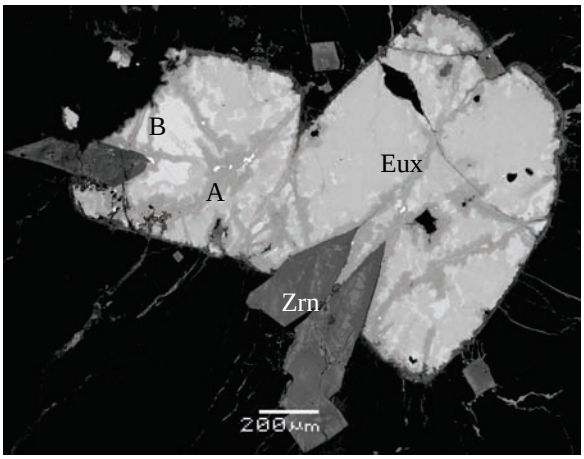

Fig 1: Back Scattered Electron image of an euxenite (Eux) –zircon (Zrn) assemblage in a pegmatite from Iveland, Norway, showing intense alteration coupled with irradiation effects.

Partitioning of As and Sn among among apatite, vesuvianite, Ca-garnet and malayaite in calc-silicate rocks

Houzar, S.[1*], Hrazdil, V.[1], Škoda, R.[2] & Cempírek, J.[1,2]
[1]Dept. of Mineralogy & Petrography, Moravian Museum, Brno, Czech Republic ([*]shouzar@mzm.cz)
[2]Dept. of Geological Sciences, Faculty of Science, Masaryk University, Brno, Czech Republic

Geochemically significant As,Sn-rich mineralization was found in a skarn-like rock enclosed in a marble close to Kozlov near Nedvědice, Svratka Unit, eastern Bohemian Massif. The mineral assemblage consists of predominant Sn-bearing andradite (with relics of grossularite), As-rich vesuvianite, malayaite and rare As-bearing fluorapatite, nordenskiöldine and cassiterite.

Three stages of skarn evolution were distinguished from textural and geochemical features. The first, high-temperature stage features low Fe-content in the system. It is represented by diopside, clinozoisite and grossularite (< 0.300 apfu Fe^{3+}). The second stage, characterized by introduction of Fe, Sn and As in the system, produced malayaite, tin-bearing andradite (85-90 % Adr; 10-13% Grs), As-bearing fluorapatite and arsenic-rich vesuvianite. The third, retrograde stage caused alteration of the primary assemblages and produced secondary cassiterite (*"hydrocassiterite"* or *"varlamoffite"*), stokesite and unidentified Ca,Fe-arsenates [1].

The green Sn-bearing andradite overgrows the grossularite; vesuvianite intergrows with fluorapatite and malayaite. Uncommon relics of diopside and clinozoisite were observed. Rare accessory phases represent nordenskiöldine and löllingite in calcite [2]. The characteristic features of the assemblage are high contents of tin, arsenic and boron, and lack of sulfur.

Distribution of As and Sn among the individual minerals is uneven. Highest contents of tin are present especially in malayaite and nordenskiöldine, but the most important tin carrier in the system is andradite (1.2-2.4 wt.% SnO_2; 0.038-0.081 apfu Sn), replacing grossularite with low Sn-contents (≤ 0.17 wt.% SnO_2; ≤ 0.005 apfu Sn). Grossularite and andradite exhibit very low content of As (< 0.05 wt. % As).

Arsenic is preferentially accommodated in fluorapatite (up to 12.24 wt.% As_2O_5; ≤ 0.56 apfu As) due to AsP_{-1} substitution. It also is an important component in vesuvianite (up to 1.97 wt.% As_2O_5; ≤ 0.597 apfu As), the observed As -contents are the highest recorded worldwide. Similar As-bearing vesuvianite was found at Hemlo, Canada [3]. The LA-ICP-MS data show elevated contents of boron (~8000 ppm). On the other hand, tin contents in vesuvianite are rather low (≤ 0.30 wt.% SnO_2; ≤ 0.060 apfu Sn).

The assemblage originated in relatively oxidizing conditions, in environment with elevated $a(F)$ and $a(H_2O)$, locally also $a(B)$. The equilibrium textures of the prograde second stage (Sn-, As-, Fe-rich) of skarn evolution implies that the distribution of As and Sn among mineral phases was constrained rather by structures of individual phases than by the P-T-X conditions (T_{min} > 300°C, elevated activity of fluids) alone.

Progressive alteration of spinel phases in listvenitization

Huang Ko-Chun[*] & Jiang Wei-Teh
Dept. of Earth Sciences, National Cheng Kung University, Tainan, Taiwan ([*]chinkuahshih@yahoo.com.tw)

Listvenitic rocks from the Miocene Kenting Mélange in southern Taiwan are possibly among the youngest of the rock type found in the world, without overprinting by regional metamorphism. The rocks were highly fractured, sheared, serpentinized, and subsequently carbonatized and silicified, which provided an excellent opportunity to understand evolution of spinel phases under changing hydrothermal conditions typical of listvenitic rocks. Initial transformation of primary chromium spinel $[(Mg_{0.45}Fe^{2+}_{0.55})(Fe^{3+}_{0.12}Al^{3+}_{0.78}\text{-}Cr^{3+}_{1.10})O_4]$ to thin ferritchromite rims during the serpentinization was followed by formation of thick ferritchromite $[(Mg_{0.15}Fe^{2+}_{0.85})(Fe^{3+}_{0.59}Al^{3+}_{0.16}Cr^{3+}_{1.25})O_4]$ skirts and a reaction with serpentine to form Cr-bearing Mg-rich chlorite in a carbonatization event. The process led to pervasive crystallization of magnesite and dolomite and subsequently gave rise to rapid diminishment of Cr-bearing chlorite and serpentine, locally in association with the formation of disseminated sphalerite and galena and Cr magnetite arcs surrounding ferritchromite relics. In the final stage of listvenitization, ferritchromite was completely replaced by Cr magnetite having hollow cores filled by quartz, apparently coeval with precipitation of euhedral Cr magnetite, intensive replacement of carbonates by silica, and local massive crystallization of pyrite. The first stage of listvenitization (carbonatization) was associated with increased fCO_2 and possibly enhanced fO_2 as well, leading to the extensive formation of Fe^{3+}-increased ferritchromite and the second stage (silicification) involved a relatively acidic fluid with a raised total activity of dissolved sulfur and fO_2, producing a magnetite-quartz-pyrite assemblage. The progressive changes of spinel phases in listvenitization appear to be different from those occurring in simple serpentinitization of ultramafic rocks in which nearly no increase of the Fe^{3+} content in spinels was recorded and occasional occurrence of magnetite was commonly attributed to a later regional metamorphic event.

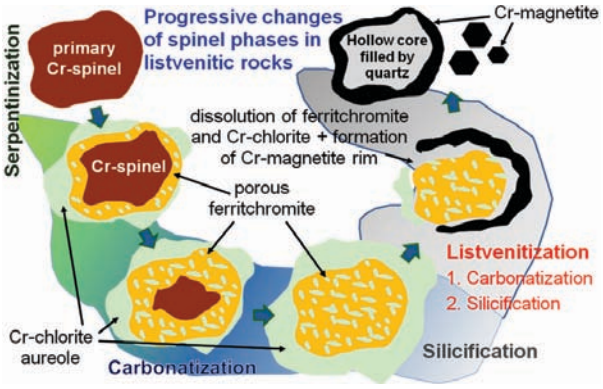

Fig. 1: Evolutionary model of progressive mineralogical and microtextural changes of spinel species observed in the listvenitic rocks from southern Taiwan.

Cathodoluminescence spectra of zircons from some eruptive and endogenous rocks located in Romanian Western and Southern Carpathians

Iancu, O.G.[1*], Robu, I.N.[2] & Brandtstaetter, F.[3]
[1]Dept. of Geology, University „Al. I. Cuza", Iaşi, Romania
([*]ogiancu@uaic.ro)
[2]Geological Institute of Romania, Bucharest, Romania
[3]Naturhistorisches Museum, Vienna, Austria

The main purpose of this study is to investigate the SEM-CL signature of zircons from some volcanic rocks located in the Apuseni Mountains (andesites of Băiţa, Faţa Băii, Roşia, Barza, Cetraş and Săcărâmb types), plutonic rocks from Southern Carpahians (Tismana granitoids, Albeşti granites and Bârsa Fierului granitoids) and metamorphic rocks (metagranites and metapelites from Semenic, Făgăraş, Sebeş and Iezer-Păpuşa Mountains). Cathodoluminescence measurements were made at the Museum of Natural History from Vienna in a JEOL JSM-6400 SEM with an Oxford Instruments CF302 CL system (Room Temperature), a computer-controlled SPEX 340S spectrometer, and a Hamamamtsu-R928 GaAs photomultiplier tube detector. Cathodoluminescence spectral measurements of all zircons analyzed in this study revealed peaks located both in the blue and the yellow parts of the electromagnetic spectrum. The most important spectral features of the zircons from plutonic rocks (9 samples from Tismana granitoids – T3, T6, T8, Albeşti granites – 1154, 1156, 1157 and Bârsa Fierului diorites – 5001, 5002 and 5006) are the peaks located at: 315 nm, 405 nm, 485 nm and 580 nm. The peak with the highest intensity is the 485 nm one, in the blue area of the spectrum, similar with the kimberlitic zircons [1] (Fig. 1).

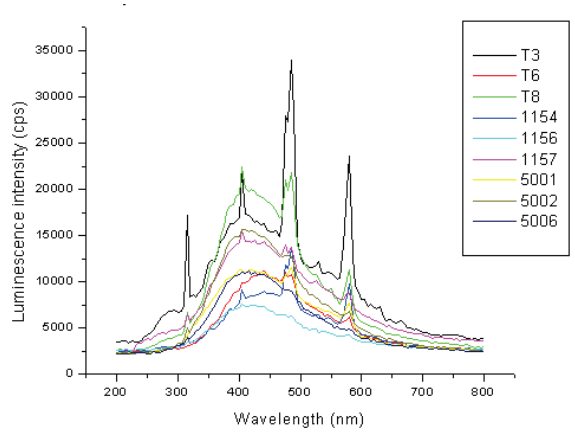

Fig. 1: CL spectra of zircons from plutonic rocks (Southern Carpathians)

The most important spectral features of the zircons from volcanic rocks (7 samples) are the peaks located at: 282 nm (which has the highest intensity) and 352 nm. The most important spectral features of the zircons from metamorphic rocks (5 samples) are the peaks located at: 280 nm (which has the highest intensity), 486 nm, 354 nm and 580 nm. Dy^{3+} is probably the dominant activator element in the zircons analyzed in this study [2]. CL spectra of zircons from the rocks investigated in this study indicate a genesis from fluid or melts with mixed character (crust + mantle). In the case of zircons from plutonic rocks the mantle signature prevails whereas the volcanic and metamorphic zircons formed at the boundary between upper mantle and lower crust [3].

Recrystallisation of monazite as a potential monitor of cryptic fluid events

Kelly, N.M.[1*] & Möller, A.[2]
[1]Dept. of Geology & Geological Engineering, Colorado School of Mines, Golden, CO, USA ([*]nkelly@mines.edu)
[2]Dept. of Geology, University of Kansas, Lawrence, KS, USA

Monazite has proven to be a remarkably versatile mineral for providing absolute time constraints on event histories and the rates of geological processes across a range of crustal conditions. However, robust interpretation of age data requires that we not only understand the mechanisms of monazite growth, but also its ability to recrystallise either in the solid state or in the presence of fluids. This requires that textural *and* geochemical indicators for the origin of the monazite grain or zone being dated are recognised. An integrated micro-analytical study has revealed age and chemical complexity in monazite that was altered during a medium-T fluid event subsequent to its initial formation at high-temperature conditions.

Monazite grains targeted in this study occur in orthopyroxene-sapphirine granulites from the Oygarden Islands, East Antarctica, deformed and metamorphosed to peak temperatures in excess of 900°C and at pressures of 9-10 kbars, during the Rayner Structural Episode at ~930-900 Ma. The textural context of monazite suggests that initial growth or recrystallisation at, or near peak conditions, with dominant EMP chemical ages for formation (or closure) falling between ~910-890 Ma. Backscattered Electron (BSE) imaging of monazite grains exposed zoning patterns that are typically characterized by BSE-bright rims developed on either near-homogeneous or more complex patchy, lobate cores. BSE-bright rims commonly form irregular and lobate boundaries with cores reminiscent of chemical fronts penetrating into the monazite grains. In addition, narrow BSE-bright veins that may envelope pores or inclusions within the monazites cut some grains. Critically, grain boundaries of most monazite grains are in textural equilibrium with peak (~900°C) major minerals such as sapphirine. Electron microprobe (EMP) data indicate that bright zones are depleted in Y, HREE, U and Ca, and enriched in Th, Si and LREE. EMP chemical ages reveal partial to complete resetting of ~910-890 Ma monazite core ages to ~500 Ma with resetting clearly correlated with BSE zoning where core-rim geometries are preserved.

Vein-like zoning patterns in monazite indicate that fluid may have been a driver of composition and age alteration. However, the preservation of high-T Rayner mineral textures and compositions in the host rocks and absence of retrogression, suggests that resetting of monazite must have occurred during a relatively low-T event and by low water-activity fluids. In addition, the presence of altered boundaries between monazite and its orthopyroxene host supports the notion of fluid-driven alteration to a radiation-damaged host mineral.

Preliminary data from Focused-Ion-Beam thin-foils extracted from across rim-core boundaries in age and chemically altered monazites suggests that the mechanism of resetting did not involve complete destruction of the monazite rim prior to regrowth, but likely occurred as a result of either a diffusion-related process, or more likely due to coupled dissolution-reprecipitation along a chemical front moving inwards into the grains. Importantly this process did not alter the textural context of grain margins initially formed during a previous high-grade event, but chemically records an event that did not have a major impact on major minerals in the rocks. Monazite has therefore acted as a sensitive monitor of a fluid-mediated event not otherwise recorded by rocks in the terrane.

First report of apatite with pyrrhotite exsolution lamellae in retrogressed Ky-eclogites from the Rhodope UHP metamorphic province (Greece)

Kostopoulos, D.K.[1], Moulas, E.[2*] & Burg, J.-P.[2]
[1]Dept. of Mineralogy and Petrology, National and Kapodistrian University of Athens, Greece
[2]Geological Institute, Dept. of Earth Sciences, ETH-Zürich, Switzerland ([*]evangelos.moulas@erdw.ethz.ch)

Apatite crystals with pyrrhotite exsolution lamellae have been found in kyanite (ky)-eclogites from the Rhodope metamorphic province (RMP), northeastern Greece. RMP is a synmetamorphic nappe stack that was formed during Jurassic-Cretaceous times and underwent extension during the early Cenozoic. Kyanite eclogites occur as boudins in orthogneisses located in the lower parts of the structurally upper unit of the RMP in Greece. These rocks have recorded an early (U)HP event followed by a metamorphic overprint at granulite-facies conditions. The (U)HP mineral assemblage is omphacite, garnet, kyanite and phengite, while rutile, apatite and zircon occur as accessories. Diopside, amphibole and biotite symplectites with plagioclase were formed upon decompression during which corundum, spinel and plagioclase symplectites were formed at the expense of kyanite at granulite-facies conditions (T~800°C, P≈1.0GPa).

The apatite grains often reach 0.5 mm in size and contain a dense network of crystallographically-oriented, needle-like pyrrhotite exsolution lamellae (Fig.1a). The exact composition of the lamellae could not be determined directly, due to their very fine nature. Careful energy-dispersive (EDS) microprobe analyses have nonetheless revealed the existence of a sulphide phase composed of Fe and S (Fig.1b) in atomic proportions of 1:1, thus allowing us to deduce the presence of pyrrhotite.

The occurrence of apatite with pyrrhotite exsolution lamellae is pivotal in the reconstruction of the metamorphic evolution of the RMP since similar occurrences have been reported from eclogites of the Sulu UHP province, China [1,2] as well as from non-HP metamorphosed rocks such as granites [3]. The exsolution of Fe and S from the apatite lattice bears witness to high-temperature conditions since the initial incorporation of Fe in the apatite lattice is restricted because of its limited solubility. An alternative scenario [3] suggests the simultaneous crystallisation of apatite and pyrrhotite from a melt. Although there is no constraint for the pressure at which this process occurred, two scenarios seem possible at present. Either the exsolution lamellae formed during decompression and cooling from UHP/HT conditions or they formed during cooling following the granulite facies overprint. Partial melting may have occurred in both cases.

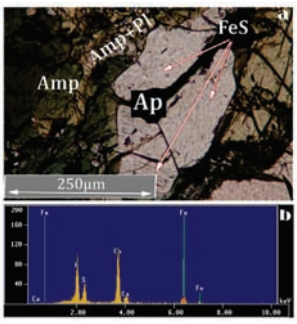

Fig. 1: (a) Photomicrograph of matrix apatite where the lamellar FeS is indicated. (Amp: amphibole, Pl: plagioclase, Ap: apatite); (b) EDS spectrum of FeS in apatite.

Yttrium mineralization in the north-west of Russia (Pre-Polar Urals)

Kozyreva, I.V.[*] & Shvetsova, I.V.
Institute of Geology UB RAS, Syktyvkar, Russia
([*]kozyreva@geo.komisc.ru)

The aluminium- and iron-rich metamorphic rocks are developed in the Pre-Polar Urals. The nature of these metamorphites is convergent: partly they are metamorphized Precambrian crusts of weathering and their resedimentation products; on the other hand they are products of Late Paleozoic fault metasomatism. These rocks are geochemically special: they are anomalous by Sn, Be, Ge, Zr, As and especially TR. Their study has revealed a wide complex of accessory minerals both widespread, and exclusively rare. The present report shows results of study of yttrium-containing minerals. At present about 150 carriers and concentrators of yttrium are known; more than 10 of them are determined in the studied rocks (minerals are given according to decrease of Y content). *Thalenite-(Y)* ($Y_2[Si_2O_7]$) is found as accretions of brown-red thick tabular crystals. *Xenotime-(Y)* (YPO_4) has three morphotypes: xenomorphic xenotime-1, idimorphic xenotime-2 (prismatic) and xenotime-3 (dipyramidic). *Churchite-(Y)* ($YPO_4 \times 2H_2O$) forms grains and radial yellow and milk-white nodules. *Chernovite-(Y)* ($YAsO_4$) is represented by two varieties: xenomorphic cryptocrystalline structures and idiomorphic yellow crystals. *Kainosite-(Y)* ($Ca_2(Y, Ce)_2Si_4O_{12}(CO_3) \times H_2O$) is represented by pink-yellow short prismatic crystals. *Yttrocrasite-(Y)* ($(Y,Th,Ca,U)(Ti,Fe^{3+})_2(O,OH)_6$) is observed as red-brown isometric grains. *Paraniite-(Y)* ($Ca_2Y(AsO_4)(WO_4)_2$) forms yellow dipyramidal crystals. *Allanite-(Ce)* ($(Ce, Ca, Y)_2(Al, Fe)_3(SiO_4)_3(OH)$) shows four varieties: rare separate grains of allanite-1, allanite-2 has thin and cryptocrystalline structure, radial aggregates of allanite-3 columnar crystals and reticulate undulate structures of allanite-4. *Davidite-(La)* ((La, Ce, Ca)(Y, U)$(Ti, Fe)_{20}O_{38}$ is represented by black grains with metal shine and tabular crystals with side faces of phombohedron. *Gramaccioliite-(Y)* $(Pb, Sr)(Y, Mn)Fe_2(Ti, Fe)_{18}O_{38}$ is found as well formed tabular crystals of trigonal shape with black side faces of rhombohedron with metal shine. *Keilhauite* $Ca_3YFeTi_3Si_4O_{20}$ is of sealing wax and red-brown color and forms roundish, almond-shaped structures. Metamict *zyrtolite* $Zr_{0.9}Hf_{0.05}REE_{0.05}SiO_4$ is represented by idiomorphic, prismatic, dipyramidal, tabular, pancake-shaped crystals and grains of brown, grey and orange colors. The studied minerals are characterized by complex variable composition, unusual look, microcrystallinity or poor crystallinity and apparently connected with authigenic mineral formation in old crust of weathering. In the process of green shale metamorphism they formed more perfect crystalline generations. The variability of mineral forming solutions at various stages of metamorphism conditioned formation of crystals of various habits and various chemistry.

Experimental constraints on the partitioning of REE between fluorapatite and monazite at high pressures and temperatures

Krenn, E.[1*], Harlov, D.E.[2], Heinrich, W.[2], Wunder, B.[2] & Finger, F.[1]
[1]Dept. of Materials Engineering and Physics, University of Salzburg, Austria ([*]erwin.krenn@sbg.ac.at)
[2]GeoForschungsZentrum, Potsdam, Germany

Natural observation implies that high-pressure rocks often bear REE (Nd-MREE) enriched fluorapatite that reacts during decompression to REE-poor fluorapatite plus secondary Nd-rich monazite [1,2]. Due to the presence of Nd- and MREE-rich fluorapatite, high pressure monazite is often particularly rich in La and poor in Nd and MREEs.

We have studied REE partitioning between fluorapatite and coexisting monazite in a series of piston cylinder experiments at 800°C and 1.5, 3 and 4 GPa. Experimental runs utilized synthetic REE-free Ca-fluorapatite, allanite (as REE source), albite and a 1 molar NaF solution as reactants.

As predicted [3], monazite crystals formed in all experiments from the reaction between fluorapatite and allanite. At the same time REE-rich fluorapatite formed through partial replacement of REE-free Ca-fluorapatite via dissolution and repricipitation (Fig. 1). These newly formed apatite rims yield up to 20 wt.% ∑REE. While fluoarapatite rims show a strong enrichment in Nd relative to the bulk, the experimentally produced monazite crystals are enriched in La.

The results from this study confirm the existence of a strong fractionation of La and Nd between monazite and apatite in high pressure rocks, similar to what has been observed in nature. They also demonstrate that fluorapatite at high pressures can contain considerable amounts of REEs and thus serve as a major storehouse of REE as well as source of secondary monazite during decompression.

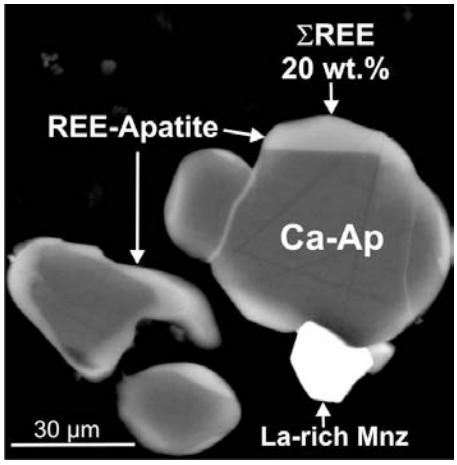

Fig. 1: BSE image showing La-rich monazite (La/Nd 2.5) and newly formed REE-rich apatite at the margin of REE-free, Ca-fluorapatite. Starting materials and run conditions: allanite + Ca-fluorapatite + 1M NaF-H_2O; 800°C, 30 kbar, 5 days).

Textural features and geochemistry of titanite in granitic rocks from Ciborro – Aldeia da Serra area, Ossa-Morena Zone (southern Portugal)

Lima, S.S.M[1*], Neiva, A.M.R.[1] & Ramos, J.M.F.[2]
[1]Dept. of Earth Sciences and Geoscience Centre, University of Coimbra, Portugal ([*]selmalima252@gmail.com)
[2]LNEG, S. Mamede de Infesta, Portugal

Titanite, $CaTiSiO_4(O,OH,F)$, occurs in rocks from a wide range of geological environments. In Ciborro – Aldeia da Serra area, Ossa-Morena Zone (southern Portugal), titanite is the dominant titanium-bearing mineral in biotite>amphibole tonalite, biotite trondhjemite and biotite>amphibole granodiorite.

In tonalite and granodiorite, titanite is euhedral to subhedral, wegde-shaped and light-brown in colour. It occurs mainly as individual matrix grains and rarely as inclusions in biotite and amphibole. In backscattered imaging, the grains present sectorial zoning, which is indicative of magmatic origin [1]. In general, the lighter zones present higher values of $Al+Fe^{3+}$than the darker zones. Titanite from tonalite has slightly lower Ca and Ti concentrations than titanite from granodiorite.

In trondhjemite, titanite occurs as rims around ilmenite in close association with biotite (Fig. 1A, B). Although this titanite is optically unzoned, it presents a higher chemical variation, mainly in Ca, Ti and $Al+Fe^{3+}$ contents than titanite from the other lithologies. On the other hand, backscattered images show that this ilmenite is chemically zoned (darker zone is richer in Mn than lighter zones) and presents exsolved lamellae (Fig. 1B). A similar texture to that presented in Fig. 1 was reported by [2] for titanite from metamorphic rocks and interpreted that titanite was formed due to hydratation and oxidation reactions.

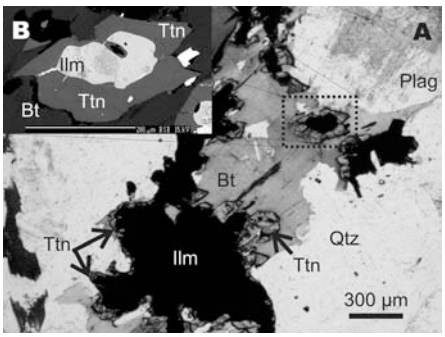

Fig. 1: Titanite from the biotite trondhjemite: A) titanite rimming ilmenite showing that both minerals are closely associated with biotite (plain polarized light); B) backscattered image showing ilmenite zonation and the exsolved lamellae. Abbreviations to biotite (Bt), ilmenite (Ilm), plagioclase (Plag), titanite (Ttn) and quartz (Qtz).

In general, in titanite from the three granitic rocks the $(Al+Fe^{3+})$-OH component exceeds the $(Al+Fe^{3+})$-F component. The parameters used to distinguish between primary and secondary titanite are the contents in $Al+Fe^{3+}$ and F, $X_{Fe}{}^{3+}=Fe^{3+}/(Al+Fe^{3+})$, $Al+Fe^{3+}$ vs F diagram [3] and the $Al\text{-}Fe^{3+}$-Ti ternary plot [4]. Titanite from all lithologies falls within the accepted ranges for a primary origin, including titanite rimming ilmenite that presents values from 0.075-0.124 for $Al+Fe^{3+}$, 0.005-0.031 for F and 0.263-0.387 a.p.f.u. for $X_{Fe}{}^{3+}$. Tonalite and granodiorite present the following values for the same parameters of titanite: $Al+Fe^{3+}$=0.070-0.101 and 0.078-0.096; F=0.000-0.058 and 0.005-0.041 and $X_{Fe}{}^{3+}$=0.315-0.440 and 0.304-0.370 a.p.f.u., respectively.

Alkali-rich beryl from Fe-deposit Skály near Rýmařov, Czech Republic; an example of coupled substitutions in CH-, O- and T_2-site

Novák, M.[1*], Filip, J.[2], Gadas, P.[1] & Přikryl, J.[1]
[1]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic ([*]mnovak@sci.muni.cz)
[2]Centre for Nanomaterial Research, Palacký University, Olomouc, Czech Republic

Beryl-group minerals feature the following principal substitutions including O-site e.g.: (1) Al = Fe^{3+}; CH-site + T_2-site: (2) $^{CH}\square$ $^{T}Be^{2+}$ = $^{CH}R^{+}$ $^{O}Li^{+}$ and CH-site + O-site: (3) $^{CH}\square$ $^{O}R^{3+}$ = $^{CH}R^{+}$ $^{O}R^{2+}$, where R^{+} = Na, Cs, Rb, K; R^{2+} = Mg, Fe^{2+} and R^{3+} = Al, Sc, Fe^{3+}. Subhedral to euhedral columnar crystals of deep blue beryl, up to 2 cm long, occur in quartz>calcite>Fe-chlorite veins, up to ~10 cm thick, cutting hematite-rich ore. They were mobilized from host rocks of the Lahn-Dill type deposit where one of the rock types - magnetite-chlorite rock - yielded up to 60 ppm of Be [1]. Accessory hematite, albite, dravite, bornite, digenite, chalcopyrite, monazite-(Ce), REE-epidote, and fluorapatite were also identified in the veins. Beryl is locally cut by late veins of calcite, quartz and chlorite and occasionally shows corrosive contacts chiefly to calcite. Crystals of beryl contain small subhedral inclusions of euclase, up to ~200 μm in size, partly replaced by calcite. The fluid inclusion study of quartz yielded temperatures of homogenization of aqueous inclusions 110 - 180 °C, low fluid salinity (2.2-4.3 wt.% of NaCl equiv.) and Na-Mg-Cl salt composition [1]. Zoned beryl crystals are built of volumetrically dominant homogeneous core of beryl I and homogeneous narrow rims and minor euhedral inclusions of beryl II, up to ~200 μm in size, located chiefly around rims. Beryl exhibits a unique chemical composition (based on the EMPA, room- and low-temperature Mössbauer spectroscopy and LA-ICP-MS data): Li_2O = 0.20 and 0.43; Na_2O = 2.43 and 2.46; MgO = 2.41 and 2.36; FeO_{tot} = 4.07 and 0.90 (Fe^{3+} = 39 at.% from total Fe for beryl I) and Al_2O_3 = 11.69 and 14.34 for beryl I and beryl II, respectively (all in wt.%) with the empirical formulas: $^{CH}Na_{0.45}$ $^{T}(Be_{2.92}Li_{0.08})_{3.00}$ $^{O}(Al_{1.31}Fe^{3+}_{0.13}Mg_{0.34}Fe^{2+}_{0.19})_{1.97}$ $Si_{6.06}$ O_{18} and $^{CH}Na_{0.45}$ $^{T}(Be_{2.84}Li_{0.16})_{3.00}$ $^{O}(Al_{1.59}Mg_{0.33}Fe^{2+}_{tot0.07})_{1.99}$ $Si_{6.04}$ O_{18}, respectively. The LA-ICP-MS study revealed concentrations of the trace elements similar in beryl I and beryl II (all in ppm): Sc ≤ 38; Mn ≤ 45; Co ≤ 18; Cu ≤ 84; Ga ≤ 46; As ≤ 94; Rb ≤ 39; except for Ti≤ 91; V ≤ 38; Cs ≤ 242 (all higher in beryl I) and Zn ≤ 373 (higher in beryl II). Beryl I exhibits two dominant substitutions (1) up to 0.13 apfu of Fe^{3+} and (3) up to $\sum R^{2+}$ = 0.53 apfu (Mg > Fe^{2+}); whereas the substitution (2) is only minor up to 0.08 apfu of Li. In beryl II, where Mössbauer data are not available, the substitution (1) is likely less important due to low amount of Fe_{tot}. The substitution (2) is more significant, up to 0.16 apfu of Li, and the substitution (3) is dominant with $\sum R^{2+}$ = 0.40 apfu (Mg >> Fe^{2+}). Participations of the substitutions (1), (2) and (3) within single crystal of beryl are remarkable, because usually substitutions affiliated to O-site or T-site are dominated [2,3]. The textural relations of both compositional types of beryl characterized by coupled substitutions in CH-site, O-site and/or T_2-site, respectively, indicate their immiscibility.

Two types of monazite and the REE tetrad effect in the Surovec Li-F-P micro- and leucogranite (Gemeric Unit, Western Carpathians, Slovakia)

Petrík, I.[1*], Broska, I.[1] & Konečný, P.[2]
[1]Geological Institute, Slovak Academy of Sciences, Bratislava, Slovakia ([*]igor.petrik@savba.sk)
[2]D. Štúr State Geological Institute, Bratislava, Slovakia

Two varieties of specialised S_s-type granite occur in the area of Surovec in western part of the Gemeric unit. A small body of the Li-F-P microgranite contains topaz, Li-mica (zinnwaldite), and a variety of rare phosphates (lacroixite, arrojadite, viitaniemiite). Accompanying ordinary leucogranite contains phengitic mica, but topaz and rare phosphates are absent. Both types are characteristically poor in REE contents which results in virtual absence of REE accessories. Only couple of monazites was found and their analyses showed that while leucogranite monazite is Th-poor, Li-F-P microgranite contains extremely Th-rich monazite (25 % ThO_2). The latter was convenient for chemical dating which yielded a well defined age of 263 ± 3 Ma, identical with Re-Os dating of molybdenite from the nearby Hnilec body [1].

Whole rock REE contents of both granite types are very low (14REE=5-10 ppm) showing characteristic pronounced tetrad patterns: positive curvature La-Nd, Gd-Ho and Er-Lu segments. The tetrad effect originates in fluid environment where chemical properties of the REE are controlled by filling 4f orbitals (e.g. [2]). The positive pattern, called M-type, is conventionally explained by removal of a phase with reciprocal tetrads (W-type)[3]. Such a phase is however not commonly found, on the contrary, the analysed late minerals (fluorite) show also the M-type pattern [4]. This means that late fluids were equilibrated with already M-type bearing residual melt. The Th-rich monazite from microgranite with the distinct M-type tetrad pattern is interpreted in such a way. However, a single monazite found in leucogranite shows a distinct W-type pattern (Fig. 1). Because whole rock patterns of both rock types are almost identical it is suggested that fractionation of W-type monazite (possibly accompanied by some apatite) could explain the tetrad effect in both rocks. While the fractionation may have removed early monazite from microgranite some has been preserved in leucogranite. A local enrichment of Th in the late melt may have promoted the M-type monazite formation in microgranite.

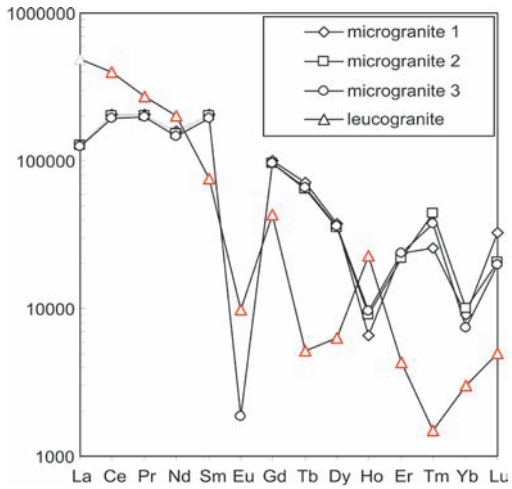

Fig. 1: Two types of tetrad REE patterns in monazites from Surovec leuco- and microgranite.

Allanite–monazite–xenotime–zircon–apatite assemblage in two-mica granites of the Moldanubian (South Bohemian) batholith

René, M.
Institute of Rock Structure and Mechanics, Academy of Sciences of the Czech Republic, Prague, Czech Republic (rene@irsm.cas.cz)

Two-mica Variscan granites of the Moldanubian (South Bohemian) batholith represent the most significant rock type of this magmatic body. Three main geochemical two-mica granite types can be distinguished in the SBB: the low-Th Deštná granite, the intermediate-Th Eisgarn granite and the high-Th Lipnice and Steinberg granites. All these granites were emplaced at shallow levels (equivalent to 100–200 MPa) and at relatively reducing fO_2 conditions (presence of ilmenite). The two-mica granites are peraluminous (A/CNK = 1.02–1.34) with low CaO concentrations. Th concentrations and REE element patterns are quite distinct class marks for the above mentioned three geochemical types of two-mica granites. The highest bulk content of REE is significant for the Lipnice and Steinberg granites, whereas the lowest bulk of REE was observed in the Deštná granites. These granites are also characterized by the smallest amounts of accessory minerals. The Eisgarn granites typically show highly variable bulk contents of REE, controlled by variable amount of biotite and accessories (allanite, monazite, zircon, apatite). In the Lipnice, Steinberg and Eisgarn granite types, apatite is the most common accessory mineral. Large (100–600 μm), anhedral to subhedral grains of apatite often contain inclusions of zircon and monazite. In the Deštná granite apatite, zircon and monazite are usually included in K-feldspar and/or biotite grains.

The Deštná granites are leucocratic biotite-muscovite granites with predominance of muscovite. They contain very common schlieren or small nodular aggregates of restitic biotite. Their accessory minerals assemblage consists of monazite, zircon, apatite, and a significant occurrence of xenotime. The Eisgarn granites are texturally highly variable granites (porphyritic and/or equigranular, fine- to medium-grained), with a variable ratio of muscovite and biotite. The accessory minerals assemblage is formed by allanite, monazite, zircon and apatite. The Lipnice granite is a medium-grained monzogranite usually containing high amounts of restite enclaves. The Steinberg granite is a hiatalporphyritic, medium-grained monzogranite with a strong dimensional fabric of K-feldspar phenocrysts. The accessory minerals assemblage of monazite, zircon and apatite is significant for both granite types.

Whole-rock geochemistry is notably controlled by chemical composition of the accessory minerals assemblage. The highest Th contents in monazite and high Th/U ratios are significant for monazites from the Lipnice and Steinberg granites. On the other hand, monazites from the Deštná granites show higher values of U and Y. The relatively high contents of Y in the Deštná granites are also expressed by the presence of xenotime. Considerable differences in the Mn/Fe ratio were observed for apatites from different two-mica granite types. The highest values of this ratio are characteristic for the Deštná granite. Zircon compositions in all three granite types are quite variable, with the occurrence of zircon grains enriched in P, Y and Sc. In the Lipnice and Steinberg granites, the zircon composition is closest to a stoichiometric zircon.

Zirconium-bearing minerals in phonolites of northern Bohemia

Skála, R., Ulrych, J., Böhmová, V.*, Korbelová, Z. & Novák, J.K.
Institute of Geology, Academy of Sciences of the Czech Republic, Praha, Czech Republic (*bohmova@gli.cas.cz)

The Tertiary nepheline phonolites of the České Středohoří and the Lužické hory volcanic mountain ranges are characteristic by extremely high Zr contents ranging from 950 to 2650 ppm. Zirconium is concentrated mainly in otherwise rare zirconium silicates as hainite and fluorian eudialyte [1]. Hainite is a mineral occurring exclusively in northern Bohemia within the region of the Central European Volcanic Province (CEVP).

Hainite was first described from the phonolite of the Chlum (or Hradiště) Hill near Raspenava in the Lužické hory Mts. [2]. It occurs as either (i) acicular crystals in amygdales vugs and bands enriched in aegirine-augite, in places also in the phonolite matrix reaching up to 1 mm length (called here hainite I) or (ii) thin lobate lamellae in matrix (called here hainite II). Crystal structure of the hainite I was published in [3]. The microprobe analyses of original hainite I were published in [4]. Corresponding empirical formula recalculated considering 18 (O,F) per formula unit is:

$(Ca_{1.356}Zr_{0.400}Mn_{0.166}REE_{0.077})_{\Sigma 2.000}(Ca_{0.880}Na_{0.762}Al_{0.006}\square_{0.353})_{\Sigma 2.000}Ca_2Na(Ti_{0.759}Fe_{0.125}Mn_{0.061}Nb_{0.045}Ta_{0.010})_{\Sigma 1.000}[(Si_{1.951}\square_{0.049})O_{6.918}F_{0.082}]_2F_4$

The analyses of hainite II from the matrix of phonolite of the same locality are first presented in this abstract recast to empirical formula based on 18 (O,F) per formula unit:

$(Ca_{1.002}Zr_{0.802}Mn_{0.139}Si_{0.047}REE_{0.010})_{\Sigma 2.000}(Ca_{1.070}Na_{0.833}K_{0.010}Al_{0.006}U_{0.001}\square_{0.080})_{\Sigma 2.000}Ca_2Na(Nb_{0.534}Ti_{0.224}Fe_{0.142}Mn_{0.096}Ta_{0.004})_{\Sigma 1.000}[Si_2O_7]_2(F_{2.224}O_{1.776})_{\Sigma 4.000}$

The hainite II occurs also at many other phonolite localities of the region, e.g., the Klíč Hill or the Rýdečský vrch Hill in the České Středohoří Mts.

Next to hainite, another zirconium-bearing mineral was found in the phonolite of the Sokol Hill in the Lužické hory Mts. This rock is extremely enriched in Zr (2650 ppm) and other incompatible elements (Rb, REE, Hf, U, Th, Nb, Ta). The mineral forms irregular lamellae that are similar to hainite II but their colour is deeper brown. The phase was identified as fluorian eudialyte.

The appearance of hainite and fluorian eudialyte in phonolites as well as the accompanying mineral association comprising aegirine-augite, apatite, titanite, carbonates, analcime and zeolites imply that these zirconium-bearing minerals represent products of the late-stage hydrothermal or metasomatic processes.

2.90 to 2.40 b.y. old monazites from the Archaean Sargur Group and the Biligirirangan and Male Mahadeshwara Hill granulites, Dharwar craton, south India

Srikantappa,C.[*] & Gobi, R.
DOS in Geology, University of Mysore, Mysore, India
([*]srikantappa@googlemail.com)

Along the southern margin of the Archaean Dharwar craton, the two crustal blocks, the Sargur Group (SG) and the Biligirirangan and Male Mahadeshwara Hill (BRH-MMH) granulites, are juxtaposed along a narrow, sub-vertical to steeply dipping, ductile-brittle Kollegal shear zone (KSZ).

Sargur Group consists of meta-sediments like quartzites, BMQ's, meta-pelites and carbonates, intruded by layered ultramafic-mafic igneous complex. All these rocks occur within the Peninsular gneiss, forming part of the Western Dharwar craton. In BRH-MMH, enderbitic granulites are predominant rock types, with garnet-cordierite bearing gneiss, forming part of the Eastern Dharwar craton.

The rocks of SG show upper amphibolites facies metamorphism (T=643 - 741°C; P=7.2 - 9.0 Kbar) in contrast to granulites exposed in the BRH-MMH (T= 645 - 722°C; P= 6.8 – 7.2 kbar)[1]. The rocks show IBC cooling P-T path with reaction of CPx+Plag → Grt+qtz. Crustal melting results in the formation of garnet and cordierite according with the reaction Bio+Sill+qtz → Grt+K-felds+Melt and Bio+Sill+qtz (+Plag) → Cord+K-fedls+Melt (+Ilm). U-Pb ages for zircon in meta-sediments vary from 3.58 to 2.96 Ma [2]. The timing of regional high grade metamorphism is not well constrained in these two crustal blocks, which is essential to unravel tectanometamorphic process in the Dharwar craton.

Monazite occurs predominantly in metapelitic rocks in both the SG and BRH-MMH granulites. They occur as euhedral crystals, either as inclusions in biotite and garnet or as intergranular crystals within the quartz matrix and few grains occur along the grain boundary of apatite crystal. Some of monazite show zoning. EPMA, in-situ U-Pb dating carried out for monazite in different textural relations in both SG and BRG rocks, show varying isotopic ages from 2.90 to 2.40 Ma. The older ages are obtained for the BRH and the younger ages for SG. The older ages (2.90 and 2.63 Ma) are recorded mainly in monazite bordering apatite grains and as inclusion in porphyroblastic garnet, suggesting a closed system behavior of isotopes. Younger ages of 2.4 Ma are obtained for monazites associated with biotite in the matrix, suggesting an open system behavior. U-Pb isotopic study on monazite, combined with micro-textural and mineral P-T data reveal that the two crustal blocks, show contrasting geological set up and metamorphic history. Deeper part of the crust is exposed in the WDC when compared to relatively shallower crustal levels in the EDC.

The present data suggest an early metamorphic event around 2.9 Ma followed by the regional high-grade metamorphism around 2.63 Ma, suggesting a collissional and crustal melting event in the Dharwar craton.

Zircons in Variscan granites from the Slavonian Mountains, Croatia

Starijaš, B.[1*], Gerdes, A.[2], Balen, D.[3], Tibljaš, D.[3] & Finger, F.[1]
[1]Dept. of Materials Engineering and Physics, University of Salzburg, Austria ([*]biljana.starijas2@sbg.ac.at)
[2]Geozentrum, Dept. of Mineralogy, Goethe University, Frankfurt am Main, Germany
[3]Institute of Mineralogy and Petrology, University of Zagreb, Croatia

The Slavonian Mountains in Croatia expose Variscan crystalline basement of the Tisia terrane. Apart from different metamorphic units, this basement comprises large bodies of Variscan granites [1]. In the course of current attempts to constrain the formation ages of these granitic rocks by means of LA-SF-ICP-MS-based U-Pb zircon dating, a detailed study of the accessory zircon crystals was undertaken with reference to morphology, internal growth textures and crystal chemistry. Eight samples of granites from Papuk and two granite samples from Psunj were prepared for the study. The work was carried out using a combination of methods, including optical microscopy, cathodoluminescence (CL) and backscattered-electron imaging (BSE), electron microprobe and laser ICP-MS analysis.

The granite samples from Psunj carry a distinctive zircon population characterized by relatively large, stubby to normal prismatic zircons with prominent {100} and {101} crystal faces. {211} and {110} faces are small or missing, as is often the case in high-temperature I-type and A-type granites [2]. Characteristic are numerous inclusions of tiny apatite needles (Fig. 1a) and uranium rich inner zones, which are sometimes metamict (Fig. 1b).

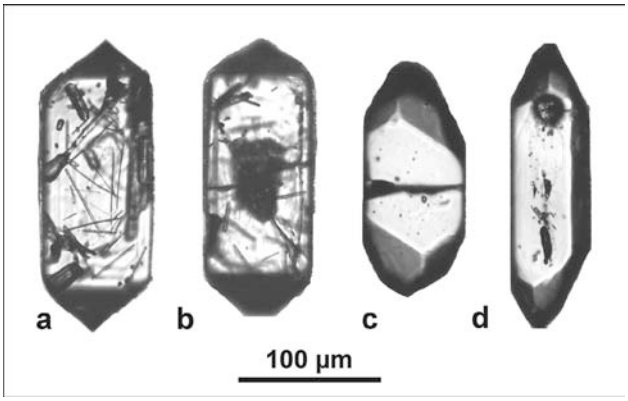

Fig. 1: Typical zircons from Psunj granite (a, b) and Papuk S-type granites (c, d).

Zircons in the Papuk granites are short prismatic to normal prismatic, with prominent steep pyramids {211} and a dominance of the {110} prism (Fig. 1c, d). Short prismatic crystals often contain a large inherited core with bright CL signal, mantled by an oscillatory zoned outer growth shell. Zircon types are consistent with the interpretation of [1], according to which the granites from Papuk have an S-type origin.

Zircon growth in granulites: relationship to metamorphic mineral formation (Irkut block of Sharyzhalgai Uplift)

Sukhorukov, V.P.* & Urmantseva, L.N.
Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (*svp@uiggm.nsc.ru)

The Irkut block is the SW part of the Sharyzhylgai Uplift of the Siberian Craton. Metamorphic complex of the Irkut block is composed of metasedimentary and metavolcanic rocks. The available data indicate that the magmatic protoliths were undergone at least two stages of metamorphism during Neoarchean (2.55-2.57 Ga) and Palaeoproterozoic (1.85-1.87 Ga) [1-3]. In turn, in metasedimentary gneisses detrital zircon cores with ages of 2.7, 2.3 and 1.95-2.0 Ga were found. Metamorphic rims of these cores yield the age interval between 1.85 and 1.95 Ga [4]. Therefore it can be concluded that the sediments deposition occurred 1.95-1.85 Ga. For better understanding of relationship between the zircon growth and metamorphic conditions is necessary to study the mineral paragenesis and zircon's REE composition as well.

Metasedimentary rocks are represented by migmatites with mineral assemblage Grt+Crd+Sil+Bt+Kfs+Pl+Qtz. Leucosome composed of Kfs+Qtz+Pl+Grt+Bt is characterized by magmatic structure. Melanosome is represented by mineral association Grt+Crd+Sil+And+Bt+Sp+Crn+Kfs+Pl+Qtz+Ilm+Mt with accessory Rt, Zrn, Mnz. Several types of reaction structures are developed in rocks: 1) Spl is surrounded with Sil rim and located into Crd grains. 2) Bt within Crd grains is replaced by Sil and Ilm with formation of pseudomorphoses. 3) Crd grains are surrounded with Grt rims with inclusions of Sil. 4) Crn grains always contact with Mt and Spl located within Bt. We suggest mineral reactions Crd→Grt+Sil+Qtz; Bt+Crd+Spl→ Grt+Sil+Ksp+Ilm; Sp→Mt+Crn on the base of observed reaction structures. Therefore reaction structures observed in the rock have been formed at progressive stage of metamorphism [5]. PT – parameters of metamorphism was obtained using mineralogical geothermobarometers and TWQ and THERMOCALC programmes. Compositions of contacting Crd and Grt grains were used for PT – estimations. The F value (Fe/(Fe+Mg)) of Grt increases from 0.68 in the center to 0.73 on the rim of grain, the F of Grt decreases from 0.23 to 0.17 in direction to the contact with Grt. PT – parameters of regressive stage of metamophism was 600°C at 5.8-6 kbar. It has been obtained using contacting rims of cordierite and garnet. Values about 700°C at 6.5 kbar was obtained using inner parts of grains are close to the peak of metamorphism.

Zircon detrital cores are characterized by HREE enrichment ($(Lu/Gd)_n$=9-24). They have positive Ce (Ce/Ce*=2.4-5.3) and negative Eu (Eu/Eu*=0.1-0.3) anomalies and high Y concentrations (551-999 ppm) typical in magmatic zircons. Metamorphic rims show lower HREE concentrations ($(Lu/Gd)_n$=0.9-2.6), Y contents (131-290 ppm). Also there is LREE concentrations similar to the cores but differ by weaker Ce anomaly (Ce/Ce*=1.2-3.9). The sharp decreasing of HREE contents in metamorphic rims is typical for zircons formed during high grade metamorphism. It can be considered as a result of the concurrent Grt crystallization at PT-conditions close to peak of metamorphism.

Mixing of karstic and basinal fluids affecting hypogene cave formation and mineralization in the Buda Thermal Karst, Hungary

Poros, Zs.[1,2*], Erőss, A.[1], Mádl-Szőnyi, J.[1], Mindszenty, A.[1], Molnár, F.[2], Ronchi, P.[3] & Csoma, A. É.[4]
[1]Dept. of Physical and Applied Geology, Eötvös L. University, Budapest, Hungary ([*]poroszsofi@gmail.com)
[2]Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary
[3]ENI S.p.A. Exploration & Production Division, S. Donato Milanese, Italy
[4]Shell International E&P, The Netherlands, currently ConocoPhillips Upstream Technologies

The Buda Thermal Karst (BTK) is located at the boundary of uplifted Mesozoic-Tertiary carbonates and the adjacent sedimentary basin with carbonatic basement. Being a "marginal" area, the BTK serves as the discharge zone of regional fluid flow. This implies that it may receive fluid components from several sources, resulting in a wide range of discharge features, including springs, caves and mineral precipitates.

Recent- and palaeo-hydrogeology were studied in parallel, to understand the effects of palaeo-fluid migration on the recent hydrogeological setting and the distribution and development of the extensive hypogene cave-systems in the BTK. On the basis of geochemical analyses of recent waters, petrography and fluid inclusion analyses of palaeo-precipitates (calcite and barite), three types of fluids from different sources were distinguished: (i) regional karst water, (ii) local karst water and (iii) basinal fluid. The basinal contribution to the BTK from the East was suggested first by Alföldi [1], whose hypothesis was confirmed by the present study. Moreover, based on the HC indications detected in both palaeo- and recent waters it is proposed that the basinal contribution had been continuous from the late Middle Miocene. The age of initiation of basinal fluid migration to the Buda Hills was estimated by structural geological considerations and fluid inclusion data. Compressional tectonics (inversion of the Pannonian Basin) has been maintaining flow from the basin side up to now.

Changes in mineral assemblages and paragenesis, as well as an increase in dissolution at the expense of precipitation from the Miocene to present suggest an evolving groundwater system in which the proportion of karst waters increased at the expense of the basinal component. The increase likely has been the result of accelerating Neogene uplift and gradual exposure of the Mesozoic-Tertiary carbonates.

Along with the omnipresent calcite, in the Miocene, barite was the only sulphate mineral in the paragenesis, while recently gypsum is the predominant sulphate phase with minor amounts of barite. This change may indicate that originally there were equal amounts of Ba and S in the fluid, however, later on S of different origin must have been added to the system, resulting in the precipitation of gypsum following the barite. This assumption was confirmed by $\delta^{34}S$ values measured in the sulphate minerals. Barite showed positive values restricted to a rather narrow interval (22.7–27.6‰), while gypsum precipitates of various morphologies are characterised by negative values with a much wider range (-32.3 – -1‰). Microbial activity was detected in the case of the recent precipitates that may explain the occasional extreme negative $\delta^{34}S$ values.

Cave formation in the BTK has been most likely influenced by the complex hydrogeological system and the various fluid components. In addition to the frequently mentioned mixing corrosion, other processes might have been effective in dissolution, e.g. aggressive gases (H_2S, CO_2) from the basin fluids, the presence of microbial activity, or the cooling of upwelling waters.

The present day genesis and evolution of cave minerals inside the Ojo de la Reina cave (Naica Mine, Mexico)

Badino, G.[1], Calaforra, J.M.[2], Forti, P.[3*], Garofalo, P.[4] & Sanna, L.[3]
[1]Dept. of Physics, University of Torino, Italy
[2]Dept. of Geological Sciences, University of Almeria, Spain
[3]Italian Institute of Speleology, University of Bologna, Italy ([*]paolo.forti@unibo.it)
[4]Dept. of Earth and Geological-Environmental Sciences, University of Bologna, Italy

The Naica caves and their amazing gypsum crystals were discovered almost a century ago inside a silver mine in the state of Chihuahua (Mexico). From 2000 to 2008 mining activities at -290 met 4 small caves hosting the largest gypsum crystal of the world. Ojo de la Reina is one of the smallest caves, therefore it was the first cavity in which the lowering of temperature induced by ventilation caused condensation since 2006. The consequent dissolution of the gypsum crystals and subsequent evaporation lead to the deposition of several new diagenetic minerals, among which some highly soluble Mg/Na compounds (Blödite, Halite, Epsomite, Hexahydrite, Kieserite, Starkeyite), the presence of which in a extremely moist environment was completely unexpected. Moreover no evident source for Mg and Na ions is available within the cave because its entire walls are completely covered by the giant gypsum crystals. The study proved that their existence is the consequence of several boundary conditions, the most important of which may be summarized as follow. During the process of cooling down thermal stresses induced the slight opening of the main exfoliation planes (010) within the giant crystals. When the dew point was reached, the strong uplift of hot moist air was forced to condensate over the cold crystal surfaces, the preferential place where this phenomenon occurs being just inside the widened exfoliation planes. Here the capillary flow brings the unsaturated water to dissolve gypsum deep inside the crystals, until some of the giant fluid inclusions (the only possible source for Mg and Na ions) just along these planes are reached. Thus the Mg/Na rich fluids stored inside them have the possibility to drip outside the crystals, giving rise to small pools in the depression between two or more crystals on the cave floor. Finally the strong air current flowing within the cave causes the total evaporation of these pools, thus the very soluble salts are deposited as whitish powder.

Peculiar minerogenetic mechanisms occurring in the cavern environment

Forti, P.
Italian Institute of Speleology, University of Bologna, Italy
(paolo.forti@unibo.it)

Caves are among the longest-lasting components of the environment and throughout their complete lifespan they act as accumulation traps for physical, biological and chemical deposits. Perhaps man's first motivation to explore caves was the search for substances that were not available elsewhere: most of them were minerals. Anyway the genesis of many of the minerals found in caves is unrelated to the existence of the cavern itself: in fact often they were brought inside by flowing water or exposed by corrosion on the cave walls. By definition a cave mineral is a secondary mineral developed within a natural cave due to the peculiar environmental conditions existing there. For a long time it was believed that the cavern environment was scarcely interesting from the mineralogical point of view. This was because most cave deposits are normally made of a single compound: calcium carbonate. Therefore the systematic study of cave mineralogy started only recently, but although only a limited number of natural cavities have been analysed in detail, more than 350 cave minerals have already been observed, some of which are new to science. Each year some new cave minerals are found somewhere. The presence of such unexpected richness is obviously the direct consequence of the variety of the different formations crossed by water before entering a cave, but there is much more. The different cavern environments allow the development of several minerogenetic mechanisms, the most important of which are: sublimation, deposition from aerosols and vapours, evaporation, diffusion, oxidation, hydration-dehydration, double exchange, digestion, self-combustion, segregation. Most of them are strictly controlled by the cavern temperature, while some are driven by micro-organisms. Each of them gives rise to different cave minerals and/or different forms of the same chemical deposit. Sometimes the cavern environment, due its stability lasting over long time periods, allows for the development of huge euhedral crystals like those found in the Naica caves (Chihuahua, Mexico), but the presence of extremely small complex aggregates of different minerals is by far more common. Future development in the field of cave mineralogy will be focused mainly on hydrothermal caves and on the role played by micro-organisms in controlling some of the most important cave minerogenetic processes. In conclusion, the recent studies proved that the cavern environment is surely one of the most complex and interesting minerogenetic environments on our planet.

Secondary minerals inside the Argentiera mine galleries (Nurra region, NW Sardinia, Italy)

Ara, D.[1], De Waele, J.[2*], Galli, E.[3], Rossi, A.[3] & Sanna, L.[1]
[1]Gruppo Speleo Ambientale Sassari, Sassari, Italy
[2] University of Bologna, Italy ([*]jo.dewaele@unibo.it)
[3]Dept of Earth Sciences, University of Modena and Reggio Emilia, Modena, Italy

The Pb-Zn-Ag-Sb deposit of the Argentiera mine has been known since the Roman times. Furthermore, this one of the most important silver mines of Sardinia, Italy hosted within late-Hercynian veins that cut into a Palaeozoic basement (Silurian graphite-siderite rich finely laminated phyllites of black shale facies and pinkish metasandstones). During the last century, the extensive mining activities dug deep shafts and several kilometres of galleries at different levels. In 1963, the mineral exploitation was not economical and production at the mine ceased. This study focuses on the secondary minerals (crusts or coatings) and speleothems (stalactites, flowstones, and gours) formed in a strongly oxidizing environment in the ancient mine galleries in atmospheric conditions similar to those found inside caves. Mineral samples were collected on wooden supports, on abandoned equipment, and on the rock wall inside the main mine galleries: Pozzo Alda (PA), Fornello Centrale di Ripiena (GA), and Miniera Vecchia (MV). In addition, mineral samples were collected in small exploration galleries along the coast (SAG). A detailed analysis of all the samples under stereoscopic microscope was performed to distinguish and to separate the different mineralogical phases present. Then the single phases were analyzed by an X-ray diffractometer (Philips PW 1050/25) when the material was sufficient enough and homogeneous. A Gandolfi camera (Ø: 114.6 mm, exposition: 24/48 hrs) was used for analyses when the material was scarce or inhomogeneous. In all mineral analysis, the experimental conditions used in the Philips PW were a 40Kv and 20 mA tube and CuKα Ni filtered radiation (λ = 1.5418 Å). The analyses of the clay minerals were done before and after glycerine treatment. Most of the samples analyzed by Gandolfi camera were later used to obtain images and chemical qualitative analyses through an electron scanning microscope (ESEM Philips XL40) with an electronic microprobe (EDS-EDAX 9900) at the C.I.G.S. (Centro Interdipartimentale Grandi Strumenti) of the Modena and Reggio Emilia University. This research has revealed a diversity of minerals for this abandoned mine environment: about 20 crystalline phases have been observed, 11 of which are rare for the artificial caves (akaganeite, copiapite, dypingite, giorgiosite, hydromagnesite, hydrozincite, jarosite, melanterite, metavoltine, sideronatrite, and todorokite), and 2 were previously cited, but inadequately described, in the literature (giorgiosite and todorokite). Most of the detected mineral deposits are sulphates (barite, copiapite, epsomite, gypsum, jarosite, melanterite, metavoltine, and sideronatrite) and carbonates (aragonite, calcite, dypingite, giorgiosite, hydromagnesite, and hydrozincite). Also present are oxides (hematite and akaganeite), hydroxides (goethite and todorokite) and silicates (quartz, illite, feldspar). Few metallic amorphous compounds have been found. Quartz is ubiquitous as well as illite. The most uncommon mineral association (akaganeite, dypingite, giorgiosite, and hydromagnesite) grew on a derelict nail that was the source for iron and magnesium. The development of some metallic sulphates on the mine wall is the direct consequence of the oxidation of the polysulphides dispersed in the host rock. The minerogenetic processes are driven by small volumes of water flowing, dripping, or condensing over the mine equipment/wall and are strictly related to the evaporation induced by the ventilation of the mine tunnel network. All the minerals developed in a short interval of time (in a few tens of years) while others are seasonal (i.e., epsomite).

Speleothems in the Gamslöcher-Kolowrat Cave System, Untersberg (Austria)

Bieniok, A.[1*], Zagler, G.[2] & Brendel, U.[2]
[1]Dept. of Materials Research & Physics, University of Salzburg, Austria ([*]anna.bieniok@sbg.ac.at)
[2]Landesverein für Höhlenkunde, Salzburg, Austria

The Untersberg is a 70 km^2 large karst massif southwest of Salzburg in Austria. It belongs to the upper Juvavikum of the Northern Calcareous Alps and consists mainly out of dolomite (Ramsaudolomite) and limestone (Dachstein-, Hierlatz-, Plassenkalk). The karst plateau (1500 m to 1970 m) is characterized by dolines, shafts and pits. More than 300 caves are described from the Untersberg massif, some of them with remarkable depths [1,2].

One famous Untersberg cave is the Kolowrat Cave, known since 1842 for adventurously ice skating. In 1979 a connection to the Gamslöcher Cave and in 2004 to the Salzburgerschacht have been found [3], comprising a large cave system of 34 km length. Dripstone formations are rare in the Gamslöcher-Kolowrat Cave system; their occurrences are rather locally limited.

Recent speleological research [4] has been carried out in the Kolowrat Cave at ca. 1000 m, discovering unexpectedly dry parts, which hardly resemble the other parts of the cave. Low passages alternate with large halls of 10 to 40 m in height over a total length of 4 km. The inner part of the labyrinth does not show any indications of flowing water. The area is characterized by a stronger air current, compared to any other part of the cave, and it is rich in speleothems. Samples of white coloured minerals with different morphologies were collected and later analyzed by X-ray diffraction.

Needle-like minerals (e.g. gypsum) are dominating the transition zone of the dry section. Within the dry zone gypsum also occurs as white crusts composed of skeletal crystals. In the windy corridors calcite is the main speleothem, but it occurs in a snowflake-like form with a remarkably low density of 75 kg/m^3. The rock walls are covered by this white dusty coatings and the air is filled with calcite flakes. In the 'White Hall' near the central part of the dry zone, thenardite Na_2SO_4 was found. Thenardite in association with its hydrated form mirabilite was described earlier from the Salzburgerschacht (Untersberg) but in a quite different environment and with different morphology [2]. Another cave mineral, which was described earlier from the Salzburgerschacht is hydromagnesite $Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$. It occurs here as hard, white, cauliflower-like crusts, associated with aragonite.

The cause for the development of the dry parts in the Gamslöcher-Kolowrat Cave system is not yet clear. Further explorations are planned to get better insight into this part of the cave system.

High-resolution trace-element data from a Sardinian flowstone as evidence of environmental change

Caddeo, G.A.[1], Railsback, L.B.[2], Frau, F.[1] & De Waele, J.[3*]
[1]Dipto. di Scienze della Terra, Università degli Studi di Cagliari, Italy
[2]Dept. of Geology, University of Georgia, Athens (GA), USA
[3]Dipto. di Scienze della Terra e Geologico-Ambientali, Università di Bologna, Italy ([*]jo.dewaele@unibo.it)

In a study of many speleothems from southern Sardinia (Italy), a highly variable flowstone has been analysed by X-ray diffraction, Scanning Electron Microscopy / Energy Dispersive X-ray Spectroscopy and Laser Ablation-ICP-MS. This flowstone is from a natural cave intercepted by San Giovanni mine (Iglesias), which exploited Pb and Zn sulfides. Most of the sample is composed of alternating layers of blue-green and light aragonite. Beneath the aragonite, at the base of the sample, primary brown calcite is found. In the upper part of the sample, an irregular section of secondary light calcite has partially replaced some blue and light aragonite.

Mg concentration in the primary calcite increases strongly toward the lowest aragonite, reaching its maximum value of 5 mol% $MgCO_3$ just below the latter. Concentrations of Zn, Cu, Sr, and Ba also increase upward in the calcite, reaching about 1 mol% $ZnCO_3$. Increasing concentration of Mg in a speleothem is commonly attributed to upstream precipitation of calcite and resultant increase of the solution's Mg/Ca ratio [1,2]. That may be the case here, but a residual solution should be depleted of Zn and Cu, rather than enriched, because their partition coefficients in calcite are more than 1, opposite those of Mg, Sr and Ba. We hypothesize that the increase in Zn and Cu was driven by more extensive oxidation of sulfides in the overlying ore deposit during a change to drier conditions that favoured higher saturation states and more thorough precipitation of $CaCO_3$.

Concentrations of many elements change abruptly at the transition from calcite to aragonite. Mg, Zn and Cu concentrations decrease, and Ba and Sr increase, because of the difference in distribution coefficients for these elements in calcite and aragonite. The aragonite layer can be divided in two sublayers on the basis of Pb content, with the higher sublayer much richer in Pb. The transition from the first to second sublayer of aragonite is very evident in backscatter-SEM images because of a sharp increase of brightness. In some minor horizons of the second aragonite sublayer, small crystals of cerussite ($PbCO_3$) were observed. We attribute this increase in Pb content to oxidation of Pb sulfides and mobilization in descending waters, and thus as a continuation of the trend noted with regard to Zn and Cu in calcite.

Secondary calcite shows much lower Mg concentration with respect to primary one. Instead, Sr is greater in secondary calcite probably because Sr was inherited from the precursor aragonite.

Morphology and genesis of halite cave deposits in the Iranian salt karst

Filippi, M.[1*], Bruthans, J.[2] & Palatinus, L.[3]
[1]Inst. of Geology, Academy of Science, v.v.i., Prague, Czech Republic ([*]filippi@gli.cas.cz)
[2]Charles University in Prague, Faculty of Science, Czech Republic
[3]Inst. of Physics, Academy of Science, v.v.i., Prague, Czech Republic

South-western Iran represents area with the highest number of piercing salt diapirs in the world. Tens of diapirs offer variability of well developed karst phenomena, including countless salt caves. Various types of halite cave deposits were observed in these caves. This contribution characterizes them from the morphological and genetic point of view.

Among the numerous forms of halite cave deposits found in the Iranian salt karst the following types were observed as most abundant: a) euhedral crystals and their clusters, b) macrocrystalline speleothems, c) microcrystalline (fine grained) speleothems, d) straw (tubular) stalactites, and e) filamentary speleothems (helictites). A new and unusual subtype of macrocrystalline halite formations (form b) was recognized – the „skeletal" speleothems with more or less regularly developed shape. They consist of a central column composed of adjacent cubes stacked along their body diagonal. Other stair-step organized cubes grow away down-dip from the cube surfaces (Fig. 1).

Fig. 1: Macrocrystalline skeletal stalactite.

The occurrence of particular forms depends strongly on the environment, especially on the type of the water (brine) flow (capillary water, gravity driven flow, splashing water), flow-rate intensity and oscillation, evaporation rate and in some cases on air direction. Therefore, combined or transitional speleothem formations may be observed, if the conditions change during the deposition. Euhedral halite crystals and clusters originate solely below the water table of supersaturated streams and lakes. Macrocrystalline and skeletal speleothems occur at places with rich irregular dripping and splashing (i.e., waterfalls, places with strong dripping from the cave ceilings, etc.). Microcrystalline (fine grained) speleothems are generated by evaporation of capillary water at places where water is not present in a macroscopically visible form. These forms with laminated internal structure are the most widespread secondary halite deposits in all caves. Straw stalactites form at places where dripping is concentrated into small spots and is frequent enough to assure that the tip of stalactite will not overgrow by halite precipitates. In case the tip is blocked by halite precipitates, brine remaining in the straw will seep through the walls and helictites start to grow in some places.

The macrocrystalline and skeletal forms and straw stalactites usually grow after the rains when dripping is strong, while the microcrystalline speleothems are formed continuously during much longer periods and ultimately, (usually) overgrow the other types of speleothems during dry periods.

Mineralogical investigation of cave rims and vents in Cova des Pas de Vallgornera (Mallorca Island, Spain)

Hunt, G.A.[1*], Merino, A.[2], Fornós, J.J.[3], Onac, B.P.[1,4], Ginés, J.[2,3] & Ginés, A.[2,3]
[1]Dept. of Geology, University of South Florida, Tampa, Florida, USA ([*]gahunt2@mail.usf.edu)
[2]Federació Balear d'Espeleologia, Palma de Mallorca, Spain
[3]Dept. de Ciències de la Terra, Universitat de les Illes Balears, Palma de Mallorca, Spain
[4]"Babeş-Bolyai" University Cluj/"Emil Racoviţă" Institute of Speleology, Cluj, Romania

Recent exploration of Cova des Pas de Vallgornera, a coastal cave located in the southern region of the island of Mallorca, has revealed rim features surrounding vents and cracks which connect upper and lower levels of the cave [1]. The mineral assemblage of the rims consists not only of minerals common to limestone/dolostone caves (e.g., calcite, aragonite, gypsum, huntite, dolomite, and goethite), but also of unexpected hydrothermal-related minerals (e.g., strontianite, celestine, barite, and nordstrandite) [2,3].

Fig. 1: Typical vertical vent and mineral rim (view is from above).

The vents in this cave allow air movement that results in condensation corrosion and mineral precipitation as described by Audra [4]. Two vent morphologies exist in Cova des Pas de Vallgornera: simple vertical cracks or dissolution pipes and complex horizontal dissolution features. Vertical vents (Fig. 1) are small, internally smooth, lined with weathered limestone and mineral deposits and connect an upper air-filled chamber with a lower chamber at the level of the water table [3]. Horizontal vents may be large enough for human entry, are lined with precipitated minerals and may contain secondary vertical vents with mineral rims [3].

When considered alongside discrete dissolution features distributed throughout the cave's galleries and passages, the unexpected suite of hydrothermal minerals supports a partial hypogenic origin in addition to the initially deduced mixing zone dissolution typical of coastal caves such as Cova des Pas de Vallgornera [3,5].

Allophane-like deposits in Izvor Cave (NW Romania)

Onac, B.P.[1,2*], Provencio, P.[3] & Polyak, V.J.[4]
[1]Dept. of Geology, University of South Florida, Tampa, USA ([*]bonac@usf.edu)
[2]Dept. of Geology, Babeş-Bolyai University/Emil Racoviţă Institute of Speleology, Cluj Napoca, Romania
[3]Sandia National Laboratories, Albuquerque, New Mexico, USA
[4]Dept. of Earth & Planetary Sciences, University of New Mexico, Albuquerque, New Mexico, USA

Izvor (Spring) Cave, located in the Padurea Craiului Mountains (NW Romania), is formed in middle Triassic limestone that is overlain by early Jurassic micro-conglomerates and sandstones rich in biogenic sulfides. The length of the cave is approximately 230 m with a shallow water underground stream that is present throughout most of the cave [1]. In the main chamber, the stream forms several large, shallow pools. The stream bed (including the breakdown blocks) is covered along its entire length by a thick, white to slightly yellowish gel-like material. The thickness of the deposit varies from a few millimeters up to 5-6 cm on the sides of the pools. The pH of the water is acidic (4.3 to 5.2) and its mean electric conductivity value is 1127 µS/cm. The chemical composition of the gel-like material is dominated by Al_2O_3 (> 45%), SiO_2 (7-9.2%), SO_3 (12.9-14.0%), K_2O (~1.5%), and Fe_2O_3 (~1.25%). The mean $\delta^{34}S$ value of this compound is -20.1‰.

A sample of this white deposit, amorphous to x-ray diffraction, consists of submicron-sized particles, ranging from 0.05 to 0.2 µm. High resolution transmission electron microscopy (HRTEM) imaging shows an amorphous-like nature with some short-range crystalline structure. Small nm-sized domains of lattice fringes, ranging from 5 to 10 nm, yielded electron diffraction spots (Fig. 1). Generally, broad electron diffraction rings were observed.

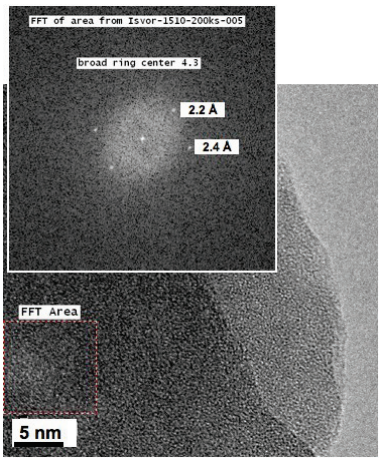

Fig. 1: Short-range crystalline structure in the white deposit from Izvor Cave.

This white deposit from Izvor Cave is similar in occurrence and composition to an allophane-like compound earlier described in a nearby cave [2]. The negative δ34S values suggest oxidation of biogenic sulfides (mainly pyrite) as the main source of sulphate in this material. Al, Si, Fe, and K are probably leached by acidic waters from the fireclay mines located in the vicinity of the cave. While this material seems amorphous, HRTEM shows some crystalline structure indicating that it might be a not yet identified or new mineral.

Rapidcreekite, $Ca_2(SO_4)(CO_3)•4H_2O$, in the H_2S-rich environment of Diana Cave (Romania)

Onac, B.P.[1,2*] & Effenberger, H.S.[3]
[1]Dept. of Geology, University of South Florida, Tampa, USA
([*]bonac@usf.edu)
[2]Dept. of Geology, Babeş-Bolyai University/Emil Racoviţă Institute of Speleology, Cluj, Romania
[3]Institute of Mineralogy and Crystallography, University of Vienna, Austria

Diana Cave, located in SW Romania, is developed along a fault line at the contact between upper Jurassic limestones and lower Cretaceous marls. The cave gives access to a hot spring (T = 42-53°C) with near-neutral pH water containing 44 mg/l SO_4^{2-}, 37 mg/l S^{2-}, 76 mg/l HCO_3^-, 107 mg/l Ca^{2+}, and 58.5 mg/l K^+, from which H_2S rises into the cave atmosphere [1-3]. The $\delta^{34}S$ values of the sulfate and sulfide in the thermal water as well as in the mineral association from Diana Cave range from 18 to 19.5‰ [3].

Rapidcreekite, ideally $Ca_2(SO_4)(CO_3)•4H_2O$, is one of a suite of secondary, hydrated sulfate minerals reportedly formed by oxidation of hydrogen sulfide degassing from the thermal water in Diana Cave. To date, this mineral was documented in only two other locations worldwide [4,5]. In Diana Cave, rapidcreekite commonly occurs as radiating sprays of white to colorless acicular crystals, closely associated with minerals of the halotrichite group. Precise single crystal X-ray diffraction analysis combined with micro-chemical and scanning electron microscope investigations enabled us to characterize this rare mineral species. This is the first time rapidcreekite is documented in a cave environment. Stable sulfur isotopic results reported in this presentation will shed light on the redox processes, the source of dissolved sulfur in the hot water of Diana Cave, and the precipitation of rapidcreekite in this unique thermo-mineral cave.

Revisiting three minerals from Cioclovina Cave (Romania)

Onac, B.P.[1,2*], Kearns, B.J.[3], Effenberger, H.S.[4] & Collins, N.C.[1]
[1]Dept. of Geology, University of South Florida, Tampa, USA
([*]bonac@usf.edu)
[2]Dept. of Geology, Babes-Bolyai University/Emil Racovita Institute of Speleology, Cluj, Romania
[3]Materials Research Institute, Pennsylvania State University, USA
[4]Institute of Mineralogy and Crystallography, University of Vienna, Austria

Cioclovina Cave, in Romania's Southern Carpathians, is a world renowned cave site for its paleontological, anthropological, and mineraological (type locality of *ardealite*) findings [1,2]. During the cave evolution, large amounts of allogenic sediments were deposited along the main cave passage. At times of low flow conditions, thick guano layers accumulated on top of the siliciclastic deposits. Subsequently, washed-in sediments buried each of these organic layers. Due to the presence of interbedded guano material, the sandy-silty sediments were highly phosphatized (~35% P_2O_5) generating within them and at the contact with the limestone bedrock a suite of interesting minerals. To date, over 20 mineral species have been documented, some of these rather unusual for the cave environment [3-6].

This paper presents details on the occurrence of collinsite [$Ca_2(Mg,Fe^{2+})(PO_4)_2·2H_2O$], atacamite [$Cu_2^{2+}Cl(OH)_3$], and kröhnkite [$Na_2Cu^{2+}(SO_4)_2·2H_2O$] based on single crystal X-ray diffraction, electron microprobe analyses, and scanning electron microscope imaging. Collinsite occurs near the entrance in the *Bivouac Room* and is closely associated with apatite-(CaOH)-rich crusts in the upper part of the sedimentary sequence. The collinsite crystals line millimeter-sized dissolution cavities developed within the apatite-(CaOH) crusts. Atacamite and kröhnkite were collected just outside the *Bivouac Room* at its southern edge. Both minerals were identified within a thick layer of white-yellowish brushite. Atacamite (mismatched with paratacamite in our previous powder diffraction) forms delicate and crumbly greenish nodules (millimeter size in diameter) and represents the weathering product (in the presence of chlorine from meteoric water) of copper minerals washed into the cave from nearby ore deposit. Kröhnkite forms sky blue platy crusts (sub-millimeter thick) in the vicinity of atacamite and around minute crystals of gypsum. It was found at a depth of 25 to 35 cm below the sediment surface and is highly soluble when it comes in contact with dripping water. As the case of atacamite, in kröhnkite copper comes from the outside ore deposit, whereas the sodium originated from clay minerals.

Peculiarities of gypsum in the Great Cave from Şălitrari Mountain (SW Romania)

Puşcaş, C.M.[1,2*], Onac, B.P.[1,2,3], Tămaş, T.[2,3] & Kearns, B.J.[4]
[1]Dept. of Geology, University of South Florida, Tampa, USA ([*]cpuscas@mail.usf.edu)
[2]Dept. of Geology, Babeş-Bolyai University, Cluj-Napoca, Romania
[3]Emil Racoviţă Institute of Speleology, Cluj-Napoca, Romania
[4]Materials Research Institute, Pennsylvania State University, USA

Several caves situated along the Cerna Valley (SW Romania) have formed under complex settings involving epigene, phreatic, and hypogene speleogenetic phases. Only a few of these caves, in particular the Great Cave from the Şălitrari Mountain (GCSM), host a rich variety of mineral associations. Detailed presentations of the mineral species discovered in this cave have been presented in [1,2]. This paper reports unusual patterns of gypsum occurrences throughout the GCSM and how these features shed light on the cave's speleogenesis.

The Main Passage (MP) and Nitrate Passage (NP) in GCSM display the highest mineralogical variety. The MP exhibits a transition from surface climate (near the cave entrance) to an anomalously warm and dry (11.7°C and 75% RH) climate in the NP. Except for these two sectors, the cave atmosphere throughout the Final Passage (FP) and Speo-Timiş Passage (SP) is cooler (~10ºC) with a constant relative humidity of ~99%. Gypsum in the MP occurs predominantly as thin crusts on the walls and in the alluvial sediment sequence as nodules or micro-crystals. In the FP, where clastic sediments are absent, gypsum forms crusts on the walls and aggregates on the floor, whilst in the SP it is completely absent.

Based on $\delta^{34}S$ ratios of gypsum, darapskite, and alunite from the NP [1] and stable isotope mass balance calculations, the origin of sulfate in solution can be traced back to a marine sedimentary source [4]. Redox reactions in the presence of ascending thermo-mineral waters, mediated by bacterial activity led to the precipitation of SO_4-bearing minerals with $\delta^{34}S$ values between -2.6‰ and 6.5‰ (NP) [1, 3], similar to the sulfur isotope ratios of modern sulfates from the present-day H_2S-rich caves in the region [1]. The $\delta^{34}S$ value of gypsum from the MP is -19.8‰, leading us to conclude that it originated from the oxidation of biogenic pyrite nodules disseminated either within the limestone bedrock or from the alluvial sediments. The lack of sulfate minerals in the SP can be explained by considering it the youngest section of the cave, unaffected by hypogene fluids.

Hypogene speleogenesis has certainly played an important role in the evolution of GCSM [1-3], but the three main passages were either affected in different ways by hypogene fluids or developed within different time intervals. Thus, evidence for thermo-mineral fluids affecting these parts of the cave has now been documented.

A Late Holocene cave ice geochemical record of atmospheric metal deposition in the Apuseni Mountains, Romania

Vereş, D.[1*], Onac, B.P.[2,3,1], Perşoiu, A.[2] & Atlas, Z.D.[2]
[1]"Emil Racovita" Institute of Speleology, Cluj-Napoca, Romania ([*]danveres@hasdeu.ubbcluj.ro)
[2]Dept. of Geology, University of South Florida, Tampa, USA
[3]Dept. of Geology, Babes-Bolyai University, Cluj Napoca, Romania

Independent sedimentary records of air-borne metals may provide a strong basis for investigating the development of mining and metallurgy through time. Here we report the initial results of a geochemical investigation of approximately two thousand year old ice-core section recovered from Scărişoara Cave, Apuseni Mountains, Romania. Trace metals in melted ice relevant to historical mining techniques (Cu, Pb, As, Sb, Sn, Au, Pd, Pt, Rh, etc.) were determined at high resolution by ICP-MS. The ~26 m thick ice deposit from Scărişoara Cave, archives a detailed atmospheric deposition record of volatized metals, fly ashes and other particulates related to mining and smelting activities in the nearby mining fields. It could provide one of the first long records of anthropogenic pollution in Romania; the trends in most metals seem to reflect various pollution events related to historical episodes of mining and smelting of the region's widespread polymetallic ores. The new data could have immediate implications in better constraining the magnitude and extent of mining activities and anthropogenic impact in the well-known mining districts of Transylvania. This work is part of on-going efforts by the authors to explicitly document the anthropogenic impact and the long-term mining and metallurgical history of this region in a securely-dated, multi-proxy approach. Lead isotope studies are on-going and the new data are expected to provide an accurate evaluation of metal sources and clear insights into the developments of metallurgy in one of the oldest mining regions of Europe.

The crystal chemistry of the dumortierite group

Groat, L.A.[1*], Grew, E.S.[2], Evans, R.J.[1], Pieczka, A.[3] & Ercit, T.S.[4]
[1]Dept. of Earth and Ocean Sciences, University of British Columbia, Vancouver, Canada ([*]lgroat@eos.ubc.ca)
[2]Dept. of Earth Sciences, University of Maine, Orono, Maine, USA
[3]Dept. of Mineralogy, Petrography, and Geochemistry, AGH-University of Science and Technology, Krakow, Poland
[4]Canadian Museum of Nature, Research Division, Ottawa, Ontario, Canada

The dumortierite group comprises dumortierite [c. $(Al,\square)Al_6(BO_3)Si_3O_{13}(O,OH)_2$], magnesiodumortierite [c. $(Mg,\square)(Mg,Al)_6(BO_3)Si_3O_{13}(O,OH)_2$], and holtite [c. $(Al,Ta,\square,)Al_6(BO_3)(Si,Sb,As)_3O_{12}(O,OH,\square)_3$]. Dumortierite may contain up to several wt% of TiO_2, Fe_2O_3, MgO, Bi_2O_3, Sb_2O_3, As_2O_3, Ta_2O_5, Nb_2O_5. In holtite the last four constituents taken together exceed 30 wt.%, although none dominate their crystallographic site. Single-crystal X-ray refinements and FTIR results suggest[1] a general formula for holtite, $Al_{7-[5x+y+z]/3}(Ta,Nb)_x\square_{[2x+y+z]/3}BSi_{3-y}(Sb,As)_yO_{18-y-z}(OH)_z$, where x is the total number of pentavalent cations, y is the total amount of Sb + As, and $z \leq y$ is the total amount of OH. Holtite compositions tend to cluster into Sb-poor and Sb-rich varieties having the approximate general formulae, respectively, $Al_{5.83}(Ta,Nb)_{0.50}\square_{0.67}BSi_{2.50}(Sb,As)_{0.50}O_{17.00}(OH)_{0.50}$, and $Al_{5.92}(Ta,Nb)_{0.25}\square_{0.83}BSi_{2.00}(Sb,As)_{1.00}O_{16.00}(OH)_{1.00}$, with Ta + Nb content not correlated with Sb + As content, which is also true of dumortierite. The crystal structure refinements do not indicate a fundamental difference in cation ordering or anion composition that might serve as a criterion for recognizing the two holtite compositions as distinct species, or for that matter, for recognizing holtite as a distinct species from dumortierite. Moreover, new analyses of dumortierite showing up to 4.30 wt.% As_2O_3, 1.51 wt.% Sb_2O_3, and 3.94 wt.% Ta_2O_5 have blurred the compositional distinctions between dumortierite, Sb-poor holtite and Sb-rich holtite, although dumortierite tends to have As > Sb. Crystal structure refinements of dumortierite samples with moderate Sb, As and/or Ta contents show very high disorder at the channel Al1 and (As,Sb) sites, much more than is seen in holtite.

A more precise definition of holtite and its distinction from dumortierite awaits detailed study of both minerals, including experiments to determine the maximum amount of As and Sb that can be accommodated in the dumortierite-holtite structure. Such a definition will have to consider differences in diffraction behaviour (i.e. presence or absence of superstructure maxima), not just changes in bulk chemistry.

Boron-bearing magnesium minerals of the humite group: chemical, IR-spectroscopic and structural data

Gerasimova, E.I.[1,2*], Kononkova, N.N.[2], Pekov, E.I.[1,2] & Zubkova, N.V.[1]
[1]Dept. of Mineralogy, Lomonosov Moscow State University, Moscow, Russia ([*]ekgera@gmail.com)
[2]Vernadsky Inst. of Geochemistry and Analytical Chemistry of Russian Academy of Sciences, Moscow, Russia

Boron is a typical impurity in the magnesium minerals of the humite group. This fact is confirmed by IR-spectroscopy and electron microprobe data. We have studied 376 samples from 108 localities and in 63 of them the boron was found in quantities which are detected by this method (> 0.1 - 0.2 wt.%). The maximum content is 4.9 wt.% B_2O_3.

We found boron in each of the five magnesium members of the humite group but it is the most common for chondrodite. Distribution of boron in crystals of humite-group minerals is typically quite irregular, frequently spotted. Two bands in the IR-spectrum of humite from Vesuvius, Italy, are assigned as corresponding to B-O stretching vibrations. Their wavenumbers are 1271 and 1323 cm^{-1} (Fig. 1); the band near 1410 cm^{-1} in some spectra of different samples is also corresponding to B-O.

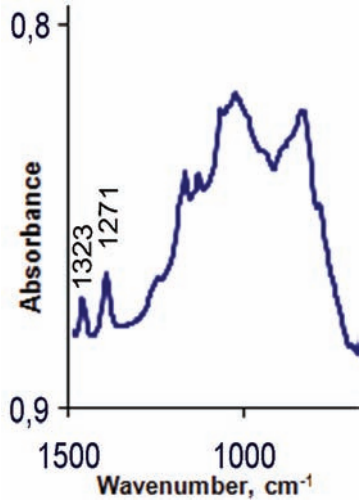

Fig. 1: IR spectrum of B-bearing humite from Vesuvius; wavenumbers of bands corresponding to B-O stretching vibrations are marked.

We assume that B occupies tetrahedral positions in humite-group minerals, together with Si. This assumption is based not only on stoichiometry (there is a Si deficiency in B-bearing samples), but also on the structural data. Refinement of the crystal structures of B-bearing humite and clinohumite showed that the tetrahedral positions are characterized by lower number of electrons than if they would be occupied only by Si. It allows to consider that B substitutes Si, according to the following scheme: Si + O <=> B + (F,OH), like in pertsevite, $Mg_2(B,Si)O_3(F,OH,O)$, a natural silicate with olivine-related structure [1].

The hard-rock isotope geochemistry of boron: obstacles and future potential

Marschall. H.R.
Dept. of Earth Sciences, University of Bristol, UK
(*Horst.Marschall@bristol.ac.uk)

Boron is a moderately volatile, lithophile non-metal with a low atomic mass and two stable isotopes (^{10}B and ^{11}B). The $^{11}B/^{10}B$ ratio in terrestrial materials is ~4, but the high relative mass difference (~10 %) of the two isotopes has produced a variation of ~100 permil in nature. The large B isotopic fractionation at low temperatures has encouraged the use of the B stable isotope system for studies of processes acting on the Earth's surface and for the detection of material altered at low-*T* in the source of fluids, and in metamorphic and magmatic rocks.

More than 25 % of the Earth's B budget is stored in the continental crust. Upper crustal rocks are typically enriched in B, while B concentrations in the mantle are very low. Boron is highly mobile in hydrous fluids and in silicate melts. Hence, the great potential of B is as an isotopic tracer for subducted material in fluids, mud volcanoes, serpentinite diapirs and mantle-derived volcanic rocks sampled in volcanic arcs, ocean islands or mid-ocean ridges.

However, the very low abundance of B in mantle rocks and primitive volcanics confronts us with a major analytical problem. B isotope analyses of silicate materials at the trace abundance level are highly challenging with fractionation and contamination being the major obstacles. The B isotopic compositions of the Earth's major reservoirs (i.e., continental crust, primitive and depleted mantle, MORB) are still poorly constrained, despite a decade-long history of B isotope geochemistry. Inter-laboratory calibration studies in the past have demonstrated that B isotope work is still a long way from routine and discrepancies between various mass spectrometric and sample-preparation methods are still significant.

First-order B isotope fractionation is governed by the coordination of B to O in minerals, melts and fluids. Boron is either trigonally or tetrahedrally coordinated to oxygen, with a strongly covalent character of B-O bonds. Experimental studies have determined the temperature dependence of B isotopic fractionation between phases of different B coordination (e.g. silicate melt, hydrous fluid, minerals), and have quantified the systematic decrease of isotopic fractionation from ambient to magmatic temperatures. Fractionation between phases containing B in identical coordination to O has also been identified. The underlying mechanisms, however, are a matter of speculation and require further investigation.

Recently, the isotope geochemistry of lithium underwent a major reinterpretation, after experimental and natural evidence had demonstrated that Li isotopes are kinetically fractionated during diffusion, outstripping the effects of equilibrium fractionation. In the case of boron, kinetic fractionation by diffusion through melts and fluids is unlikely, as B forms large complexes with O that are expected to marginalise the mass difference effect of the two B isotopes during diffusion. Experiments on B diffusion have shown that diffusive B isotope fractionation is insignificant in silicate melts, but experiments and natural studies are required to quantify potential kinetic fractionation in melt-fluid-rock systems.

In addition to studies on modern subduction systems, the strong enrichment of B in the crust and the significant difference in B isotopic compositions between continental crust, modern seawater and the depleted mantle make B a potentially powerful tracer for the *secular* evolution of the ocean-crust-mantle system, once the analytical hurdles have been cleared.

Three- and four-coordinated boron minerals in pegmatites hosted in dolomitic marble in Central Madagascar; paragenesis and boron isotopes

Pezzotta, F.[1*], Dini, A.[2] & Tonarini, S.[2]
[1]Mineralogy Section, Natural History Museum, Milan, Italy
(*fpezzotta@yahoo.com)
[2]C.N.R., Istituto di Geoscienze e Georisorse, Pisa, Italy

A number of gem-bearing granitic pegmatites of Neo Proterozoic age, hosted in the dolomitic marbles of the Itremo Formation, in central Madagascar, are characterized by exceptionally abundant boron minerals. Minerals with B in 3-fold coordination with O (3BM), dumortierite and tourmaline group minerals (dravite-elbaite-liddicoatite), and danburite with B in 4-fold coordination (4BM), formed during all stages of crystallization of the pegmatitic veins. Dravite and dumortierite are confined to the most primitive rock units; elbaite-liddicoatite and danburite formed up until the latest stages of crystallization (miarolitic zone) of the veins. The central, most evolved zone of numerous pegmatites is characterized by a suite of borates that include the 4BM rhodizite-londonite solid solution, with local strong Rb enrichments, the 4BM behierite-schiavinatoite solid solution (Ta borate and Nb borate, respectively), and, occasionally, the 3BM hambergite.

The most typical of such B-enriched pegmatites are quartzofeldspathic in composition, with significant quantities of the above listed B-minerals and spodumene. Pollucite and numerous other rare accessory phases can occur in the core zone. The narrowest veins (mostly sub-vertical fissure-like veins, only a few centimetres in width) are occasionally composed only of tourmaline-group minerals and danburite, with or without quartz, and with rare accessory rhodizite and Ta-Nb oxides. The largest veins, occasionally up to several meters in width and of sub-horizontal attitude, can contain geochemically highly evolved core zones characterized by the occurrence of abundant Li-bearing micas. Such mica-bearing units can host giant cavities containing large crystals of numerous minerals including multicoloured liddicoatite and, occasionally, danburite and rare hambergite. Rhodizite, londonite, behierite, and schiavinatoite are totally absent in such mica-bearing units.

B isotopic studies were conducted on: (1) "tourmaline", danburite, and hambergite sampled from the border zone to the mica-rich, highly evolved, core zone of the famous and large Anjanabonoina pegmatite (AJB); (2) "tourmaline", danburite, rhodizite-londonite, and behierite-schiavinatoite sampled in the border zone and in the highly evolved core zone (mica free) of two representative pegmatites, in the Tetezantsio area (TTZ).

For primitive rock units, the results indicate for AJB: $\delta^{11}B_{dravite}$ 4.70‰ and $\delta^{11}B_{danburite}$ -0.83‰; and for TTZ: $\delta^{11}B_{dravite\text{-}elbaite}$ -2.33‰ and $\delta^{11}B_{danburite}$ -8.45‰.

For zoned crystals of "tourmaline" from AJB formed in pegmatitic units of intermediate geochemical evolution, $\delta^{11}B$ is homogeneous with values between 6.21 and 7.38‰. Cogenetic hambergite crystals have similar values ($\delta^{11}B$ 7.02‰).

For the most evolved rocks from AJB: $\delta^{11}B_{elbaite\text{-}schorl\ core}$ 6.94‰ and $\delta^{11}B_{liddicoatite\ rim}$ 14.72‰ and $\delta^{11}B_{danburite}$ from -0.26‰ to 8.03‰ $_{(rim)}$; and for TTZ: $\delta^{11}B_{elbaite\text{-}liddicoatite}$ 0.60‰, $\delta^{11}B_{danburite}$ -6.72‰, $\delta^{11}B_{rhodizite}$ -6.93‰, $\delta^{11}B_{behierite}$ -10.70‰.

These data indicate that cogenetic 3BM ("tourmaline", hambergite) and cogenetic 4BM (danburite, rhodizite, behierite) represent two distinct B isotopic populations, characterized by rather homogeneous values, with $\delta^{11}B$ of 4BM systematically shifted to lower values with respect to the cogenetic 3BM. Whatever was the nature of the crystallizing medium, the data reported above indicate that an isotopic fractionation process occurred in response of the distinct boron coordination in the two major minerals, "tourmaline" and danburite.

Boron isotopes in tourmaline of dravite–schorl series from granitic pegmatites of the Moldanubian Zone, Czech Republic

Míková, J.[1], Novák, M.[2*] & Janoušek, V.[1]
[1]Czech Geolological Survey, Prague, Czech Republic
[2]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic ([*]mnovak@sci.muni.cz)

Prismatic tourmaline sections cut perpendicular to c axis from three groups of granitic pegmatites distinct in mineralogy, geological setting and origin were examined using EMPA and SIMS. (i) Homogeneous Tur occurs in the simple mineral assemblage Kfs+Qtz+Ab±Bt of metaluminous, intragranitic, NYF pegmatites derived from the ultrapotassic, quartz syenitic–melagranitic Třebíč Pluton [1]. (ii) Tourmaline associated with the assemblage Kfs+Qtz+Ab+Ms±Crd, And, Bt was obtained from peraluminous, LCT pegmatites cutting the HT felsic granulites of the Bory Massif [2]. (iii) Heterogeneous Tur from the assemblage Kfs+Qtz+Ab+Ms±Crd, And is typical of peraluminous, anatectic pegmatites enclosed in migmatites surrounding the Bory Granulite Massif, where this mineral, in contrast to the other pegmatite occurrences, typically crystallized in pockets [2]. The δ^{11}B signatures of the individual pegmatite groups and crystals (Fig. 1) vary from highly homogeneous (most of the analyses from Třebíč Pluton, 2DB) to highly variable, even within single grains (8LAV, 1DB, 3HB). Isotopic zoning is commonly independent of the compositional variations in major and minor elements except for slightly heavier δ^{11}B in Ca, Ti-enriched domains [3] of the sample 3HB. The concentric zoning developed in some crystals (1DB, 8LAV, 3HB) is characterized by isotopically heavy rims (Fig. 1).

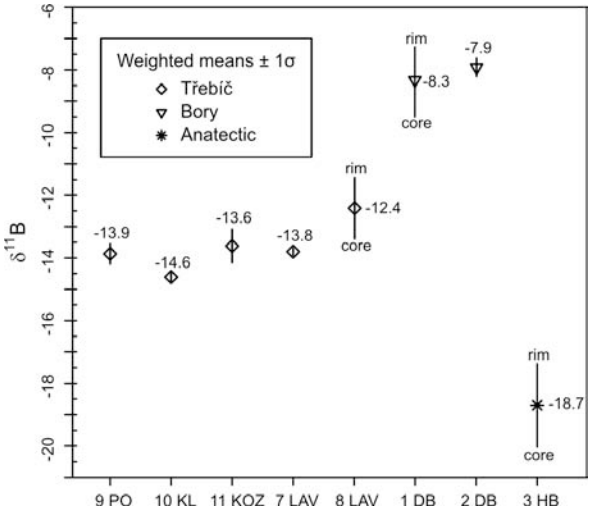

Fig. 1: Isotopic composition of tourmaline.

The homogeneous δ^{11}B signature of Tur from pegmatites of the Třebíč Pluton implies a closed-system evolution, perhaps as it is the only mineral incorporating B both in the pegmatites and the host syenite except for the sample 8LAV associated with rare Ms from pegmatite enclosed in leucocratic granite related to Třebíč Pluton. The heavier δ^{11}B signature of the Bory Tur requires a different source compared to the Třebíč pegmatites. The tourmaline from the anatectic pegmatite (3HB) differs strikingly from the other groups by its crystallization from fluid phase. Thus its δ^{11}B signature could have been controlled by abundant Ms, affecting the isotopic ratio of the co-existing fluid phase.

Incorporation of fluorine in tourmaline: internal crystallographic vs. external environmental influences

Henry, D.J.[*] & Dutrow, B.L.
Dept. of Geology and Geophysics, Louisiana State University, Baton Rouge, Louisiana, USA ([*]glhenr@lsu.edu)

Tourmaline is a common mineral in a wide variety of rock types largely because it is the primary mineral host for boron in rocks, it can accommodate a large array of chemical constituents and it has an extreme stability range. The manner in which chemical constituents are incorporated into the tourmaline structure depends on external influences such as temperature, pressure, local mineral assemblage and fluid composition. It also depends on internal influences such as crystallographic and surface energy constraints. The general systematics of F contents in natural tourmaline are particularly intriguing and the relative importance of the crystallographic constraints and the petrologic environment in which the tourmaline forms make an interesting case study of these dynamics.

A general formula for tourmaline is $XY_3Z_6(T6O_{18})(BO_3)_3V_3W$; with the most common site occupancies being: X = Ca, Na, K, $^{X}\square$ (vacancy); Y = Li, Mg, Fe^{2+}, Mn^{2+}, Al, Cr^{3+}, Fe^{3+}; Z = Al, Mg, Fe^{3+}, Cr^{3+}; T = Si, Al; B = B; V = OH, O; W = OH, F, O. Of particular importance is that F occurs at a single anion site, the W site. Incorporation of F in this site is influenced by the occupancy (total charge) of the X and the Y sites. The X-site is generally occupied by cations of variable charge (Na^{1+} or Ca^{2+}) and/or is vacant (zero charge). There are three Y-site cations that can have charges of +1, +2, +3 and +4. However, the local bond valence arrangements are most commonly +6 (e.g. Mg_3) or +7 (e.g. Mg_2Al). Because of local bonding of the W site anion to three neighboring Y-site cations and an X-site cation, the charge of the X-site and the Y site cationic affects the F occupancy in the W site. Natural tourmaline data verifies the threshold charge level at the X-site at which significant amounts of F are supported. A summary of >900 tourmaline analyses from different tourmaline environments illustrates that if the X-site charge is <0.5 little F is present, but at higher X-site charge F ranges from 0-1.0 apfu (Fig. 1).

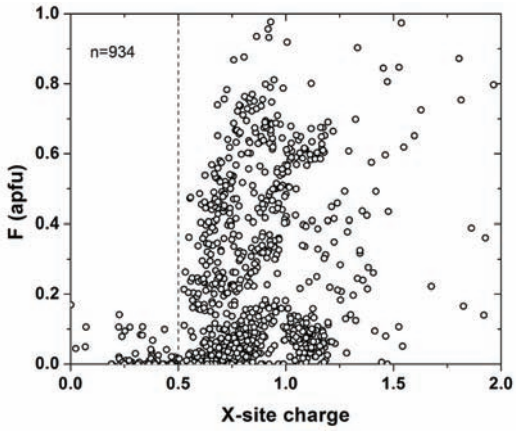

Fig. 1: Tourmaline data from multiple rock types.

Petrologic factors superimpose local environmental influences on F concentrations. Features such as F-saturating phases (e.g. fluorite), local mineral assemblages and fractionating fluids control the amount of F that can be made available to and incorporate in tourmaline.

Tourmaline: from short-range to long-range arrangements

Bosi, F.
Dept. of Earth Sciences, Sapienza University of Rome, Italy
(ferdinando.bosi@uniroma1.it)

Tourmaline is a complex borocyclosilicate that occurs in a wide variety of igneous, metamorphic and sedimentary environments. The general formula is $XY_3Z_6(T_6O_{18})(BO_3)_3V_3W$. The stability of tourmaline has been investigated to understand the effect of long-range disordered distributions of Al, Mg, Fe^{3+} and Fe^{2+} over the *Y* and *Z* non-equivalent octahedral sites, coupled with Mg and Fe^{2+} occurring at *Z* [1], as well as to the short-range occupancies around the *V* and *W* anion-sites. In this regard, only local arrangements involving Mg and Al were examined in Li-free tourmaline [2].

Extension of the local bond-valence approach from Mg-Al to Fe^{2+}-Fe^{3+} short-range arrangements has been explored. Stable local configurations involving R^{3+} cations (Al, Fe^{3+}) and R^{2+} cations (Mg, Fe^{2+}) around *W* and *V* have been determined as a result of short-range bond-valence requirements. The coupling of these stable local arrangements determines the formation of larger clusters of octahedra of general form $[WY_3VZ_2]$, Fig. 1, which can have either ordered or disordered distributions of R^{3+} and R^{2+} cations.

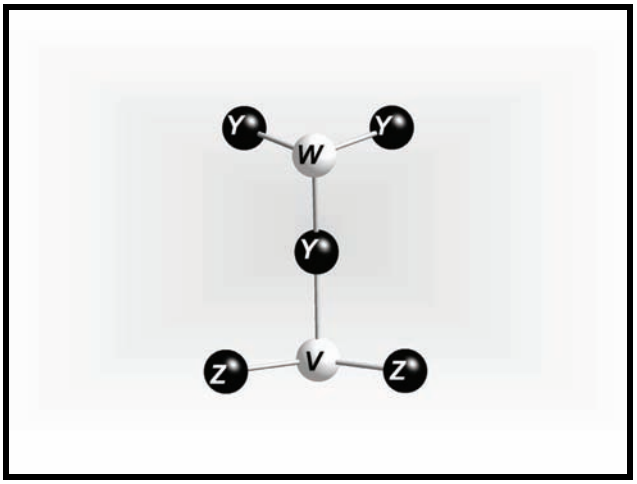

Fig. 1: Schematic view of part of the tourmaline structure around the *W* and *V* anions. Cations are shown as black circles, anions are shown as white circles.

These clusters are related through four different relations:

$$2\ {}^{Y}R^{2+} + {}^{Z}R^{3+} + {}^{W}(OH,F)^{1-} \rightleftarrows 2\ {}^{Y}R^{3+} + {}^{Z}R^{2+} + {}^{W}O^{2-}$$

$$2\ {}^{Y}R^{2+} + 2\ {}^{Z}R^{3+} + {}^{W}(OH,F)^{1-} \rightleftarrows 2\ {}^{Y}R^{3+} + 2\ {}^{Z}R^{2+} + {}^{W}O^{2-}$$

$$^{Y}R^{2+} + 2\ {}^{Z}R^{3+} \rightleftarrows {}^{Y}R^{3+} + 2\ {}^{Z}R^{2+}$$

$$^{Y}R^{2+} + {}^{Z}R^{3+} \rightleftarrows {}^{Y}R^{3+} + {}^{Z}R^{2+}$$

Such relations describe the occurrence of both R^{3+} cations at the octahedrally coordinated *Y* site and R^{2+} cations at the octahedrally coordinated *Z* site of tourmaline, and lead to long-range ordered or disordered arrangements.

In nature disordered configurations are the rule owing to long-range requirements of geometrical fit and minimization of strain.

The correct formula for Mg- and Fe^{3+}-bearing tourmaline: the influence of the <*T*-O> distance on the <*Z*-O> bond length

Ertl, A.[1*], Hughes, J.M.[2] & Tillmanns, E.[1]
[1]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria ([*]andreas.ertl@a1.net)
[2]Dept. of Geology, University of Vermont, Burlington, Vermont, USA

The general chemical formula of the tourmaline-group minerals is $XY_3Z_6(BO_3)_3[T_6O_{18}]V_3W$. Several efforts have been made in the past to address the Mg-Al disordering between the *Y* and *Z* sites in the tourmaline atomic arrangement (e.g., [1]). It has been demonstrated that Mg and Fe^{3+} not only occupy the *Y* site, but also the *Z* site in tourmaline. However, in many cases it is not possible to assign the cations in a way that the average ionic radius of the *Y*-site occupants fits the <*Y*-O> bond length, while simultaneously the average ionic radius of the *Z*-site occupants fits the <*Z*-O> bond length. However, with Mg-rich tourmaline samples from the Austroalpine basements units, Styria, Austria, we were very successful in developing accurate formulae [2]. We attribute the difference to the varying *T*-site occupancy in many tourmalines compared to the samples from the Austroalpine basement units and suggest a relationship between *T*-site occupancy and the <*Z*-O> bond length. Whereas all tourmalines from the Austroalpine basement units show a <*T*-O> distance of 1.620 Å, the recently investigated tourmalines from the Moldanubicum have <*T*-O> distances varying from 1.614 to 1.623 Å. This results from mixed occupancy among Si, Al and B at the *T* site in these tourmalines, whereas in the samples from the Austroalpine basements unit the *T* site is exclusively occupied by Si [2]. Hence, we checked the possibility of an influence of the <*T*-O> bond length on the <*Z*-O> bond length. To be sure that the *Z* site is exclusively occupied by Al we used only samples of the elbaite-olenite-rossmanite series, without Mg and Fe^{3+} (e.g., [3,4]). Indeed, we found a positive correlation between the <*T*-O> bond length and the <*Z*-O> bond length in tourmalines where the *Z* site is only occupied by Al (R^2 = 0.778). This is not unexpected because the TO_4 tetrahedron is connected through two oxygens (O6 and O7) to the ZO_6 octahedron. The influence of the <*T*-O> bond length on the <*Z*-O> distance (for a *Z* site which is only occupied by Al) can now be calculated by using the following formula (1): $\langle Z\text{-O}\rangle_{Al} = (\langle T\text{-O}\rangle_{meas.} + 2.3651\ Å)/2.0885$. Then the <*Z*-O> bond length (corrected for the inductive effect of the varying <*T*-O> bond length) can be calculated. The <*Z*-O> bond length was calculated for a *T* site only occupied with Si by using the following formula (2): $\langle Z\text{-O}\rangle_{calc.} = \langle Z\text{-O}\rangle_{meas.} + 1.9079\ Å - \langle Z\text{-O}\rangle_{Al}$. The value of 1.9079 Å was calculated for a <*Z*-O> distance for a Z site which is only occupied by Al while the *T* site is only occupied by Si by using the average value of the <*T*-O> bond lengths of tourmalines from the Austroalpine basement units [2], because of the high-quality structure refinements ($R1$ = 0.013-0.015). Finally the *Z*-site occupants can be assigned by optimising the relation between the <*Y*-O> bond length and the average ionic radius of the *Y*-site occupants and also the relation between the $\langle Z\text{-O}\rangle_{calc.}$ bond length and the average ionic radius of the *Z*-site occupants.

Crystal chemistry of Al-rich tourmalines from metamorphic and hydrothermal systems (Western Carpathians, Slovakia)

Bačík, P.*, Uher, P. & Ozdín, D.
Dept. of Mineralogy and Petrology, Comenius University, Bratislava, Slovak Republic (*bacikp@fns.uniba.sk)

Aluminium-rich tourmalines were found in several distinctive occurrences in Slovakia. A pebble of tourmalinite from Orlové has two generations of tourmaline – Al-rich prismatic tourmaline and Al-poor tourmaline matrix. The origin and genetic environment of the tourmalinite are unclear, but the influence of the hydrothermal processes is possible. Prismatic tourmaline contains 0.54-0.77 Na *pfu*, 0.65-1.27 Fe *pfu*, 0.75-1.63 Mg *pfu*, and 6.53-7.07 Al *pfu* [1]. Al-rich tourmaline occurs also in hydrothermally altered andesite near Detva. It contains up to 8.23 Al *pfu*, 0.52-0.57 *X*-site vacancies, 0.30-0.35 Ca *pfu*, but only up to 0.81 Mg *pfu* and 0.51 Fe *pfu*. Tourmaline in an Alpine-type vein from Limbach contains up to 6.69 Al *pfu*, 0.90 Fe *pfu*, 1.31 Mg *pfu*, and has moderate *X*-site vacancy (0.55-0.59). The degree of Al-Mg disorder was calculated from the lattice parameters of tourmaline [a = 15.9387(5) Å, c = 7.1636(4) Å] determined by powder XRD; 0.95-1.21 Al *pfu* and 0.46 Mg *pfu* might occupy the *Y* site and *Z* site, respectively [2]. Metamorphic Al-, Mg- and V-enriched (up to 3.3 wt. % V_2O_3, 0.40 V *pfu*) tourmaline with strong chemical zonality occurs in metachert from Chvojnica. The Al content attains 6.50 *apfu* in two Al-rich zones and it is lower than 6.25 *apfu* in other two zones (intermediate and rim2). Central Al-rich zone has more vacancies (0.42-0.46), Al-rich rim1 has dominant Na (0.45-0.52 *apfu*) in the *X* site. The content of Mg is quite uniform in all zones (2.15-1.38 *apfu*), V is concentrated in Al-poorer zones (up to 0.40 *apfu*) but it is also high in Al richer zones (0.21-0.29 *apfu*). The content of Fe is very low (up to 0.01 *apfu*). Mineral classification of Al-rich tourmalines is complicated by the Al-Mg disorder between the octahedral sites. If the Fe/(Fe+Mg) ratio in the *Y* site dividing schorl and dravite (or foitite and magnesiofoitite) varies between 0.4-0.6, there is no possibility to exactly determine the mineral species without structural refinement. Moreover, in Al-enriched disordered tourmalines, Al may be a major cation in the *Y* site; tourmaline that seems to be dravite as suggested by the total Al content may be olenite [2]. Another complication results from unknown valence of Fe and proportion of $(OH)^-$ vs. O^{2-} in *V* and *W* anion sites determined by EMPA. Tourmaline from Orlové may be classified as schorl as well as dravite or olenite, but there is a possibility that it belongs to a new mineral species ("*oxyschorl*" or "*oxydravite*"). The Al content of tourmaline from Detva suggests the composition of olenite, but the proportion of *X*-site vacancy and the Fe and Mg content may be closer to the composition of a new *X*-vacant oxytourmaline. Tourmaline from Limbach belongs to magnesiofoitite. *X*-site vacant tourmaline from Chvojnica is likely magnesiofoitite, but Na-dominant Al-rich tourmaline may belong to dravite as well as olenite if there were more Al-Mg disorder. The Al increase is likely controlled by the several distinct substitution mechanisms. Alkali-deficient substitution $^{X}\square AlNa_{-1}(Fe,Mg)_{-1}$ may explain the Al enrichment in *X*-site vacant tourmalines from Detva, Limbach and Chvojnica. However, there must be an influence of proton-deficient substitution $AlO(Fe,Mg)_{-1}(OH)_{-1}$ not only in alkali tourmalines from Orlové and Chvojnica, but also in *X*-site vacant tourmalines with Al content over 7.0 *apfu*.

Magnesiofoitite in the "*Equador Quartzites*", Borborema Pegmatite Province, Northeast Brazil

Beurlen, H.[1*], DaSilva, M.R.R.[1] & Soares, D.R.[2]
[1]Dept.of Geology, Univ. Federal de Pernambuco, Recife-PE, Brazil (*beurlen@terra.com.br)
[2]Federal Inst. Of Education,Science and Technology-IFPB, Campina Grande-PB, Brazil

Color banded gray, light green to pink quartzites of the Neoproterozoic Equador Formation in northeast Brazil are widely explored as dimension stones under the fashion name *"Zinwalita"* or *"Equador Quartzite"*. They present an easy cleavage along foliation planes with concentration of light green or pink micas. The quartzites host over hundred Li-Ta-Be bearing pegmatites and are the exclusive host rock of five granitic lithium rich pegmatites of the Borborema Pegmatite Province mined for the prized gem-quality elbaite known as "Paraíba Tourmaline". Within the foliation planes, the pink quartzites sporadically contain up to 10cm sized acicular to long prismatic pink to reddish brown tourmaline, occurring as isolated crystals or as radial arrangements of late metamorphic porphyroblastic origin. Tourmaline with the same color and habit is also observed with quartz in fractures perpendicular to the foliation, interpreted as late to post metamorphic metasomatic lateral segregations. Electron microprobe analyses allowed identify the pink micas as phlogopite. The tourmaline composition spreads around the center of the triangular classification diagram [1] according to the dominance of (Na+K), Ca or vacancy in the X-site of the tourmaline formula (Fig 1).

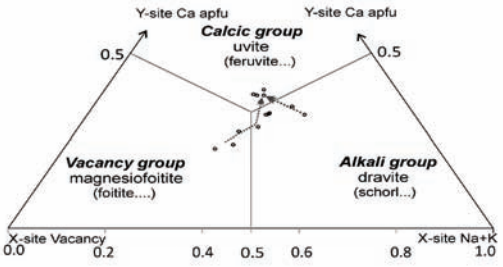

Fig. 1: Compositional variation in the X-site of zoned magnesiofoitite-dravite-uvite tourmaline in quartzites of the Equador Formation.

Taking into account the dominance of Mg in the Y-site [Mg/(Mg+Al+Fe) > 2.0/3.0 apfu)], the tourmaline plots either in the magnesiofoitite [2], uvite or dravite field of this diagram. In two zoned crystals the core had respectively magnesiofoitite or dravite compositions, both with uvite rims as indicated by the arrows in Fig. 1. This tourmaline seems unusual due to the fact that even small compositional variations in the X-site would lead to classify the mineral in three different tourmaline sub-groups and due to the composition very far from any of the corresponding end-member compositions (Table 1).

Table 1: Variation of X- and Y-site compositions of studied tourmaline

Magnesiofoitite	$^{X}[vac_{0.46}, Na_{0.31}, Ca_{0.22}]$ $^{Y}[Mg_{2.1}, Al_{0.4}, Fe_{0.3}, Li_{0.2}]$
Dravite	$^{X}[vac_{0.29,}\ Na_{0.44}, Ca_{0.34}]$ $^{Y}[Mg_{2.2}, Al_{0.3}, Fe_{0.4}, Li_{0.1}]$
Uvite	$^{X}[vac_{0.30}, Na_{0.30}, Ca_{0.40}]$ $^{Y}[Mg_{2.3}, Al_{0.1}, Fe_{0.4}, Li_{0.2}]$

The also uncommon Mg- and B-enrichment in quartzites is ascribed to volcano-exhalative syn-sedimentary activity.

[1] Hawthorne, F.C. & Henry, D.J. (1999) *Eur. J. Mineral.*, **11**, 201-215. [2] Hawthorne, F.C. et al. (1999) *Can. Mineral.*, **37,** 1439-1444.

Tourmalines in the Naipa Li-Cs-Ta granitic pegmatite group and adjacent host rock, Mozambique

Neiva, A.M.R.[1*] & Leal Gomes, C.A.A.[2]
[1]Dept. of Earth Sciences, University of Coimbra, Portugal (*neiva@dct.uc.pt)
[2]Dept. of Earth Sciences, University of Minho, Braga, Portugal

The Naipa granitic pegmatite group has been mined for tourmaline and beryl gems. The Naipa blue tourmaline gem crystals are significant for their sizes and quality. Electron-microprobe compositions of magmatic tourmalines from the Naipa Li-Cs-Ta pegmatite group, such as schorl and 'fluor-elbaite' from the inner intermediate zone and pockets (concentrations) in this zone, and 'fluor-elbaite' from core zones record a differentiation sequence. Progressively zoned magmatic tourmaline crystals from the inner intermediate zone contain green Fe-rich 'fluor-elbaite' outer and inner cores and a blue 'fluor-elbaite' rim, showing increases in Al_Y+Li content, Al/(Al+Fe) at the Y site, and X site vacancy together with decreases in Fe^{2+} and Na contents from core to rim. In pockets from the inner intermediate zone, the progressively zoned magmatic crystals have: a) a black schorl core and a black Fe-rich 'fluor-elbaite' rim; b) a bluish grey Fe-rich 'fluor-elbaite' core and a blue Fe-bearing 'fluor-elbaite' rim. Reversely zoned magmatic crystals also occur with a Naipa blue Fe-bearing 'fluor-elbaite' core and a bluish grey Fe-rich 'fluor-elbaite' rim showing increase in Fe^{2+} content and decrease in Al/(Al+Fe) at the Y site from core to rim.

The magmatic tourmaline crystals from the pegmatite core zones are up to 70x5 cm, reversely zoned and consist of a red 'fluor-elbaite' inner core, a colourless to light pink 'fluor-elbaite' outer core and a green or blue Fe-rich 'fluor-elbaite' rim, showing decreases in Al_Y+Li content, Al/(Al+Fe) at the Y site, and X site vacancy, together with increases in Fe^{2+} and Na contents from inner core to rim. Progressive zoning is attributed to fractional crystallization and reverse zoning is due to nucleation and growth of evolved cores and back-reaction of them with the more primitive bulk magma. In pockets of the pegmatite core zones, 'fluor-liddicoatite' is either mainly blue with blue or pink tips or is only pink, which is the richest in Ca. The magmatic tourmalines result from strong fractionation of an uncontaminated (Na, Al, Li, B)-rich pegmatite melt and 'fluor-liddicoatite' formed due to added Ca by late interaction with fluids derived from the wall rocks. The main substitution $3Fe^{2+} \leftrightarrows 1.5Al+1.5Li$ at the Y site corresponds to the fractionation schorl-elbaite trend. The substitution Na⇆□ at the X site also takes place in 'fluor-elbaite' and the substitution Ca for Na at the X site occurs in 'fluor-liddicoatite'.

In replacement units of the inner intermediate zone, individual zoned hydrothermal crystals consist of a green core and a pink rim, both of 'fluor-elbaite', showing increases in Al_Y+Li content and Al/(Al+Fe) at the Y site, together with decreases in Fe^{2+} and Mn contents from core to rim. The main substitutions are $3Fe^{2+} \leftrightarrows 1.5Al+1.5Li$ at the Y site and $(\square Al)(NaR)_{-1}$. Hydrothermal 'fluor-elbaite' has higher Al, Li contents and lower Fe^{2+} and Na contents than magmatic 'fluor-elbaite' from the inner intermediate zone and pockets.

Hydrothermal 'fluor-dravite' from metasomatized chlorite phyllite adjacent to the granitic pegmatite group resulted from mixing of magmatic-hydrothermal fluids carrying Na, Al, Li, F and B with a meteoric fluid that interacted with this Fe-Mg-bearing pelitic country rock. Fe⇆Mg is the main substitution in this tourmaline.

Reexamination of Mg-Li tourmalines from the elbaite pegmatite Bližná I, Czech Republic

Cempírek, J.[1*] & Novák, M.[2]
[1]Dept. of Mineralogy and Petrography, Moravian Museum, Brno, Czech Republic (*jcempirek@mzm.cz)
[2]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic

Tourmaline of elbaite-dravite solid solution is extremely rare due to the strong fractionation of Li from Mg in geological environments. To date, it has only been reported from elbaite-subtype pegmatite Bližná I, which intrudes dolomite-calcite marble [1]. Part of the pegmatite exhibits in-situ fluid exchange with the surrounding marble, resulting in an Ca,Mg-contaminated pegmatite border zone and a B-enriched exocontact of the pegmatite. The tourmaline composition in the pegmatite varies in a range typical for elbaite-subtype pegmatites [2], i.e. from Ca-rich schorl-elbaite to Mn-rich elbaite and Mn-rich elbaite-liddicoatite. The tourmaline from contaminated pegmatite ranges from Na-rich uvite and Ca-rich schorl-elbaite-dravite to Mg-bearing Ca-rich elbaite and Mn-rich liddicoatite-elbaite. The tourmaline from the exocontact ranges from Na-rich uvite to dravite-elbaite and liddicoatite-elbaite [1,3].

Preliminary study of the crystal structure of the various types of tourmaline started with a sample from the contaminated zone. The dark brown core of a zoned tourmaline with composition $^{X}(Na_{0.52}Ca_{0.34}\square_{0.13})$ $^{Y,Z}(Li_{0.32}Mg_{2.39}Fe_{0.32}Mn_{0.06}Al_{5.83}Ti_{0.02})$ Si_6 $(BO_3)_3$ $(OH_{3.8}F_{0.2})$ has a = 15.946(2) Å, and c = 7.1977(14) Å. Its average <T-O> is 1.620 Å and the T-site is fully occupied by Si. The refined occupancy of the Z-site and the average <Z-O> = 1.927 Å shows that it is partially occupied by Mg (~ 0.6 *apfu*) and that Mg and Al are significantly disordered between Z and Y sites. The refined formula of the tourmaline is $^{X}(Na_{0.52}Ca_{0.34}\square_{0.13})$ $^{Y}(Li_{0.32}Mg_{1.83}Fe_{0.32}Mn_{0.06}Al_{0.43})$ $(Mg_{0.60}$ $Al_{5.40})$ Si_6 $(BO_3)_3$ $(OH_{3.8}F_{0.2})$ and it represents a solid solution dominated by dravite, liddicoatite and feruvite.

The light brown crystal rim shows significantly different composition $^{X}(Na_{0.44}Ca_{0.43}\square_{0.12})$ $^{Y,Z}(Li_{1.72}Mg_{0.28}Fe_{0.08}Mn_{0.11}$ $Al_{6.71}Ti_{0.11})$ Si_6 $(BO_3)_3$ $(OH_{3.8}F_{0.68})$ and has a = 15.872(2) Å, c = 7.1203(14) Å. Its average <T-O> is 1.619 Å, which implies that the T-site is fully occupied by Si or contains only a very small amount of tetrahedral B. The refined occupancy of the Z-site and the average <Z-O> = 1.907 Å suggest that Al is dominant in the site, with only minor Mg (~ 0.01 *apfu*). The refined formula of the tourmaline is $^{X}(Na_{0.44}Ca_{0.43}\square_{0.12})$ $^{Y}(Li_{1.72}Mg_{0.18}Fe_{0.08}Mn_{0.11}$ $Al_{0.81}Ti_{0.11})$ $(Al_{5.98}$ $Mg_{0.02})$ Si_6 $(BO_3)_3$ $(OH_{3.8}F_{0.68})$; it represents a solid solution of elbaite, liddicoatite and dravite.

The crystal chemistry of tourmalines from the Bližná I pegmatite reflect the processes of fractionation/contamination in a system enriched in Li, Mn, Ca and Mg. Magnesium played a significantly greater role during crystallization of the Bližná I pegmatite than during crystallization of other highly fractionated complex pegmatites. Further data will provide valuable information on solid solutions and range of possible immiscibility among the tourmaline-group minerals in this unusual system.

Werdingite from SW Norway: the role of iron in a borosilicate with a mullite-type structure

Grew, E.S.[1*], Armbruster, T.[2], Lazic, B.[2], Yates, M.G.[1], Medenbach, O.[3] & Huijsmans, J.P.P.[4]
[1]Dept. of Earth Sciences, University of Maine, Orono, Maine, USA ([*]esgrew@maine.edu)
[2]Mineralogical Crystallography Institute of Geological Sciences, University of Bern, Switzerland
[3]Institut für Geologie, Mineralogie und Geophysik – Mineralogie, Ruhr-Universität Bochum, Germany
[4]Shell Global Solutions International B.V., Amsterdam, The Netherlands

Werdingite from a pegmatite on Almgjotheii in the aureole of the Rogaland anorthosite complex, Norway was reported as the "Fe-dominant analogue" because of its high total Fe (to 8.00 wt% as FeO) and atomic Fe/(Mg + Fe) ratio (X_{Fe} to 0.75) [1,2]. A crystal of composition $Fe_{1.27}Mg_{0.48}Al_{14.44}Be_{0.10}B_{4.18}Si_{3.61}O_{37}$ (Be from [2], B by EMPA) from sample HE138B has α = 1.619(2), β = 1.652(2), γ = 1.658(2), $2V_x$ = 43(2)°, space group *P*-1, *a* = 7.9696(2) Å, *b* = 8.1559(3) Å, *c* = 11.3607(3) Å, α = 110.364(1)°, β = 110.881(1)°, γ = 84.670(2)°, *V* = 646.41 Å^3, calc. ρ = 3.12 g/cm^3, *Z* = 1. Comparison with literature data [2-5] shows refractive indices increase with increasing X_{Fe}, but cell *V* does not. A crystal structure refinement (R_1 = 0.057) gave 1.21 Fe occupying the one tetrahedral and two 5-coordinated sites present in type werdingite [4-5] plus a new, largely vacant tetrahedral site, FeX (Table 1).

Table 1: Iron site occupancies in HE138B and type werdingite

Site	Fe(1)	Fe (2)	Al(1)	Al (2)	Mg(1)	Mg (2)
Al(4)1	0.12	0.21	0.75	0.79	0.00	0.00
Al(5)1	0.04	0.00	0.96	1.00	0.00	0.00
Mg(5)1	0.35	0.16	0.41	0.00	0.24*	0.84
FeX	0.09	羊	0.00	羊	0.00	羊

(1) HE138B [this study], (2) Type [5]. *Fixed in refinement

Fe is not dominant at any site. As we have no data on Fe valence, we cannot determine whether divalent cations are dominant at Mg(5)1, i.e., we cannot show that HE138B werdingite is a Fe-dominant analogue of type werdingite.

Werdingite in HE138B is intergrown with boralsilite, ideally $Al_{16}B_6Si_2O_{37}$, also related to mullite. B varies inversely with Si in a single trend for both minerals (per 37 O): 5.91-5.11 B and 1.95-2.56 Si in boralsilite [6] and 4.76-4.02 B and 3.05-3.74 Si in werdingite, whereas Al and (Mg + Fe) show no trend with Si in werdingite. Charge balance for B → Si substitution could be achieved by oxidation of Fe rather than loss of O in werdingite. Subparallel prisms of werdingite and boralsilite have a ladder-like appearance due to plates of one mineral oriented perpendicular to prism length of the other [2,7], i.e., perpendicular to the mullite-type chains of Al octahedra. Matching the two structures in this plane is possible: the pseudo-tetragonal cell perpendicular to the mullite-type chains is 7.65 x 7.42 Å in werdingite vs. 7.54 x 7.38 Å in boralsilite [8]. Moreover, the two structures have in common Si_2O_7 dimers and 5-coordinated sites. Thus, our data are consistent with the suggestion [7] of limited solid solution between the two minerals with subsequent exsolution of one from the other.

A new boron feldspar, $KBSi_3O_8$: synthesis, crystal structure and thermal behaviour

Krzhizhanovskaya, M.G.[1*], Bubnova, R.S.[2], Depmeier, W.[3], Smirnova, D.A.[2], Rahmoun, N.S.[3] & Filatov, S.K.[1]
[1]Dept. of Crystallography, St. Petersburg State University, St. Petersburg, Russia ([*]krzhizhanovskaya@mail.ru)
[2]Institute of Silicate Chemistry RAS, St. Petersburg, Russia
[3]Dept. of Earth Sciences, University of Kiel, Germany

Up to now in the $K_2O–B_2O_3–SiO_2$ system two synthetic compounds were known: boroleucite $KBSi_2O_6$ [1] and borodanburite $KBSi_3O_8$ [2], prepared by cooling of stoichiometric melt and hydrothermal synthesis, respectively. Also there are the structural data on naturally occurring lisitsynite, $KBSi_2O_6$ [3], considered as a polymorph of boroleucite. In present work the results of hydrothermal synthesis experiments in $K_2O–B_2O_3–SiO_2$ system are discussed. Single crystals as well as powder sample of $KBSi_3O_8$ feldspar-type phase were obtained at 180 and 550°C. Both single crystals and powder were obtained always mixed with quartz.

Crystal structure of $KBSi_3O_8$ was determined by direct methods: it is monoclinic *C*2/*m*, *a*=8.4377(8), *b*=12.4152(11), *c*=6.8769(7) Å, *β*=116.133(7)°, *V*=646.75(11) Å^3, d_{calc}=2.693 g/cm^3. The structure is identical to that of monoclinic feldspar with a difference only in size and density of tetrahedral framework due to the presence of boron instead of alumina. The distribution of Si and B over tetrahedra is partially ordered with one Si-rich tetrahedra (<T–O>=1.60 Å) and 2nd one occupied by Si and B almost in equal proportion (<T–O>=1.55 Å).

According to the high temperature X-ray diffraction study the expansion of structure is highly anisotropical: α_1=19, α_2=2, α_3=5×10^{-6} °C^{-1}, ∠(α_3c)=9°. The direction of maximal expansion approximately coincides with the short diagonal of *ac* parallelogram. The expansion is similar to that of intermediate monoclinic member of Na-K feldspar series (Or_{38}) described in [4] with the mean linear expansion coefficient 24 and 26×10^{-6} °C^{-1} for alumino- and borosilicate correspondingly.

$KBSi_3O_8$ obtained by hydrothermal synthesis is stable up to 600°C. Above it decomposes by solid state reaction with the boroleucite $KBSi_2O_6$ phase formation.

Acknowledgements: The work was supported by Russian Foundation for Basic Research (10-03-00732-a).

Multi-disciplinary investigation of datolite from basalts in the Northern Apennines ophiolites (Italy): genetic implications

Zaccarini, F.[1,2*], Garuti, G.[1,2], Scacchetti, M.[2], Bartoli, O.[2] & Bakker, R.J.[1]
[1]Dept. of Applied Geosciences and Geophysics, University of Leoben, Austria ([*]federica.zaccarini@unileoben.ac.at)
[2]Society of Natural Sciences of Reggio Emilia, Italy

A multi-disciplinary investigation based on fluid inclusion petrography and microthermometry, X-ray diffraction, electron microprobe and inductively coupled plasma mass spectrometry (ICP-MS) and Raman spectroscopy, was carried out on datolite, ideally $CaBSiO_4(OH)$, from hydrothermal veins crosscutting pillow basalt in ten different localities of the Northern Apennine ophiolites (Italy). Two-phase (L + V) fluid inclusions texturally identifiable as primary and secondary were observed, yielding average homogenization-temperatures of 236°C and 173°C respectively. Fluid-inclusion cooling data yield calculated salinity in the range of 10-16 wt% NaCl equivalents, thus relatively higher compared with seawater. Results of electron microprobe analysis indicate that probably B-OH is the predominant substitution and not B-Si. Chlorine and fluorine were also analyzed but their concentration was below detection limit. Bulk analyses of datolite crystals show REE contents below chondritic, except for La and Ce. With respect to host rock, datolite is occasionally enriched in La, Rb, Cs, Be, and shows relatively high contents of chalcophile elements (Cu, Zn, Pb, Ni) when occurring in contact with sulfide mineralized basalt. Fluid inclusion results are compatible with those reported for fluids formed under diagenetic conditions rather than in the seafloor hydrothermal systems and/or emanating from magmas. Compositional data of datolite indicate that the mineral is able to concentrate only a few elements such as La, Rb, Cs, Be, Ni, Cu, Zn and Pb. The lithophile elements can be hosted in the datolite lattice, whereas the chalcophile metals and Ni are probably carried in sub-microscopic inclusions

Tourmaline nodules – 3D insight into late-stage boron separation from granite melt

Balen, D.* & Petrinec, Z.
Faculty of Science, University of Zagreb, Croatia
(*drbalen@geol.pmf.hr)

Spatial distribution, shape and internal structure of tourmaline nodules found in the peripheral parts of the Cretaceous Moslavačka Gora (Croatia) peraluminous granite pluton [1] have been visualized and reconstructed using BLOB3D software [2]. Data acquisition included serial cutting and lapping i.e. serial sectioning tomography. The "data brick" obtained from investigated granite consisted of a series of grayscale images with physical resolution of 3.5 mm (cutting) or 0.35 mm (lapping) between individual slices.

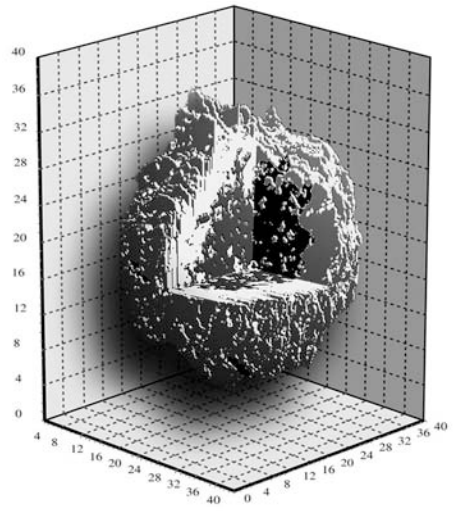

Fig. 1: 3D reconstruction of tourmaline nodule displaying a complex internal structure with separated volumes pertaining to the nodule's core and envelope (halo). Data obtained by serial lapping. Scale in mm.

The origin of tourmaline nodules and their peculiar textures has been related to the separation of a late-stage boron-rich volatile fluid phase from the granite magma [1]. Based on the field, mineralogical and textural observations, it is evident that tourmaline nodules formed during the final stage of granite evolution, when an undersaturated granite magma intruded shallow crustal horizons, becoming saturated and exsolving the fluid phase from the residual melt in the form of buoyant bubbles or pockets. Immiscibility of aluminosilicate and water-rich melts seems like a plausible mechanism which could have produced such spherical segregations. It also produced adequate concentrations of elements essential for the formation of the tourmaline nodules, especially boron, a crucial component enabling the physical formation of bubbles or pockets, followed by tourmaline crystallisation. Tourmaline nodules (usually 1 to 10 cm in diameter) that formed from these bubbles show a complex texture (Fig. 1) comprising two clearly distinct units: tourmaline-bearing core and leucocratic envelope (halo). The core, a spherical aggregate of tourmaline crystals, consists of dravite-enriched (Fe# 0.43-0.58) and slightly Na-deficient tourmaline, together with quartz + albite + K-feldspar ± muscovite. The nodule's halo, consisting of quartz + feldspar + muscovite, represents an integral part of the nodule and envelopes the tourmaline-bearing core.

MAS NMR measurements and *ab initio* calculations of the ^{29}Si chemical shifts in dumortierite

Evans, R.J.[1*], Fyfe, C.A.[2], Groat, L.A.[1], Lam, A.E.[2] & Grew, E.S.[3]
[1]Dept. of Earth and Ocean Sciences, University of British Columbia, Vancouver, British Columbia, Canada
(*rjamesevans@gmail.com)
[2]Dept. of Chemistry, University of British Columbia, Vancouver, British Columbia, Canada
[3]Dept. of Earth Sciences, University of Maine, Orono, Maine, USA

Dumortierite, $(Al,\square)Al_6Si_3BO_{16}(O,OH,\square)_2$, is the second most abundant aluminum borosilicate after tourmaline, with a complex structure featuring a face-sharing chain of Al octahedra connected to a pseudo-hexagonal framework of edge-sharing Al octahedra via isolated Si tetrahedra. A sample of dark blue dumortierite from Madagascar, D34, was characterized by single crystal X-ray diffraction (XRD), electron microprobe analysis (EMPA), and magic angle spinning (MAS) nuclear magnetic resonance (NMR). The structure was refined to R = 1.69% in space group *Pnma* with unit cell dimensions a = 4.6882(1) Å, b = 11.7924(2) Å, c = 20.1856(3) Å. Structure refinements indicate 0.26 vacancies per formula unit (pfu) at the face-sharing octahedral M1 site, with 0.42 octahedral vacancies pfu total. EMPA indicates approximately 0.07 Mg, 0.03 Fe^{3+} and 0.03 Ti pfu, and high Al and low Si total concentrations suggest that some ^{IV}Al is present at the Si sites. Fourier transform infrared spectroscopy confirmed the presence of structural OH groups, which are believed to coordinate the Si sites when the M1 site is vacant.

Although there are only two crystallographically distinct Si sites, Si1 and Si2, in 1:2 ratio, the ^{29}Si MAS NMR spectrum of D34 contains five major peaks at –96.0, –94.2, –92.8, –90.6 and –88.2 ppm, with the most intense peaks at –96.0 and –94.2 ppm. The NMR chemical shift is highly sensitive to the local environment of the ^{29}Si nucleus, and so the various chemical substitutions and vacancies at the M1 site give rise to different chemical shifts at the nearby Si sites. Ab initio electronic structure calculations were performed on model clusters using density functional theory (DFT) with the B3LYP functional to identify the structural environments responsible for those peaks seen in the spectrum. Model clusters were constructed using the refined structure as a starting point, consisting of first and second shell of atoms around Si, with the third shell replaced by H atoms. NMR chemical shifts were calculated relative to tetramethylsilane using the gauge-including atomic orbital method (GIAO) with the 6-311++g(2d,p) basis set. Positions of the Si and M1 cations and their coordinating O and H atoms were optimized with the 6-31g* basis set when substituting at the M1 site.

Azoproite crystals with nanorod inclusions of baddeleyite

Galuskin, E.V.[1*], Kusz, J.[2], Starikova, A.E.[3] & Pertsev, N.N.[4]
[1]Faculty of Earth Sciences, University of Silesia, Katowice Poland (*evgeny.galuskin@us.edu.pl)
[2]August Chełkowski Institute of Physics, University of Silesia, Katowice, Poland
[3]Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia
[4]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM) RAS, Moscow, Russia

Azoproite $Mg_2(Mg_{0.5}Ti^{4+}_{0.5})BO_5$, which is isostructural with ludwigite, occurs with Zr-oxides (baddeleyite, calzirtite, tazheranite), spinel, geikielite, forsterite, and diopside in periclase (brucite) calciphyre in the aureole of the Tazheran Massif (Baikal area, Russia) [1]. Association with Zr-oxides and the similar ionic radii of Zr (0.72 Å) and Sn (0.69 Å), which is a characteristic impurity in orthorhombic borates of the ludwigite-vonsenite series $(Mg^{2+},Fe^{2+})_2Fe^{3+}BO_5$ [2], suggest that Zr could be incorporated in azoproite, but none yet has been reported [2]. Only the structure of Ti-ludwigite from Tazheran has been refined [3]. Based on systematic studies of crystals collected at the type locality [1] during 2006-2009, we selected the following compositions for single-crystal investigations: (1) crystals with the highest contents (= 65-67%) of the azoproite end member $(Mg,Fe^{2+})_2(Mg_{0.5}Ti^{4+}_{0.5})BO_5$, (2) aluminian azoproite with ca. 34% of the $(Mg,Fe^{2+})_2AlBO_5$ end member, 3) titanian ludwigite with ca. 37% of the azoproite end-member. Structure refinement of one crystal gave the following formula (×2) $^{M1}Mg_{0.99}{}^{M2}(Mg_{0.77}Fe^{3+}_{0.23})^{M3}Mg_{1.99}{}^{M4}(Mg_{0.58}Ti^{4+}_{0.65}Fe^{2+}_{0.32}Al_{0.28}Fe^{3+}_{0.15}Zr_{0.02})(BO_{4.99})_2$ in which site occupancies were determined in light of inter-atomic distance data for end-member borates [4]. Azoproite from Tazheran contains ca. 1 wt.% ZrO_2 and abundant monocrystal nanorod inclusions of baddeleyite less than 1 μm thick and up to 1-2 mm long (Fig. 1).

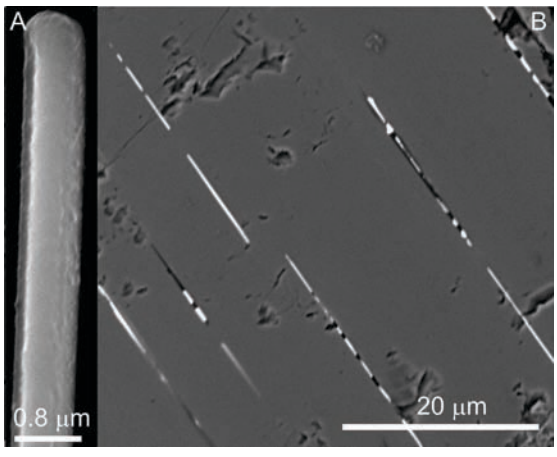

Fig. 1: Nanorod baddeleyite crystals are elongated along the Y axis (A), which in turn is sub-parallel to the Z axis of azoproite host crystals (B).

Growth of nanorod baddeleyite crystals results from the exsolution of the high-temperature compound $(Mg,Fe^{2+},Fe^{3+},)_2(Mg,Ti^{4+},Fe^{2+},Fe^{3+},Al,Zr)BO_5$. The primary solid solution is calculated to have contained up to 10-12 wt.% ZrO_2.

Rutile and tourmaline as indicators of the magmatic origin of tourmalinite levels in the São José do Barreiro area, NE Ribeira Belt, Southern Brazil

Garda, G.M.[1*], Beljavskis, P.[1], D'Agostino, L.Z.[2], Trumbull, R.B.[3] & Wiedenbeck, M.[3]
[1]Instituto de Geociências, São Paulo University, Sao Paulo/SP, Brazil (*giagarda@usp.br)
[2]Laboratório de Caracterização Tecnológica, Escola Politécnica, São Paulo University, Sao Paulo/SP, Brazil
[3]Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany

Coarse-grained tourmalinite layers associated with quartzitic lenses occur in the highly weathered, hilly area of São José do Barreiro-Formoso of the Central Ribeira Belt (São Paulo State, Brazil). Country rocks belonging to the Embu Complex include tourmaline-bearing schists (sample BM2) and gneisses of the Rio Una Unit and migmatites and gneisses of the Redenção da Serra Unit.

Tourmaline from a quartzitic lens (sample 3A) and a massive, rutile-bearing tourmalinite (sample 3B) were analyzed by microprobe (major elements and F), ICP-MS (REE, Y, Zr, Hf, Th) and SIMS (B isotopes). Mg# values for 3A and 3B fall respectively in the 0.62-0.67 and 0.69-0.76 intervals. Al_2O_3 (Fig. 1A), FeO and Na_2O contents are higher and CaO (Fig. 1B) and F contents are lower for 3A than 3B.

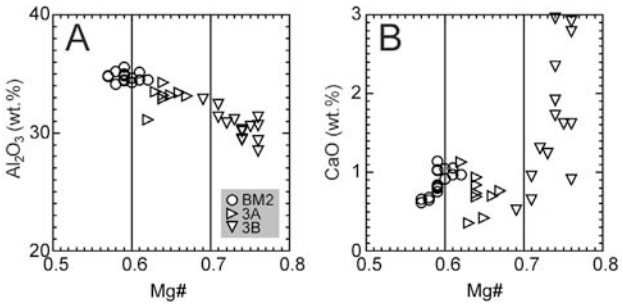

Fig. 1: Al_2O_3 (A) and CaO (B) *vs*. Mg# in tourmaline from samples BM2 (schist), 3A (quartzitic lens) and 3B (rutile-bearing tourmalinite).

The LREE pattern for 3B is approximately 70 times enriched compared to that for 3A. Eu anomalies are positive for 3A and negative for 3B. Relatively high Y (50.5 μg/g), Zr (778 μg/g), Hf (20 μg/g), Th (6.36 μg/g) contents are also observed in 3B.

$\delta^{11}B$ values fall in the –12.3 and –13.9 ‰ interval for 3A and –13.9 and –15.8 ‰ interval for 3B, typical for tourmalines occurring in metasediments and S-type granites [1].

Microprobe analyses of green and red rutile crystals from are shown in Table 1.

Table 1: Microprobe analyses of green and red rutile from sample 3B

	Ti (%)	Cr (μg/g)	Fe (μg/g)	Nb (μg/g)	Sn (μg/g)
green	56.5-58.5	433-1007	1871-10000	2000-7500	3985-28000
red	58.1-58.6	2392-6497	1393-3208	3918-5203	4578-7959

Applying the geothermometer proposed by [2], temperatures from 570°C to 700°C are obtained (112 μg/g < Zr < 454 μg/g), compatible with the observed regional metamorphic grade [3]. Our tourmaline and rutile chemical data indicate that the syn-collisional, S-type São José do Barreiro Granite [3] is a possible fluid source for tourmalinite (3B) of this study area.

[4]GFZ German Research Centre for Geosciences, Potsdam, Germany

The association of tourmaline and gold mineralization is conspicuous in the Passagem de Mariana Mine (Minas Gerais, Brazil) [1]. Tourmaline occurs as: very fine-grained foliation-parallel crystals in massive to banded tourmalinite (type 1); coarser-grained, color-zoned crystals forming massive (type 2) or comb-texture (type 3) aggregates within tourmalinite; and in associated quartz-carbonate-sulfide veins and breccias (type 4). Compositional variations in the four types of tourmaline can be expressed in terms of TiO_2 contents, which in turn reflect the color or color zones of tourmaline crystals. Generally the TiO_2 contents correlate negatively with SiO_2 and Al_2O_3, and positively with CaO and MgO. Na_2O and F contents increase from types 1 to 3. The most pronounced changes in composition can be observed in the very dark zones of type-4 tourmaline, *e.g.* related to a decrease in MgO (trend a, Fig. 1A) and the increase in FeO (trend b, Fig. 1B).

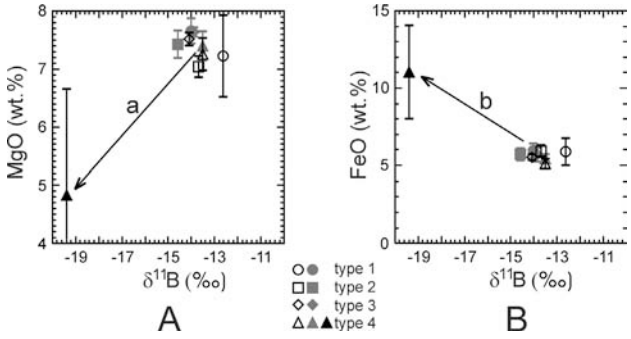

Fig. 1: MgO (A) and FeO (B) *vs.* $\delta^{11}B$ in tourmalines from the Passagem de Mariana Mine. Empty symbols: TiO_2 < 0.5 wt.%, gray symbols: 0.5 wt.% < TiO_2 < 1.0 wt.%, black: TiO_2 > 1.0 wt.%. Vertical bars on each symbol show compositional variations within the samples. The total uncertainty in $\delta^{11}B$ values (1 s) is less than 2 ‰.

$\delta^{11}B$ values obtained by SIMS for the four types of tourmaline range from –19 to –12 ‰, indicating non-marine evaporites, metasedimentary rocks and S-type granites as possible crustal B sources [2]. Considering the geological setting, the probable B source for tourmaline of types 1 to 3 (–15 to –12 ‰) would be the carbonaceous phyllites of the Batatal Formation, though a contribution of boron derived from non-marine evaporites cannot be excluded. In contrast, the much more negative $\delta^{11}B$ values of –19 ‰ from dark zones of type-4 tourmalines (Fig. 1) cannot be explained by fractionation effects during metamorphism, but instead require an external source. External B sources may be related to thermal events of the Paleoproterozoic Transamazonian Orogeny [3] or to veining and brecciation induced by the overthrusting of the Minas Group, accompanied by gold mineralization [1].

Boron variation in the calc alkaline volcanic arc of the Western Carpathians, Central Europe

Gméling, K.[1*], Pécskay, Z.[2], Harangi, Sz.[3] & Birkenmajer, K.[4]
[1]Institute of Isotopes, Hungarian Academy of Sciences, Budapest, Hungary ([*]gmeling@iki.kfki.hu)
[2]Institute of Nuclear Research of the Hungarian Academy of Sciences, Debrecen, Hungary
[3]Eötvös University, Budapest, Hungary
[4]Institute of Geological Sciences, Polish Academy of Sciences, Krakow, Poland

Boron (B) is rarely found in the solar system, while on the Earth B is concentrated in the continental crust (~10 µg/g) [1]. The most suitable analytical technique for B concentration measurements in whole rocks is prompt gamma activation analysis (there is a PGAA instrument connected to the Budapest Research Reactor). Boron is an important tracer of the recycled materials in subduction zones as it is an incompatible and fluid-mobile element, with various abundances in different reservoirs. In the slab B is concentrated in the oceanic crust and sediments, but most of it leaves at the beginning of subduction close to the suture zone. Some minerals can retain B and carry it further down into the mantle. Thus, arc volcanic rocks have relatively high B content (~35 µg/g) [2].

The Western Carpathian calc alkaline volcanic arc serves a special case, as these volcanic rocks show subduction related trace element pattern and B content, although there is no seismic sign of a subducted slab under the studied area [3]. We focused on the B geochemistry of different type of Western Carpathian volcanic rocks originating from different volcanic eruptions of various ages (9.4-16.7 Ma; B 2-90 µg/g). The variation in the B content is the highest in the Central Slovak Volcanic Field (4-76 µg/g), as is the case for the variation in the age of the measured rocks. The range of B content is also similar in the Tokaj Mts. (7-68 µg/g). Smaller the changes in the B content in the other volcanic areas: Börzsöny Mts. (11-43 µg/g); Visegrádi Mts. (7-43); Mátra Mts. (8-30 µg/g). For comparison B content of connected andesite intrusions from the Pieniny and Moravia (3-30 µg/g), flysch sediments from the Pieniny region (60-154 µg/g), lower and upper crustal xenoliths (0.1-2.5 and 50-60 µg/g) and mantle xenolith (0.1-0.26 µg/g) samples were measured from the Carpathian Pannonian region. The higher B content of volcanic rocks generally originates 1) from the subducted slab: the altered oceanic crust and sediments; 2) form the metasomatic effect of an earlier subduction; or 3) from melting the more B enriched upper crust. In active subduction zones the slab derived B content of volcanic arcs is decreasing toward the back arc region [4]. However, the age and the spatial distribution of the Western Carpathian volcanics do not show any correlations with their B content or other trace elements. The relatively high K_2O/Sm vs B/Sm ratio refers to fluid enrichment mainly originating from a crustal material rather then from subducted sediment (represented by the flysch samples). All these support the assumption [5,6] of the decompression melting of a previously metasomatised lithospheric mantle and lower crustal materials, rather then a direct fluid induced melting under the Western Carpathians.

Evidence for BO_3-groups in nominally boron-free minerals (NBFM) of mantle affinity

Hålenius, U.[1*], Skogby, H.[1] & Kristiansson, P.[2]
[1]Dept. of Mineralogy, Swedish Museum of Natural History, Stockholm, Sweden ([*]Ulf.Halenius@nrm.se)
[2]Dept. of Nuclear Physics, Lund Institute of Technology, Lund University, Lund, Sweden

The fact that boron may substitute for silicon in most rock-forming minerals has been known for a considerable time. It has generally been assumed that these relatively low amounts of B are incorporated through replacements of SiO_4 groups by BO_4 units (e.g., [1]).

Direct evidence of the structural incorporation of boron in nominally boron free minerals (NBFM) of mantle affinity, such as olivine, orthopyroxene and clinopyroxene group minerals, is very scarce. On the basis of chemical and IR-spectroscopic data on natural borian olivine, it has been suggested that the coupled substitution $B(F,OH)Si_{-1}O_{-1}$ operates in the olivine structure and that boron occurs in tetrahedral coordination [2]. However, later studies of B and OH-contents in olivine minerals could not establish a strong correlation between their atomic proportions [3].

With the aim to explore and better understand boron exchange processes and limitations for boron incorporation in NBFMs of mantle affinity we have studied in detail the crystal chemistry and, in particular, boron incorporation mechanisms in synthetic forsterite and clinoenstatite that were produced under dry and boron-saturated conditions. The results of polarised single crystal FTIR-spectroscopy (Fig. 1) in combination with EMP and high-resolution nuclear reaction analyses (NRA) show that relatively high concentrations of boron may be incorporated in these phases and that boron is preferentially occurring in trigonal BO_3-groups that replace SiO_4-groups.

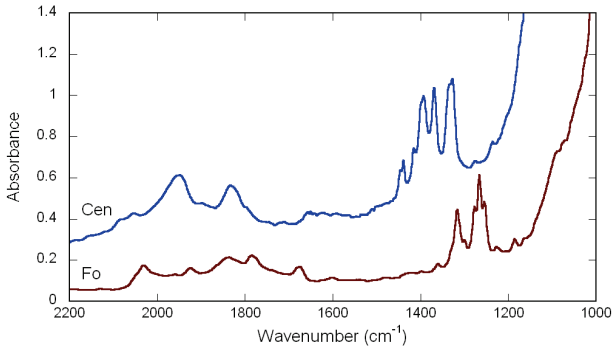

Fig. 1: IR spectra of synthetic clinoenstatite (Cen) polarised in c-direction, and forsterite (Fo) polarised perpendicular to c. Absorption bands in the 1200-1450 cm^{-1} region are assigned to BO_3 vibrations.

The replacement of SiO_4-tetrahedra by trigonal BO_3-groups must involve the breaking of one of the original T-O bonds of the olivine and pyroxene structures. This destabilises the structures and constitutes one important limiting factor for incorporation of higher B-contents in these phases.

Geochemical characteristics of Sarmatian volcanic rocks in the Tokaj Mountains, Hungary

Kiss, P.[1*], Molnár, F.[1], Gméling, K.[2] & Pécskay, Z.[3]
[1]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]geokissp@gmail.com)
[2]Institute of Isotopes, Hungarian Academy of Sciences, Budapest, Hungary
[3]Institute of Nuclear Research of the Hungarian Academy of Sciences, Debrecen, Hungary

The Tokaj Mountains are a part of the Inner Carpathian Volcanic Arc, which formed due to subduction collision and extension processes during the Miocene in the Carpathian-Pannonian Region. In the Tokaj Mountains, intermediate and acidic calc-alkaline volcanic rocks arose during the Middle-Upper Miocene (Badenian-Sarmatian-Pannonian) in a N-S oriented volcanotectonic graben that is underlain by Proterozoic to Mesozoic crystalline rocks. A large number of K/Ar age determinations have been made on the volcanic rocks. [1,2]. Newly collected samples were analysed to make a fully representative sample-set for the whole mountain range. In addition to K/Ar age determinations, major and trace element contents of the volcanic rocks, with an emphasis on B and Cl, were measured to study petrogenetic relationships. Boron is an excellent marker of the fluid circulation in the upper mantle and the lower crust, while chlorine has an important role in ore formation processes of volcanic-hydrothermal systems.

There are differences not only in major [3], but also in trace element geochemistry between the rocks from the northern and the southern part of the Tokaj Mountains. An airborne K anomaly map shows higher K intensity in rhyolite fields from the southern part of the mountains due to the presence of K-feldspar phenocrysts, whereas rhyolite lacks K-feldspar phenocrysts in the northern part. The B content of rocks is increasing from 10.1 to 68.1 µg/kg, which is a typical range for subduction related volcanic rocks [4], with increasing SiO_2 content. There is a positive correlation between the K and B content, while Cl content varies over a greater range in the K-rich rocks, except for perlitic rhyolite, in which Cl-enrichment can be attributed to perlitisation. Nonetheless, there are none of the statistical changes in the B and Cl content of rocks through time or space that is well known from recent subduction zones [5]. Therefore, we can conclude that the volcanism was generated by the decompression melting of an earlier metasomatised mantle rather than by fluid induced melting as other authors had suggested [6,7]. This conclusion is also supported by the trace element data (La/Yb vs. Ba/La, Rb vs. Ba/Rb). Comparison of the B and Ba concentrations in the rocks as a function of either Sm or Zr concentrations helped us to recognize that the fluid which had metasomatised the mantle originated from the altered oceanic crust. The higher Cl content of the high-K rhyolite in the southern Tokaj Mountains appears in agreement with the fact that volcanic centers in this area are laden with shallow zones of low sulphidization-type epithermal systems, whereas the low Cl – low K rhyolites in the northern part of the Tokaj Mountains are either unmineralized or pre-date ore mineralization.

The new microporous lead borate, leucostaurite, $Pb_2[B_5O_9]Cl \cdot 0.5H_2O$, from Atacama Desert

Meisser, N.[1*], Ansermet, S.[1], Brugger, J.[2], Krivovichev, S.[3], Belton, D.[4] & Ryan, C.[4]
[1]Musée Géologique & Inst. de Minéralogie & Géochimie, University of Lausanne, Switzerland ([*]nicolas.meisser@unil.ch)
[2]School of Earth & Environmental Sciences, University of Adelaide, Australia & South Australian Museum, Adelaide, Australia
[3]Dept. of Crystallography, Faculty of Geology, St. Petersburg State University, St. Petersburg, Russia
[4]CSIRO Earth Science and Resource Engineering, Clayton, Australia

The new mineral leucostaurite (IMA 2007-047) was discovered during systematic analytical checking of ore specimens from Mina Asunción, Sierra Gorda. These samples were collected by the consul of Switzerland in Chile, Julius Friedrich Häfliger (1834-1911) and donated by his widow in 1912 to the Natural History Museum of Bern.

Leucostaurite forms thin-tabular {010}, striated // [100], colorless, interpenetrated twinned crystals or sheaf-like aggregates up to 0.8 mm on a paralaurionite and boleite matrix. Other associated minerals are: caracolite, bindheimite, gypsum, penfieldite, challacolloite, schwartzembergite, cesanite and seeligerite.

Chemical analyses were carried out by means of an electron microprobe and by particle-induced gamma-ray emission (PIGE) for boron. The empirical formula is based on Pb+Sr+Ca = 2 *apfu*, with 1 H *pfu* from the structure refinement: $(Pb_{1.967}Sr_{0.026}Ca_{0.007})_{\Sigma 2.000}(B_{5.052}Si_{0.016})_{\Sigma 5.068}(Cl_{1.074}I_{0.004})_{\Sigma 1.078}O_{9.072}\ 0.5H_2O$. Single-crystal X-ray studies were carried with a 4-circle diffractometer and gave the following data: orthorhombic (*a* 11.3757(14) Å; *b* 11.5051(18) Å; *c* 6.5568(7) Å; *V* 858.14(19) Å^3) space group: *Pnn*2 and Z = 4.

The microporous crystal structure of leucostaurite (R_1 = 6.2%). contains a hilgardite-type 3-dimentional framework $Pb_2[B_5O_9]$. Leucostaurite shares the *P*nn2 space group with the synthetic compound $Na_{0.5}Pb_2(B_5O_9)Cl(OH)_{0.5}$ [1]. In this compound, one type of channel contains Cl^- ions, the other is disordered and contains OH^-, Cl^- and Na^+ ions; in leucostaurite these channels are occupied by Cl^- ions and Cl^- ions + H_2O groups, respectively. Upon heating to about 1000°C, the mineral releases HCl and H_2O due to mobility of the channels' content.

Located in central part of Atacama hyperarid desert, the range of Sierra Gorda hills appears as a highly Cu-Pb-Ag-Zn-mineralized area surrounded by lowlands constituted by Neogene and Quaternary salt-encrusted alluvial fans of Andean forarc endhoreic basin. These salts (chlorides, sulphates, borates, iodates, nitrates) are caliche-type salt cements, veins, and crusts within the upper few meters of unconsolidated soil and regolith. They are largely sourced from magmatic volatile compounds, exuded by Andean range volcanism or recycled by hydrothermally driven circulation [2], and in the case of nitrates, by atmospheric condensation [3]. The oxidation of base-metal deposits in the presence of these dispersed salts and/or brines leads to complex and unusual mineral associations. The exotic geochemical signature of these saline species is reflected in some typical minerals from northern and central Atacama deposits like bandylite $Cu_2[B(OH)_4]_2Cl_2$, santarosaite (IMA 2007-013) $(Cu,Pb)B_2O_4$, bellingerite $Cu_3(IO_3)_6 \cdot 2H_2O$, salesite $Cu(IO_3)(OH)$, schwartzembergite $Pb_5IO_6H_2Cl_3$ and seeligerite $Pb_3O(IO_3)Cl_3$.

Contrasting compositional trends in tourmaline from intragranitic REL-REE (NYF) euxenite-type pegmatites of the Třebíč Pluton, Czech Republic

Novák, M.[1*], Škoda, R.[1], Macek, I.[1] & Filip, J.[2]
[1]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic ([*]mnovak@sci.muni.cz)
[2]Centre for Nanomaterial Research, Palacký University, Olomouc, Czech Republic

Tourmalines from granitic pegmatites exhibit compositional trends generally characterized by increasing contents of Al, Li, Mn, F and Fe/(Fe+Mg) ratio but mostly by low Ca and Ti concentrations [1]. Tourmalines in decreasing abundance dravite>schorl>uvite>povondraite from euxenite-type pegmatites of the Třebíč Pluton [2] show several unusual features such as high concentrations of Ca≤0.45 apfu, Ti ≤0.48 apfu, Fe^{3+}/Fe_{tot} = 0.14-0.26 and generally low degree of fractionation with $Fe_{tot}/(Fe_{tot}+Mg)$ = 0.22-0.88 and Al_{tot} = 5.05-6.46 apfu (grey field on Fig. 1). The relative abundances in tourmaline (schorl> foitite>dravite>elbaite>uvite) from the most evolved euxenite-type pegmatite Klučov I [2] is characterized by moderate to high $Fe_{tot}/(Fe_{tot}+Mg)$ = 0.66-0.98, and low to high Al_{tot} = 5.04-7.03 apfu (blank field on Fig. 1). Newly discovered zoned tourmaline from the euxenite-type pegmatite Kožichovice III exhibits very distinct compositional evolution (see black arrow on Fig. 1). The black core is compositionally similar to those from the other euxenite-type pegmatites of the Třebíč Pluton [2] but dark green to dark blue narrow rims resembling rims of Fe-elbaite around schorl from complex (Li) pegmatites tend to Al-enriched dravite (Al_{tot} = 6.06-6.24 apfu, $Fe_{tot}/(Fe_{tot}+Mg)$ = 0.27-0.32) evidently Ti-depleted (≤0.02 apfu) and partly Ca-depleted (≤0.15 apfu). Different mineral assemblages of tourmaline rims: perthitic Kfs + Ab + Qtz at Klučov I and non-perthitic Kfs + Ab + Qtz + Chl at Kožichovice III, suggest distinct processes producing rims of tourmaline crystals although both show very similar textural evolution on the BSE images. Distinct $K_D^{crystal/medium}$ for Mg (at Klučov I medium ~ evolved melt, at Kožichovice III medium ~ hydrothermal fluids) may explain such compositional trends. Rather stable $Fe_{tot}/(Fe_{tot}+Mg)$ values in core and rim also confirm lack of Mg/Fe fractionation in fluids relative to melt at Klučov I (Fig. 1). Lower T and different parental medium at Kožichovice III both indicated by the mineral assemblage very likely controlled this compositional trend including very low Ti- and Ca-contents.

The influence of mineralization agents to formation of barium borates under hydrothermal conditions

Safronova, E.G.*, Mochenova, N.N. & Dimitrova, O.V.
Lomonosov Moscow State University (MSU), Moscow, Russia
(*safronova-eg@list.ru)

Boron is being reported at almost every stage of the geologic cycle, from magmatic to supergene units, which proves complex migration paths and concentration processes of boron in nature. Their study is only possible on a basis of comprehensive examination of the character of boron in geological systems. Hydrothermal synthesis allows to adjust physicochemical conditions close to the medium-temperature conditions characteristic of borate formation and provides a way to examine the problems of mineral formation and synthetic crystal genesis (including alio- and isovalent isomorphism of anions and cations).

Synthesis parameters have been set by natural borate formation conditions represented by a variety of known minerals. By using halogenides and carbonates of metalloids as additional preparation components it is possible to produce synthetic analogues of minerals in a laboratory environment. Mineralization agents had a dominant role in producing acid-base balance in solutions. Development area of the compounds with the most diverse boron-oxygen complexes, including pentaborates, corresponds to pH values ranging from 5 to 8 [1]. The experiments studied the influence of mineralization agents (Li^+, Na^+, K^+, F^-, Cl^-, Br^-, I^-, CO_3^{2-}) and the amount of B_2O_3 in the load, to generation of the boron-oxygen anion type in compounds at T = 280ºC, P ~ 70 atm. Analysis of the syntheses in a Ba-system proved that cation alkalinity and anion acidity in the mineralization agents composition have an indirect effect on the formation of compounds with a specific boron-oxygen radical, which includes determining acid-base balance of the solution.

The concentration of B_2O_3 in solution helps to adjust the influence of anions and alkaline cations to synthesize pentaborate compounds in multi-component Ba-boron systems. The new compounds and analogues of minerals with pentaborate radicals are received in solutions with BaO/B_2O_3 ratio from 0.5 to 0.3 by weight (Table 1).

Table 1: New chemical compounds synthesized in borate hydrothermal systems [2]

First description of datolite from Foresudetic Monocline, western Poland

Sokalska, E.T.* & Aagaard, P.
Dept. of Geosciences, University of Oslo, Oslo, Norway
(*e.t.sokalska@geo.uio.no)

Metavolcanic rocks of Foresudetic Monocline (western Poland) are known from numerous drillings. The volcanics are of different chemical composition, from rhyolitic to basaltic and they were formed in different environments. It is possible to recognise subvolcanic dykes, lava flows and ignimbrite layers.

The studied rocks contain a rich assemblage of secondary phases depending on whole-rock chemical composition and metamorphic conditions. The most important phases are pumpellyite, chlorite, mixed layer clays, zeolites, prehnite, epidote, quartz, albite, K-feldspar, Fe-oxides and carbonates. There are also different Ti-phases, actinolite, sulphides and sulphates.

One of studied samples taken from meta-andesite contains small amounts of datolite. This mineral was discovered in 2007 in Bolewice-1 drillcore [1]. It forms amygdule fillings and is intergrown with laumontite and other secondary phases. It was discovered by XRD analysis of amygdule fillings, but was detected in whole rock patterns as well. Unfortunately, B cannot be detected with EDS analysis and the main indicator of datolite presence in amygdule is lack of Al, which is present in Ca-zeolites from the same amygdules.

The datolite-containing rock sample was metamorphosed at temperatures close to 250°C, an estimate based on the secondary phases present. The paragenesis laumontite-datolite fits perfectly to determined metamorphic conditions according to data from Italy [2]. It is the first evidence of B metasomatism in the Foresudetic Monocline. Currently available data suggest that this process happened extremely rarely despite the fact that metamorphic temperatures were usually high enough for datolite formation (higher than 250°C). The most probable source of B for datolite formation was Zechstein brine circulating through the volcanic rocks.

[3]Inst of Problems of Chemical Physics, Russian Academy of Science, Moscow, Russia
[4]Dept.o de Física, Universidade Federal do Ceará, Fortaleza, Brazil

Pyrochlore-supergroup minerals have been studied during the last years, due to their economic importance as the major source for Nb, as well as to their exceptional physical and chemical properties. New nomenclature rules are being now introduced by a CNMNC-IMA subcommittee for the pyrochlore supergroup [1]. The investigation of pyrochlore-like materials enabled the development of significant technological applications, such as oxide superconductors, dieletric materials, and nuclear-waste disposals. Pyrochlore-supergroup minerals show $A_2B_2X_6Y$ stoichiometry and crystallize in the cubic space group $Fd\bar{3}m$, $Z = 8$, with $a = 10.4$ to 10.6 Å. A mineral of the microlite group from Volta Grande pegmatite, São João del-Rei, Minas Gerais, Brazil, was studied by electron microprobe, single crystal X-ray diffraction, Raman and FT-IR spectroscopy. Chemical analyses were carried out by means of an electron microprobe (WDS mode). The crystal structure was studied using Mo$K\alpha$ ($\lambda = 0.71073$Å) radiation on an Enraf - Nonius Kappa-CCD diffractometer. The crystal structure has been solved and refined using X-ray reflections [$I_{obs} > 2\sigma(I)$] and compositional constraints from electron microprobe analyses as $[\square_{0.81}(H_2O)_{0.57}Ba_{0.26}Sr_{0.18}U_{0.08}Ca_{0.02}\,Mn_{0.02}Bi_{0.02}\,Nd_{0.02}Ce_{0.01}Pr_{0.01}]_{\Sigma=2.00}\,(Ta_{1.59}Nb_{0.13}Si_{0.15}Sn_{0.10}Ti_{0.02}\,Fe_{0.01})_{\Sigma=2.00}\,[O_{5.21}(OH)_{0.79}]_{\Sigma=6.00}\,[(H_2O)_{0.95}Cs_{0.03}K_{0.02}]_{\sum Y=1.00}$. The occurrence of H_2O (due the cation occupancy of the A site) [2] in the vicinity of the A position (16*d*) and Y position (8*b*) was investigated during the refinement process. The micro-Raman measurements were performed using a T64000 Jobin–Yvon spectrometer equipped with an Olympus microscope and a LN_2-cooled CCD to detect the scattered light, and the infrared spectra was recorded on a Bruker FT-IR VERTEX 70 spectrometer equipped with a Nd:YAG laser (1.064nm excitation line) and a liquid-nitrogen cooled Ge detector. The bands identified, at 1600-1700 cm^{-1} and 3200–3800 cm^{-1}, were assignable to water stretching and bending vibrations. The results from Raman and FT-IR spectra confirm that water plays a significant role in the microlite structure.

Peatite-(Y) and ramikite-(Y), two new Li-Na-Y-(±Zr) phosphate-carbonate minerals from Mont Saint-Hilaire, Quebec, Canada

McDonald, A.M.[1*], Back, M.E.[2] & Gault, R.A.[3]
[1]Dept. of Earth Sciences, Laurentian University, Sudbury, Ontario, Canada ([*]amcdonald@laurentian.ca)
[2]Dept. of Natural History, Royal Ontario Museum, Toronto, Ontario, Canada
[3]Research Division, Canadian Museum of Nature, Ottawa, Ontario, Canada

Peatite-(Y), $Li_4Na_{12}(Y,Na,Ca,REE)_{12}(PO_4)_{12}(CO_3)_4(F,OH)_8$ and ramikite-(Y), $Li_4(Na,Ca)_{12}(Y,Ca,REE)_6Zr_6(PO_4)_{12}(CO_3)_4O_4$-$[(OH),F]_4$, are two new minerals discovered in a hydrothermally altered pegmatite (the 'Poudrette pegmatite') at Mont Saint-Hilaire, Rouville Co., Quebec. The two minerals develop in composite (epitaxial?) crystals, consisting of isolated or small clusters of cubes (individuals ranging from 0.1-0.5 mm in size), with ramikite-(Y) occurring as the cores of these crystals (dominant) and peatite-(Y) as very thin rims (< 50 μm in width). Ramikite-(Y) is yellow in color and translucent whereas peatitite-(Y) is pink and transparent. Associated minerals include donnayite-(Y), sabinaite, cryolite, elpidite, rhodochrosite, horváthite-(Y), catapleiite, polylithionite and others. Chemical analyses (EMPA, FTIR, Raman, LA-ICP-MS, single-crystal XRD) were used to confirm the chemistry of the two minerals (including the presence of essential Li, absence of B, Be, *etc*.).

Single-crystal XRD studies confirm that peatite-(Y) is orthorhombic [*P*222, *a* 11.167(2), *b* 11.164(2), *c* 11.162(1) Å] and ramikite-(Y) is triclinic [*P*1, *a* 10.9977(6), *b* 10.9985(6), *c* 10.9966(6) Å, α 90.075(4), β 89.984(4), γ 89.969(4)°]. The structures of both minerals have been solved and refined [R = 0.048 for peatite-(Y), R = 0.036 for ramikite-(Y)]. They both consist of two types of chains that extend along major crystallographic axes (*e.g.*, [001]): 1) alternating (PO_4) tetrahedra and [$YO_6(F,OH)_2$] polyhedra, and 2) alternating (PO_4) tetrahedra, (LiO_6) octahedra and (CO_3) groups. These chains alternate every 45° about each crystallographic axis and are linked together via (LiO_6) octahedra, forming an eight-membered pinwheel-like motif. An open framework of interconnnected eight-membered rings develops via linkages made between (LiO_6) groups and (CO_3) groups. The framework contains numerous channels within which Na and Y or Zr ions are housed in specific configurations: 1) eight-membered rings house Y or Zr in their centres and Na at their peripheries, 2) between respective eight-membered rings, alternating Y or Zr and Na ions, and 3) Y or Zr in the centres of four-membered (CO_3) rings. The crystal structures of the two minerals are intimately related but appear to be unique within the mineralogical realm. Both minerals are late-stage products that developed during the hydrothermal alteration of primary pegmatite minerals (*e.g.*, polylithionite, catapleiite, *etc.*). The interface contact and somewhat distinct chemical compositions of the two suggests early (and predominant) growth of ramkite-(Y) followed by hiatus, then subsequent (and minor) growth of peatite-(Y).

For the times they are a-changin': mineral names, groups, suffixes, the CNMNC and you

Mills, S.J.
Dept. of Earth and Ocean Sciences, University of British Columbia, Vancouver, Canada (smills@eos.ubc.ca)

2010 marks the 50th anniversary of the IMA and mineralogy is experiencing a boom of productivity and output. Recent proposals are changing the way that mineralogy organises itself, and will help move the science forward throughout the 21st Century. Some of the most recent changes are as follows.

The release of new mineral names: new procedures have been put in place to facilitate the dissemination of new mineral names in the public arena. Authors can choose to have the Commission release the new mineral name upon approval of the mineral. The names will appear in the Commission's bimonthly newsletter, which will be published in *Mineralogical Magazine*. This will enable citations to be made using the new mineral name until the full description is published. Authors are also entitled to have the name withheld until final publication, *i.e.*, the *status quo*.

The standardisation of mineral groups: the CNMMNC has recently approved a simplified definition of a mineral group, which is based on the structural and compositional aspects of a mineral. A hierarchical scheme for group nomenclature and mineral classification has been introduced which organises minerals in the following hierarchy.

1. Mineral class
2. Mineral subclass
3. Mineral family
4. Mineral supergroup
5. Mineral group(s)
6. Mineral subgroup or mineral series

A new procedure has also been put in place to facilitate the future proposal and naming of new mineral groups within the IMA–CNMNC framework. This allows for the introduction of new mineral groups as part of a new mineral submission, as part of a CNMNC subcommittee report or as a stand-alone proposal.

The introduction of suffix-based nomenclature schemes: Suffixes remain an issue of continuing debate. They are useful in some instances to simplify nomenclature and to help clarify mineral relationships, as well as to avoid the proliferation of names. However, suffixes should be used with caution, bearing in mind that what is good for one group of minerals might not be good for another and that historical and traditional aspects of mineralogy and nomenclature should always be considered before any changes are made.

Mineralogy of the Cleveland mine, Tasmania, Australia: unusual fluoride minerals in a skarn setting

Birch, W.D.
Geosciences, Museum Victoria, Melbourne, Victoria, Australia (bbirch@museum.vic.gov.au)

The Cleveland mine is situated at Luina in northwestern Tasmania, Australia. The mine exploited tin – copper ore in the form of pyrrhotite – cassiterite – stannite – chalcopyrite mineralisation, occurring as lenses within Cambrian metasediments and mafic volcanics [1]. The mineralisation was emplaced via fluids derived from the underlying Late Devonian Meredith Granite. An early stockwork system of quartz – fluorite – wolframite – molybdenite veins was followed by the sulfide mineralisation during metasomatic replacement of limestone beds. The last stage is represented by veins and vughs filled with quartz, fluorite and carbonates.

During the main period of operations, between 1968 and 1986, attractive specimens of fluorite, quartz and carbonates were collected. A suite of specimens containing assemblages of unusual fluorides and carbonates was also preserved, although where in the deposit they originated is uncertain. Exceptional crystals of rare minerals such as morinite and gearksutite are present, along with K-rich feldspar, bertrandite, siderite and vivianite. The crystal structure of gearksutite was determined using a crystal from this assemblage [2]. Several new minerals have also been characterised. Pseudo-octahedral crystals of a mineral with the stoichiometry of ralstonite, containing significant calcium, were described in the 1990s [3]; with more detailed investigation these have now been identified as a new species, approved by the IMA (CNMNC) in 2009. The new mineral has a crystal structure based on a modified pyrochlore framework that is possibly unique amongst published structures of pyrochlore-like minerals in having 1:3 ordering of Ca and Na in the *A* site and Al and Mg in the *B* site [4]. Another new species (IMA 2009-046), forming silky white dustings, has been shown to be the monoclinic polymorph of a member of the schorl–dravite (tourmaline) series, in which cation ordering of Fe^{2+} and $Mg^{2+}/Li^{+}/Al^{3+}$ cations on the *Y*- site has resulted in lowering of the symmetry.

Fluid inclusion and stable isotope data [1] indicate that these unusual assemblages probably crystallised during the final stage of mineralisation, from hydrothermal fluids that were moderately saline and low in CO_2, at temperatures between 250 and 300°C.

$Pb_2(S_2O_3)(CO_3)$: the first naturally occurring thiosulphate carbonate and its atomic arrangement

Kolitsch, U.
Mineralogisch-Petrographische Abt., Naturhistorisches Museum, Vienna, Austria (uwe.kolitsch@nhm-wien.ac.at)

A new lead(II) thiosulphate carbonate has been discovered on specimens from two Medieval mine dumps in the Leogang district, Salzburg, Austria. It forms small sprays of colourless to white prismatic crystals (up to 0.4 mm in length, with chisel-like crystal terminations) in thin fissures of massive galena. Further associated species are cerussite, anglesite, rare sulphur and very rare phosgenite.

The crystal structure has been determined using single-crystal X-ray diffraction data (Mo*Kα*, 298 K) which led to the formula $Pb_2(S_2O_3)(CO_3)$, confirmed by chemical analyses (SEM-EDS) and Raman spectroscopy. The new mineral is orthorhombic, space group *Pnma* (no. 62), with a = 16.343(1), b = 8.760(2), c = 4.592(3) Å, V = 657.4(5) Å^3, Z = 2 [$R1(F)$ = 4.2 %]. The structure is built up of an irregular Pb-O polyhedron, a thiosulphate ($S^{6+}O_3S^{2-}$ = S_2O_3) group and a CO_3 group. It has a layered character (Fig. 1), with (100) layers of Pb-O polyhedra and CO_3 groups alternating with layers of distorted $S^{6+}O_3S^{2-}$ tetrahedra. The Pb atom is coordinated by O ligands of the CO_3 groups and $S^{6+}O_3S^{2-}$ tetrahedra; there are only weak interactions between Pb and the anionic S atom.

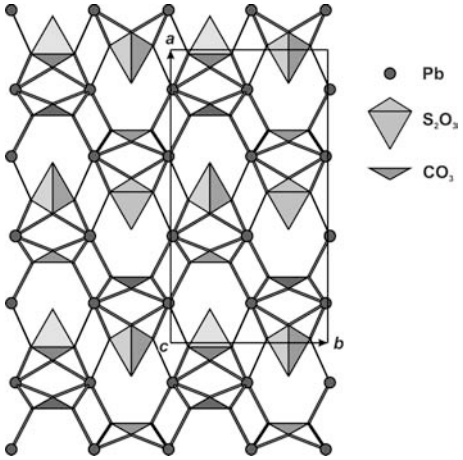

Fig. 1: Crystal structure of $Pb_2(S_2O_3)(CO_3)$, view along [001].

The lone electron pair on the Pb^{2+} cation is stereochemically active. The geometry of the thiosulphate group is in good agreement with literature data (*e.g.*, brief review in [1]). $Pb_2(S_2O_3)(CO_3)$, is a new representative in the very small group of known thiosulphate minerals [viaeneite - $(Fe,Pb)_4S_8O$, sidpietersite - $Pb^{2+}{}_4(S_2O_3)O_2(OH)_2$, steverustite - $Pb^{2+}{}_5(OH)_5(Cu^{1+}(S_2O_3)_3)(H_2O)_2)$] and naturally occurring thiosulphate phases in slags [$Ba(S_2O_3)\cdot H_2O$, $Ba_2F_2(S_2O_3)$].

$Pb_2(S_2O_3)(CO_3)$ is the product of partial oxidation of galena ore, with both S^{2-} and S^{6+} being present. A further occurrence of the new phase at an old mine in the Black Forest, Germany, has been confirmed very recently by a single-crystal structure refinement. These observations confirm previous conclusions ([2] and references therein) that thiosulphate minerals play an underrated role in the mineralogy of ore deposits.

The new species will be submitted for approval to the IMA CNMNC.

"Galloepidote" – a potential new end-member of the epidote group

Varlamov, D.A.[1*], Soboleva, A.A.[2] & Mayorova, T.P.[2]
[1]Inst. of Experimental Mineralogy, Russian Academy of Sciences, Chernogolovka, Russia ([*]dima@iem.ac.ru)
[2]Institute of Geology, Komi Scientific Centre, RAS Ural Branch, Syktyvkar, Russia

During a mineralogical study of Tykatlova gold-sulfide ore (northern area of the Sub-Polar Urals) a unique complexly zoned ultrahigh gallium (up to 14.5 wt.% of Ga) mineral of the epidote-allanite group was discovered. As far as known, no other gallium silicate mineral has been described.

The Tykatlova ore occurrence is situated in Early Ordovician acid volcanic rocks (rhyolites, rhyodacites) metamorphosed to greenshists facies, and is located in zones of schistosity and secondary silicification with superimposed sulfide mineralization. Ga- bearing phases have been found in sphalerite-pyrite veins with later galena and subordinate quantities of chalcopyrite.

Gallium-bearing phases are represented by minerals of the epidote-allanite group with complexly zoned structure. Usually they are inclusions in sulfides (often in sphalerite, seldom in pyrite), but sometimes are intergrown with sulphides; very rarely, small single grains are associated with gangue minerals.

Sizes of gallium epidote-allanite grains are typically 30-60 and, sometimes up to 100 microns across. Usually they have a complex concentric zoned structure, but in rare cases zones appear as separate homogeneous grains (10-15 microns). The general sequence of zones (from centre to rims) is (a) "galloepidote" (6-20 wt.% Ga_2O_3, REE are almost absent), (b) high-gallium allanite-(Ce) (3-11 Ga_2O_3, 3-20 wt.% REE), (c) allanite-(Ce) (0.0-2.0 Ga_2O_3, 4-19 wt.% REE), (d) epidote-allanite (Ga absent, 0-6 wt.% REE). Calculated formula of the richest Ga-bearing materials are $(Ca_{1.85}Mg_{0.11}Mn_{0.02})_{1.98}(Al_{1.89}Ga_{1.03}Fe^{3+}{}_{0.16})_{3.08}(Si_{2.93}Al_{0.07})_3O_{12}(OH)$ and $(Ca_{1.88}Mg_{0.15}Mn_{0.03})_{2.06}(Al_{1.77}Ga_{0.97}Fe^{3+}{}_{0.26})_{3.00}(Si_{2.91}Al_{0.09})_3O_{12}(OH)$.

Relationships to the epidote group have been drawn in terms of chemical composition and stoichiometry, Raman spectroscopy (measured spectra correlate very well with an epidote reference spectrum), substitution of almost half of the calcium ions by REE (characteristic for the epidote group), and morphologies of grains.

The structure of the mineral is not yet clear, but it is assumed that Ga^{3+} substitutes for Fe^{3+} ions and affect the heterovalent Ca ↔ REE substitution (epidote ↔ allanite). In external zones, lower gallium concentrations allow REE to substitute the epidote structure, as gallium vacates a large octahedral site where bivalent ions (Fe^{2+}, Mg, Mn) can enter for charge compensation for trivalent REE cations.

The richest Ga analyses almost ideally correspond to the formula $Ca_2Al_2Ga[Si_2O_7][SiO_4]O(OH)$, "galloepidote", and other analyses are placed between end-members of the ternary system epidote – "galloepidote" – allanite-(Ce). Thus, we propose that we have found a new end-member of the epidote group, "galloepidote" (a potential future name). The mineral has not yet been submitted for approval to the IMA CNMNC due to absence of the X-ray and another necessary data, but we hope to correct this lack in the near future.

Heteropolymolybdates: structural relationships, nomenclature scheme and new species

Kampf, A.R.[1*], Mills, S.J.[2] & Rumsey, M.S.[3]
[1]Mineral Sciences Dept., Natural History Museum of Los Angeles County, Los Angeles, CA, USA ([*]akampf@nhm.org)
[2]Dept of Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada
[3]Mineralogy Dept., The Natural History Museum, London, England, UK

The molybdoarsenates betpakdalite, natrobetpakdalite and obradovicite and the molybdophosphates mendozavilite, paramendozavilite and melkovite typically occur as coatings of minute, poor-quality and/or complexly twinned crystals. Heretofore, the structure of only betpakdalite had been determined. In this investigation, we examined type material for all of these minerals, as well as similar material from other sources, in an effort to elucidate the interrelationships within this enigmatic family of minerals.

Comparative powder X-ray diffraction proved effective in identifying structurally related phases and obtaining refined cell parameters for those phases for which single-crystal studies could not be conducted. Electron microprobe analyses were performed for all species studied and optimal conditions for analysis were determined. These methods indicated that natrobetpakdalite, mendozavilite and melkovite are isostructural with betpakdalite and suggested that obradovicite has a closely related structure.

Single-crystal investigations yielded several new structure refinements and the solution of the structure of obradovicite. Although crystals of paramendozavilite were inadequate for collection of structure data, cell parameters were for the first time determined. Both the betpakdalite and obradovicite structure types are based upon frameworks containing four-member clusters of edge-sharing MoO_6 octahedra which link by sharing corners with other clusters, with $Fe^{3+}O_6$ octahedra and with PO_4 or AsO_4 tetrahedra. The structures differ with respect to their linkages through the $Fe^{3+}O_6$ octahedra, leading to substantially different, but closely related framework configurations. The cell parameters of paramendozavilite indicate that its structure may be related to those of betpakdalite and obradovicite. We suggest that these minerals be termed "heteropolymolybdates".

Besides the presence of As or P in the tetrahedral site (*T*) of the frameworks, the non-framework cation sites are key to discriminating different species with these structures. One generally smaller cation site (*B*) at a center of symmetry is octahedrally coordinated to H_2O molecules and two or more disordered, partially occupied, generally larger, cation sites (*A*) are coordinated to O atoms in the framework and H_2O molecules. The general formulas for minerals with either the betpakdalite or the obradovicite structure are the same: $[A_2(H_2O)_nB(H_2O)_6][Mo_8T_2Fe^{3+}{}_3O_{30+7}(OH)_{7-x}]$, where: x is the total charge of $A + B$ and n is variable. Dominant cations noted in the *A* sites include K, Na and Ca and in the *B* sites Na, Ca, Mg, Cu and Fe. The various combinations that we identified define at least eight new heteropolymolybdate species.

We believe that a suffix-based nomenclature is most appropriate for the heteropolymolybdates with root names based upon the structure types and the *T* sites cations: betpakdalite (T = As), mendozavilite (T = P) and obradovicite (T = As); followed by two suffixes of the form: *-AB*, corresponding to the dominant cations in the two different types of non-framework cation sites. A new root name would be required for any new obradovicite structure species with T = P.

Our investigation of the paramendozavilite type specimen showed it to contain no paramendozavilite, but rather an apparently closely related new mineral. Another sample of paramendozavilite analyzed showed K > Na.

Qingheiite-(Fe^{2+}), $Na_2Fe^{2+}MgAl(PO_4)_3$, a new member of the wyllieite group

Hatert, F.[1*], Baijot, M.[1] & Philippo, S.[2]
[1]Laboratory of Mineralogy, University of Liège, Belgium ([*]fhatert@ulg.ac.be)
[2]Natural History Museum, Luxembourg

Qingheiite-(Fe^{2+}), ideally $Na_2Fe^{2+}MgAl(PO_4)_3$, is a new mineral species from the Sebastião Cristino pegmatite, Minas Gerais, Brazil [1]. It occurs as rims around frondelite grains, included in a matrix of quartz and albite. The empirical formula is $(\square_{0.65}Na_{0.35})(Na_{0.58}Mn^{2+}_{0.40}Ca_{0.02})$ $(Fe^{2+}_{0.68}Mn^{2+}_{0.32})$ $(Mg_{0.72}Fe^{3+}_{0.23}Fe^{2+}_{0.05})(Al_{0.62}Fe^{3+}_{0.38})[PO_4]_3$, and the single-crystal unit-cell parameters are a = 11.910(2), b = 12.383(3), c = 6.372(1) Å, β = 114.43(3)°, V = 855.6(3) Å^3, space group $P2_1/n$. Qingheiite-(Fe^{2+}) is the Fe^{2+} analogue of qingheiite $[Na_2MnMgAl(PO_4)_3]$, and belongs to the wyllieite group of minerals. The mineral species and its name were approved by the Commission on New Minerals, Nomenclature and Classification of the International Mineralogical Association (CNMNC-IMA) under the number 2009-076.

The crystal structure of qingheiite-(Fe^{2+}) has been refined, based on single-crystal X-ray diffraction data, to R_1 = 2.91 %. The basic structural unit is identical to that of other members of the wyllieite group, and consists of kinked chains of edge-sharing octahedra stacked parallel to {101}. These chains are formed by a succession of M(2a)-M(2b) octahedral pairs, linked by highly distorted M(1) octahedra. Equivalent chains are connected in the *b* direction by the P(1), P(2a) and P(2b) phosphate tetrahedra to form sheets oriented perpendicular to [010]. These interconnected sheets produce channels parallel to *c*, channels that contain the large X sites. The X(1a) site is a distorted octahedron, whereas the X(1b) site can be described as a very distorted cube. The morphology of the X(2) site corresponds to a very distorted gable disphenoid with a [7+1] coordination, similar to the X(2) site of rosemaryite [2] and to the A(2)' site of the alluaudite structure.

The structural features of qingheiite-(Fe^{2+}) are compared to those of other wyllieite-type phosphates: ferrorosemaryite from the Rubindi pegmatite, Rwanda ($\square NaFe^{2+}Fe^{3+}Al(PO_4)_3$, R_1 = 2.43 %, a = 11.838(1), b = 12.347(1), c = 6.2973(6) Å, β = 114.353(6)°) [3], rosemaryite from the Buranga pegmatite, Rwanda ($\square NaMnFe^{3+}Al(PO_4)_3$, R_1 = 4.01 %, a = 12.001(2), b = 12.396(1), c = 6.329(1) Å, β = 114.48(1)°) [2], wyllieite from the Buranga pegmatite ($Na_2MnFe^{2+}Al(PO_4)_3$, R_1 = 2.74 %, a = 11.954(2), b = 12.439(2), c = 6.406(1) Å, β = 114.54(1)°), and qingheiite from the Santa Ana pegmatite, Argentina (R_1 = 2.65 %, a = 11.878(3), b = 12.448(2), c = 6.438(2) Å, β = 114.49(1)°). These new structural data indicate that Al is predominant on the M(2a) site in the investigated samples, not on the M(2b) site as observed in ferrowyllieite [4]. The morphologies of the X(1a), X(1b), and X(2) crystallographic sites are also compared among the different minerals of the wyllieite group.

[2]Mineralogical Crystallography, Institute of Geological Sciences, University of Bern, Switzerland

[3]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM), RAS, Moscow, Russia

[4]Institute of Geochemistry, Mineralogy and Petrology, University of Warsaw, Poland

[5]Institute of Materials Science, University of Silesia, Poland

[6]August Chełkowski Institute of Physics, University of Silesia, Poland

[7]OOO Science-Research Center NEOCHEM, Moscow, Russia

New garnets with exotic composition: bitikleite-(SnAl) $Ca_3Sb^{5+}SnAl_3O_{12}$, bitikleite-(ZrFe) $Ca_3Sb^{5+}ZrFe^{3+}{}_3O_{12}$, toturite $Ca_3Sn_2Fe^{3+}{}_2SiO_{12}$, and elbrusite-(Zr) $Ca_3U^{6+}ZrFe^{3+}{}_2Fe^{2+}O_{12}$ [1], were found in the high-temperature skarns developed inside altered carbonate-silicate xenoliths captured by ignimbrites of the Upper Chegem caldera [2]. Primary high-temperature minerals of the ellestadite group, wadalite, rondorfite, lakargiite, srebrodolskite, kimzeyite and its Fe^{3+}-analog (IMA2009-029) are developed in three main skarn zones: I – spurrite, II – Ca-humite (chegemite, kumtyubeite, reinhardbraunsite), III – cuspidine (near-contact zone, formed after primary larnite zone). Bitikleite-(SnAl), bitikleite-(ZrFe) and toturite, and also grossular, andradite and schorlomite are found only in cuspidine zones together with fluorite. Elbrusite-(Zr) was detected both in spurrite and cuspidine zones. Low-temperature minerals are represented by garnets of the katoite-hibschite series, bultfonteinite, ettringite-group minerals, kalumite and numerous calcium hydrosilicates. Composition and structural investigations of high-temperature garnets belonging to the $Ca_3(Zr,Sn,Sb,U,Ti...)_2(Fe,Al,Si,Ti...)_3O_{12}$ solid-solution series and application of the dominant valence rule [3] allowed to distinguish additional new garnet-group minerals: 1) Sn-analog of elbrusite-(Zr) with the end-member formula $Ca_3U^{6+}SnFe^{3+}{}_2Fe^{2+}O_{12}$; 2) garnet of the bitikleite series with formula $Ca_3Sb^{5+}SnFe^{3+}{}_3O_{12}$; 3) Al-analog of toturite $Ca_3Sn_2Al_2SiO_{12}$; 4) Ti-analog of toturite $Ca_3Sn_2Fe^{3+}{}_2TiO_{12}$; 5) Ti-analog of Fe^{3+}-dominant kimzeyite $Ca_3Zr_2Fe^{3+}{}_2TiO_{12}$. Caucasian xenoliths are unique with regard to the number of different garnet-group minerals. To our knowledge, there are 16 garnet species, either new or potentially new minerals. Some of these garnets are non-silicates (ferrites and aluminates) but form a complete solid-solution series with kimzeyite and toturite. Therefore, CNMNC IMA decided to classify them in the garnet group. Such a decision opens the possibility to reorganize the garnet-group classification.

Chemical classification of tourmalines using the RHA method

Andriyanets-Buyko, A.*, Petrov, T. & Krasnova, N.
Saint-Petersburg State University, St.-Petersburg, Russia
(*a-baa@mail.ru)

A representation of the mineral chemistry for the tourmaline group needs a series of ternary diagrams (up to 16!), any of which, however, can't clearly display the complexity of even one mineral species [1]. We compiled a collection of 788 chemical analyses of natural tourmalines from 33 occurrences. These chemical data were classified using the PETROS program (author S.Moshkin), based on a method developed by T. Petrov [2], and as a result, we obtained the set of ordered RHA data.

R, the rank formula, is a sequence of chemical elements symbols of any analysis ordered on decreasing of their atomic %. En, the information entropy, is the characteristic reflecting complexity of the composition. An, the anentropy, reflects the purity of analysis. The diversity of our tourmalines compositions is represented in uniform hierarchical RHA table, where rank formulae are ordered as in dictionaries according to the number of elements in the Periodic Table. Our RHA-data can be searched in Internet by name: RHA language-method with cited files RHA-Tourmaline-2005.rar, RHA-Tur-Groups-2005.rar and Help_Turm-En on web-site: http://geology.pu.ru/.

Examples of rank formulae (R) for main tourmaline species are shown in Table 1 (elements in brackets can exchange in their rank position):

Table 1: Rank formulas of main tourmaline species

OAlSi(HB)**Li**(**Na**F...)	elbaite
OAlSi(HB**Li**)(**Ca**FNa...)	liddicoatite
O(AlSi)(HB**Mg**)(**NaV**Ca)…	vanadiumdravite
O(AlSi)(HB**MgCr**Na)...	chromdarvite
O(AlSi)(HB)**Mg**(**Na**Fe)…	dravite
OAlSi(HB)(**MnNa**FLi...)	tsilaisite
O(AlSi)(HB**Fe**)(**Na**Mg…)	schorl

In isomorphic rows, the predominance of one element over next in rank formulas can be used for impartial distinguishing of different mineral species. For example: when Mg > Fe – dravites, Fe > Mg – schorls. Combination of bold element symbols point at species inside the tourmaline group. Our suggestions for tourmaline chemical classification in more detail were published in [3].

The RHA-method gives the possibility to allocate the simple and clear-cut groups of the basic mineral species and subspecies; to define them authentically; to search for analogues without preliminary identification of a mineral variety; to estimate the originality of compositions. The RHA-method expands opportunities for improving nomenclature of minerals.

The RHA Database can be integrated in uniform classification of all mineral and rock compositions.

Manganoeudialyte, a new mineral from Poços de Caldas, Minas Gerais, Brazil

Atencio, D.[1*], Nomura, S.F.[1], Chukanov, N.V.[2], Rastsvetaeva, R.K.[3], Coutinho, J.M.V.[1] & Karipidis, T.K.[3]
[1]Instituto de Geociências, Universidade de São Paulo, Brazil
(*datencio@usp.br)
[2]Inst. of Problems of Chemical Physics, Moscow Oblast, Russia
[3]Inst. of Crystallography, Russian Academy of Sciences, Moscow, Russia

Manganoeudialyte is a new mineral with ideal formula $Na_{14}Ca_6Mn_3Zr_3[Si_{26}O_{72}(OH)_2]Cl_2 \cdot 4H_2O$, from a khibinite from the northern edge ("Anel Norte") of the alkaline Poços de Caldas massif, Minas Gerais, Brazil. It is concentrated in cm-sized patches interstitial to the main minerals of the rock. Associated minerals are eudialyte, K-feldspar, nepheline, aegirine, analcime, sodalite, rinkite, lamprophyllite, astrophyllite, titanite, fluorite, and cancrinite. Color is pink to purple, streak is white, and luster is vitreous. It is transparent to translucent and is not fluorescent. Mohs hardness is between 5 and 6, tenacity is brittle. Measured density is 2.890 g/cm^3; the calculated density is 2.935 g/cm^3. Manganoeudialyte is uniaxial (+), ω = 1.603(2), ε = 1.608(2) (white light). It is nonpleochroic.

The chemical composition is (by WDS mode electron microprobe data, H_2O content determined by the Penfield method, wt.%): Na_2O 12.01, K_2O 0.59, CaO 10.70, MnO 3.51, SrO 3.00, FeO 2.72, Al_2O_3 0.41, La_2O_3 0.15, Ce_2O_3 0.12, SiO_2 48.70, TiO_2 0.47, ZrO_2 12.08, Nb_2O_5 1.21, HfO_2 0.25, F 0.08, Cl 0.99, H_2O 3.5, -O=(Cl,F) -0.26, total 100.23. The empirical formula based on (Si + Al + Zr + Ti + Hf + Nb) = 29 is: $H_{12.08}Na_{12.05}Sr_{0.90}K_{0.39}La_{0.03}Ce_{0.02}Ca_{5.93}(Mn_{1.54}Fe_{1.18})Zr_{3.03}Nb_{0.28}Al_{0.25}Hf_{0.04}Ti_{0.18}Si_{25.20}O_{79.40}Cl_{0.87}F_{0.13}$.

The crystal structure was solved on a single crystal to R = 0.033. The mineral is trigonal, $R3m$; a = 14.2418(1), c = 30.1143(3) Å, V = 5289.7(1) Å^3, Z = 3. The coordination numbers are 6 for Mn, and 5 for Fe. The distorted octahedron $[MnO_4(H_2O)_2]$ contains two types of H_2O molecules. The crystal chemical formula of manganoeudialyte is: $[Na_{11.93}Sr_{0.81}(H_3O)_{0.70}K_{0.39}Ce_{0.07}]_{\Sigma 13.90}Ca_6]$ $[^{VI}Mn_{1.56}{}^{V}Fe_{1.20}{}^{V}Na_{0.24}]_{\Sigma 3.00}$ $[Zr_3]$ $[^{IV}(Si_{0.38}Al_{0.25})^{VI}(Nb_{0.29}Zr_{0.08})]_{\Sigma 1.00}$ $[^{IV}Si_{0.81}{}^{VI}Ti_{0.19}]_{\Sigma 1.00}$ $[Si_{24}O_{72}]$ $[(OH)_2][(H_2O)_{3.55}Cl_{0.88}(OH)_{0.84}O_{0.40}$ $F_{0.13}]_{\Sigma 5.80}$. The strongest reflection peaks of the powder diffraction pattern [d, Å (I, %) (hkl)] are: 6.421 (37) (104), 4.329 (30) (205), 3.526 (46) (027), 3.218 (100) (208), 3.023 (25) (042), 1.609 (77) (4.1.15), 1.605 (41) (4.0.16). IR spectrum shows that the mineral contains at least two locally different types of water molecules (the bands at 1620 and 1677 cm^{-1}) and the polyhedra $[Fe^{2+}O_5]$ (the band at 529 cm^{-1}). The new mineral species has been approved by the CNMNC (IMA 2009-039).

Classification and potential new minerals in the "mayenite group"

Bailau, R.[1*], Galuskin, E.V.[1], Gazeev, V.M.[2] & Pertsev, N.N.[2]
[1]Faculty of Earth Sciences, University of Silesia, Sosnowiec, Poland (*rbailau@gmail.com)
[2]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM) RAS, Moscow, Russia

The natural analogue of "Cl-mayenite" ($Ca_{12}Al_{14}O_{32}Cl_2$) and "Fe-wadalite" ($Ca_{12}Fe_8Si_6O_{32}Cl_8$), two new potential minerals, were discovered in the altered calcareous silicate xenoliths in ignimbrites of Upper Chegem caldera, Northern Caucasus, Kabardino-Balkaria, Russia. "Cl-mayenite" was formed from mayenite $^{VIII}Ca_{12}(^{IV}Al_8)^1(^{IV}Al_6)^2O_{33}$ by $O^{2-} = 2Cl^-$ replacement, for example $Ca_{12}[Al_{12.98}Fe^{3+}_{0.81}Si_{0.16}Ti^{4+}_{0.04}S^{6+}_{0.01}]_{14.00}O_{31.98}(OH)_{0.05}Cl_{2.28} \times 3H_2O$ [1]. Further, substitutions of Al^{3+} (Fe^{3+}) $\rightarrow Si^{4+} + Cl^-$, $2Al^{3+}$ (Fe^{3+}) $\rightarrow Si^{4+} + Mg^{2+}$ and $Ca^{2+} + Al^{3+}$ (Fe^{3+}) $\rightarrow Na^+ + Si^{4+}$ generated wadalite, $[Ca_{12.01}Na_{0.14}]_{12.15}[Al_{9.21}Si_{4.07}Mg_{0.15}Fe^{3+}_{0.46}Ti^{4+}_{0.03}Mn_{0.02}]_{13.95}Cl_{5.44}F_{0.03}$ and "Fe-wadalite" $[Ca_{12.10}Na_{0.02}]_{12.12}[Fe^{3+}_{9.07}Si^{4+}_{3.2}Al_{1.55}Ti_{0.06}V^{5+}_{0.01}]_{13.88}Cl_{4.91}$.

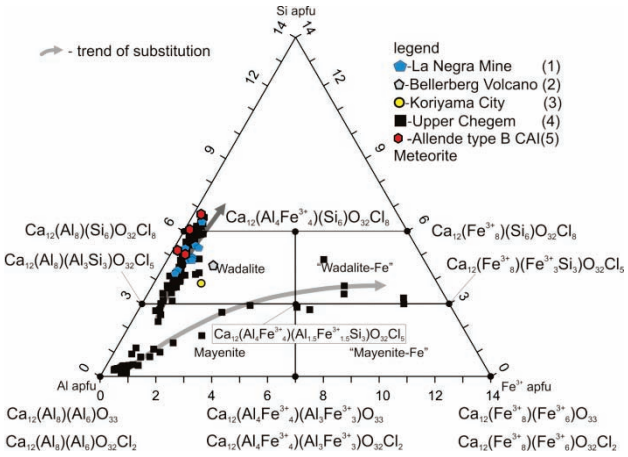

Fig. 1: Classification Si-Al-Fe^{3+}(apfu) diagram of "mayenite group" minerals: (1) wadalite from La Negra mine, Mexico [2]; (2) wadalite from Bellerberg Volcano, Germany [3]; (3) holotype wadalite from Koriyama City, Japan [4]; (4) Minerals of the "mayenite group" from Upper Chegem, Russia; (5) wadalite from Allende type B CAI meteorite [5].

Shorter Al^2-O distances compared with Al^1-O can be related to the prevailing substitution of Si in the Al^2 site [6]. The maximum number of substituted Al atoms by Si in the Al^2 site is 6 apfu [6]. Based on this fact, we propose the boundary between mayenite and wadalite-like minerals at 3 Si pfu. Some wadalite analyses show Si content higher than 6 apfu (Fig. 1), because the small amount of Si goes to the Al^1 site. The Fe^{3+} substitution of Al determines the Fe-rich wadalite and further "Fe-wadalite". The presence of a poorly bonded O atom facilitates its exchange by $2(Cl^-,OH^-)$, giving phases of composition $Ca_{12}Al_{14}O_{32}[O,(OH)_2,Cl_2]$ [7].

Kircherite, a new mineral of the cancrinite-sodalite group with a 36-layer stacking sequence: occurrence and crystal structure

Bellatreccia, F.[1*], Cámara, F.[2], Della Ventura, G.[1], Gunter, M.E.[3], Cavallo, A.[4] & Sebastiani, M.[5]
[1]Dipto. di Scienze Geologiche, Università di Roma Tre, Rome, Italy (*bellatre@uniroma3.it)
[2]CNR-Istituto di Geoscienze e Georisorse, UOS Pavia, Italy
[3]Dept. of Geological Sciences, University of Idaho, Moscow, Idaho, USA
[4]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy
[5]Dipto. di Ingegneria Meccanica e Industriale, Università di Roma Tre, Rome, Italy

We relate here the occurrence and the crystal structure of kircherite (IMA 2009-084), a new member of the cancrinite-sodalite group of minerals from Valle Biachella, Sacrofano, (Rome), in the Sabatini volcanic complex, Latium, Italy. The mineral occurs within miarolitic cavities of holocrystalline, syenitic, volcanic ejecta, associated with sodalite, biotite, iron oxides, titanite, fluorite, and a pyrochlore group mineral. The groundmass of the ejecta consists essentially of potasium-feldspar, with minor sodalite and brown mica.

Kircherite occurs typically as parallel associations of hexagonal, thin, tabular crystals (2 or 3 mm in diameter and 1 mm in thickness). Single platelets have a thickness that very rarely exceeds 0.5 mm. Crystals are colourless to light gray to white, translucent to opaque in the most altered parts of the crystals; lustre is greasy to silky. Fluorescence is in light pink under LW UV and deep red under SW UV. Hardness is (Mohs): 5.5; micro-indentation VHN load 10 g, mean 648.4 kg mm^{-2}, range ± 208.9 kg mm^{-2}. Cleavage on {001} is good. Density (calc.) is 2.457 g cm^{-3}. Kircherite is non-pleochroic and uniaxial negative with $\omega = 1.510(2)$, $\varepsilon = 1.502(2)$.

Kircherite is trigonal, space group *R*32, with , a = 12.8770(7) Å, c = 95.224(6) Å, V = 13677.2(13) $Å^3$, Z = 1. The empirical chemical formula obtained from EMP analyses is: $(Na_{89.09}Ca_{31.63}K_{18.85}Fe_{0.20}Mn_{0.06}Mg_{0.05}Ti_{0.03})_{\Sigma=139.91}$ $(Si_{108.13}Al_{107.87})_{\Sigma=216.00}O_{430.08}(SO_4)_{32.59}$ $Cl_{2.00}F_{0.53}(CO_3)_{0.09} \cdot 6.86H_2O$, which corresponds to the ideal formula $[Na_{90}Ca_{36}K_{18}]_{\Sigma=144}(Si_{108}Al_{108}O_{432})(SO_4)_{36} \cdot 6H_2O$.

The strongest six reflections in the X-ray powder pattern are [d in Å (I %) (*hkl*)]: 3.72 (100) (300), 2.65 (100) (2.1.28; 0.0.36), 3.23 (65) (2.1.19), 3.58 (60) (1.2.14), 3.60 (53) (1.0.25), 3.80 (52) (1.2.11).

The single-crystal FTIR spectrum rules out OH groups and shows the presence of H_2O and CO_2 molecules in the structural cages of the mineral.

The structure can be described as a stacking sequence of 36 layers of six-membered rings of tetrahedra along the c axis as ACABCABCABCACBCABCABCABCBABCABCABCAB…, where A, B and C represent the positions of the rings within the layers. The structure has 6 cancrinite cages (C), 24 sodalite cages (S) and 6 LOSOD cages (L) within the unit cell, and these account for a maximum of 36 SO_4^{2-} groups and 6 H_2O molecules (or Cl anions). There is a unique sequence of cages, єSSSLSSLSSSє and adjacent sequences are shifted 1/3 along [001]. Kircherite, having 36 layers, is the cancrinite with the longest complex sequence described to date.

The name is for Athanasius Kircher (1602–1680), a German Jesuit who was the founder of the museum of the Collegium Romanum in 1651, hereafter named the Museum Kircherianum.

Ambrinoite $(K,NH_4)_2(As,Sb)_8S_{13}\cdot H_2O$, the first natural (K,NH_4)-hydrated sulfosalt, from Signols (Piedmont, Italy)

Bonaccorsi, E.[1], Biagioni, C.[1], Moëlo, Y.[2], Pasero, M.[1*] & Bersani, D.[3]
[1]Dipto. di Scienze della Terra, Università di Pisa, Italy
([*]pasero@dst.unipi.it)
[2]Institut des Matériaux Jean Rouxel (IMN), Université de Nantes, France
[3]Dipto di Fisica, Università di Parma, Italy

Ambrinoite, ideally $(K,NH_4)_2(As,Sb)_8S_{13}\cdot H_2O$, occurs as a rare mineral species in Triassic evaporitic rocks from Signols, Susa Valley, Piedmont, Italy. It is associated with sulfur and orpiment; in the same occurrence galkhaite was also identified, together with enargite and stibnite. Ambrinoite is red in colour, with a vitreous to resinous lustre. Electron microprobe analyses give (wt.%): K 4.57, Na 0.05, Tl 0.13, N 0.48, As 35.69, Sb 21.69, S 34.69, O 1.52, sum 98.81. With N and O as NH_4 and H_2O, respectively, this gives the following chemical formula: $[K_{1.44}(NH_4)_{0.48}Na_{0.03}Tl_{0.01}][As_{6.00}Sb_{2.00}]S_{13.39}\cdot 1.20H_2O$.

With the data below this gives a calculated density of 3.305 g cm^{-3}. The presence of H_2O and NH_4 was confirmed by micro-Raman spectroscopy (O-H and N-H stretching and bending vibrations).

Ambrinoite is triclinic, space group $P\bar{1}$, with a 9.704(1), b 11.579(1), c 12.102(2) Å, α 112.82(1), β 103.44(1), γ 90.49(1)°, V 1211.6(3) Å^3, Z 2. The strongest X-ray powder diffraction lines [d in Å, (I), (hkl)] are: 10.78 (100) (001), 5.79 (55) (0 $\bar{2}$ 1), 4.23 (35) (102), 5.31 (34) ($\bar{1}$ 02), 5.39 (32) (002).

The crystal structure of ambrinoite was solved by direct methods and refined to R = 0.035 for 2554 reflections with $F_o > 4\sigma(F_o)$. It is based on MS_3 polyhedra (M = As, Sb) sharing corners to form double chains running along [100]; within each chain, trigonal pyramids arranged in M_3S_5 triangular groups alternate with single MS_3 pyramids. (K,NH_4) and H_2O are hosted in channels along [010]; K-S bonds crosslink the double MS_3 chains. H_2O molecules are coordinated to two K ions, but the latter are coordinated only by one H_2O molecule, plus seven or nine S atoms.

According to modular analysis, the crystal structure of ambrinoite corresponds to the stacking along c of two kinds of layer, with common parameters a = 9.7 and b = 11.6 Å, and different widths. The chemical compositions of the two layers are $[(As,Sb)_8S_{13}]^{2-}$ and $[K_2(H_2O)]^{2+}$, respectively. OD theory allowed one to derive two possible MDO polytypes, one triclinic (corresponding to the crystal studied), and the other monoclinic with symmetry $P2_1/c11$.

Ambrinoite belongs to the hutchinsonite merotypic series [1] and is closely related to gillulyite, $Tl_2(As,Sb)_8S_{13}$ [2], and gerstleyite, $Na_2(Sb,As)_8S_{13}\cdot 2H_2O$ [3].

The new mineral has been approved by the IMA CNMNC (2009-071). The name is after Pierluigi Ambrino, a mineral collector.

Tancaite-(Ce), a new molybdate from Italy

Bonaccorsi, E.[*] & Orlandi, P.
Dipto. di Scienze della Terra, Università di Pisa, Italy
([*]elena@dst.unipi.it)

Tancaite-(Ce), ideally $FeCe(MoO_4)_3\cdot 3H_2O$, is a new mineral species occurring within cavities in the quartz veins which cut the granite at Su Senargiu, Sarroch (CA), Sardinia, Italy. It is a secondary mineral formed in the oxidation zone of a sulphide ore vein. Associated minerals are quartz, muscovite, molybdenite, pyrite and mendozavilite.

Tancaite-(Ce) is red or pale brown in colour, with a vitreous to adamantine lustre. Electron microprobe analyses give (wt.%): SiO_2 0.34, CaO 0.09, Fe_2O_3 11.29, SrO 0.02, La_2O_3 5.04, Ce_2O_3 10.35, Pr_2O_3 1.07, Nd_2O_3 3.66, Sm_2O_3 0.19, ThO_2 2.58, UO_2 0.17, MoO_3 58.62, H_2O 7.43, sum 100.85. It gives the formula: $Fe^{3+}_{1.03}(Ce_{0.46}La_{0.23}Nd_{0.16}Pr_{0.05}Sm_{0.01}U_{0.01}Th_{0.07})_{\Sigma=0.99}(Mo_{2.96}Si_{0.04})_{\Sigma=3.00}O_{12}\cdot 3H_{2.00}O$, which can be simplified as $Fe^{3+}(REE)(MoO_4)_3\cdot 3H_2O$. The calculated density is 3.834 g/cm^3. The presence of H_2O was confirmed by micro-Raman spectrometry (stretching and bending vibrations of O-H).

The X-ray diffraction pattern of tancaite-(Ce) is characterised by a set of strong reflections, which indicate a cubic unit cell, with a = 6.80 Å and space group $Pm\bar{3}m$, plus a set of weaker reflections. By measuring only the strong reflections with a 4-circle diffractometer, it was possible to solve and refine the "average structure" of tancaite (R = 0.032 for 149 unique reflections). The crystal structure consists of FeO_6 octahedra (in violet, Fig. 1a) centred at the origin of the cubic cell and linked together through MoO_4 tetrahedra by corner sharing (Fig. 1b). The molybdate tetrahedra are statistically distributed in four symmetry-related positions, with ¼ occupancy. In the centre of the unit cell the REE cations exhibit 6+3 coordination, bonding six oxygen atoms and three H_2O molecules.

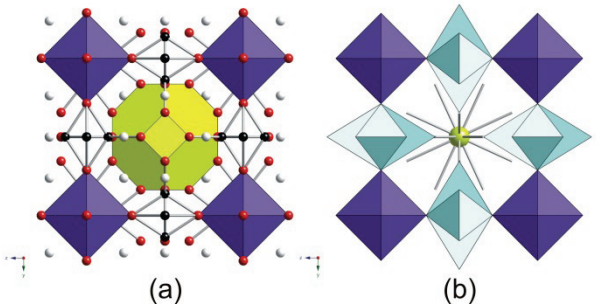

Fig. 1: Crystal structure of tancaite-(Ce) in space group $Pm\bar{3}m$; (a) the REE cation lies within the yellow polyhedron; Fe^{3+}-centred octahedra are indicated in violet; partially occupied Mo, O and H_2O sites are indicated, respectively, by black, red and white spheres; (b) the molybdate groups (light blue tetrahedra) are statistically distributed over four possible and mutually exclusive positions.

The refined structure is clearly an average structure, characterised by statistical disorder which involves the Mo cations, the H_2O molecules and the ligands of the REE cations at the centre of the unit cell. Two intensity data collections were performed in order to measure the weaker reflections and to solve the real crystal structure of tancaite-(Ce). The former was performed at the synchrotron facility Elettra, at the XRD1 beamline; the latter was carried out by means of a CCD-equipped Oxford diffractometer, operating with Mo$K\alpha$ radiation. Both sets of data indicated a larger super-cell with respect to the previous cubic cell with a = 6.80 Å. One of the possible super-cells showed rhombohedral symmetry, with a = 19.2, c = 47.4 Å in the hexagonal setting. The new mineral has been approved by the IMA CNMNC (# 2009-097). The name is after Giuseppe Tanca, mineral collector.

Capranicaite: a new mineral from Capranica, Viterbo, Italy

Callegari, A.M.[1], Boiocchi, M.[2], Bellatreccia, F.[3*], Caprilli, E.[3], Medenbach, O.[4] & Cavallo, A.[5]
[1]Dipto. di Scienze della Terra, Università di Pavia, Italy
[2]Centro Grandi Strumenti, Università di Pavia, Italy
[3]Dipto. di Scienze Geologiche, Università di Roma Tre, Roma, Italy ([*]bellatre@uniroma3.it)
[4]Institute of Geology, Mineralogy and Geophysics, Ruhr-Universität Bochum, Germany
[5]Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy

Capranicaite, ideally $KCaNaAl_4B_4Si_2O_{18}$, is a new mineral recently approved by the IMA-CNMNC (no. 2009-086), found in the Vico volcanic complex at Capranica, Viterbo, Italy. Capranicaite occurs in miarolitic cavities of a feldspathoid-bearing syenite ejectum, probably formed during late-stage metasomatic processes related to volcanic activity. Capranicaite forms small, tabular crystals no longer than 0.1 mm. Crystals are colourless, with a white streak and a vitreous lustre; they are not fluorescent and have a good {001} cleavage. Capranicaite is biaxial (-) with α = 1.495(1), β = 1.543(1), γ = 1.544(1); 2*V*(obs) = 7.3(2)°. Capranicaite is monoclinic, space group $P2_1/n$, *a* = 4.8507(2), *b* = 16.6156(6), *c* = 20.5445(7) Å, β = 90.245(1)°, *V* = 1655.82(17) Å^3, *Z* = 4. Electron microprobe analysis gives: SiO_2 20.70, Al_2O_3 32.91, B_2O_3 22.90, K_2O 5.36, CaO 11.04, Na_2O 4.08, Cs_2O 2.20, sum 99.19%. Calculated density is 2.41 g cm^{-3}. The formula unit, calculated on the basis of 18 O, is $(K_{0.69}Cs_{0.10})_{\Sigma 0.79}(Ca_{1.19}Na_{0.80})_{\Sigma 1.99}Al_{3.91}B_{3.99}Si_{2.09}O_{18}$.

Capranicaite is a Cs bearing inosilicate with a new topological arrangement of the 2-periodic Si_2O_6 single chains. The crystal structure of capranicaite consists of three overlapping layers of polyhedra (A, B, and C) normal to **c**. The A-layer contains the Si_2O_6 chains that extend along **a**. Respect than pyroxene, in capranicaite the Si-tetrahedra are rotated and the Si_2O_6 groups do not have two apical oxygens pointing towards the same direction. The B-layer is built by isolated AlO_4 tetrahedra and BO_3 triangles connected to form a continuous sheet of six-fold rings (3Al + 3B). Two B-layers are connected to a single sandwiched A-layer to forms a bi-dimensional B-A-B network. The B-A-B networks contain seven fold cavities not completely populated by K and minor Cs. Adjacent B-A-B bi-dimensional networks are linked together *via* the C-layer, constituted by isolated octahedra with a mixed (Ca,Na) population. Along **c** the sequence of layer results C-B-A-B-C-B-A-B-C (Fig. 1).

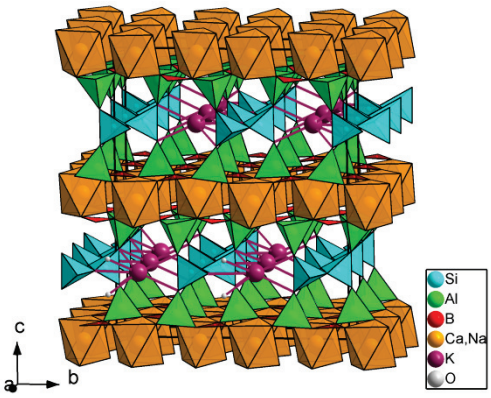

Fig. 1: A simplified sketch of capranicaite structure.

The name is for the locality, Capranica, Latium, Italy, where the holotype was found.

Ni-rich mcguinnessite from Eibenthal, Romania: an intermediate phase toward a new hypothetical rosasite-group end-member

Fehér, B.[1], Szakáll, S.[2*] & Bigi, S.[3]
[1]Dept. of Mineralogy, Herman Ottó Museum, Miskolc, Hungary
[2]Dept. of Mineralogy and Petrology, University of Miskolc, Hungary ([*]askszs@uni-miskolc.hu)
[3]Dept. of Earth Sciences, University of Modena and Reggio Emilia, Modena, Italy

Along the Danube River in the South Banat region (Romania) the gabbro-peridotite massif contains serpentinized dunites. There are some sulphides (*e.g.* chalcopyrite, pentlandite) and secondary minerals (*e.g.* nimite, theophrastite, mcguinnessite, glaukosphaerite) in the fissures of serpentinite.

In the surroundings of Eibenthal rosasite-group minerals occur in great chemical variability, among which the most interesting phase is a Ni-rich mcguinnessite so far. It forms apple green globular aggregates and crusts consisting of 1-2 µm lamellae. It was formed by reaction of primary sulphides and serpentine minerals.

General formula of rosasite-group minerals can be expressed as $M1M2(CO_3)(OH)_2$ where M1 = Cu and M2 = Mg in mcguinnessite. In Eibenthal material considerable amount of Ni substitutes Cu in M1 while M2 = Mg, so it represents an intermediate phase between mcguinnessite and a hypothetical end-member $NiMg(CO_3)(OH)_2$. We performed 15 spot analyses on this material by electron microprobe (see Fig. 1) from which the average composition: NiO 20.18, CuO 23.47, MgO 21.80, CO_2 (calc.) 24.35, H_2O (calc.) 9.97, total 99.77 wt.%. It corresponds to $(Cu_{0.53}\ Ni_{0.47})_{\Sigma=1.00}\ (Mg_{0.98}\ Ni_{0.02})_{\Sigma=1.00}\ (CO_3)\ (OH)_2$.

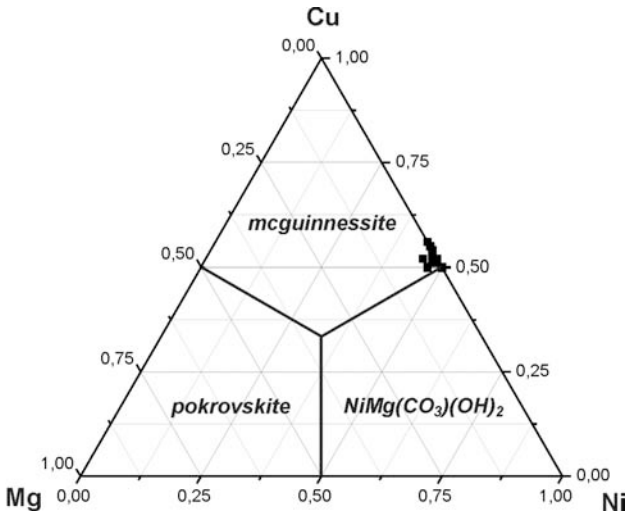

Fig. 1: Ternary diagram of cations in M1 site for Ni-rich mcguinnessite of Eibenthal, where M2 = Mg.

Ni-rich mcguinnessite is monoclinic with space group $P2_1/a$. The refined unit-cell parameters: *a* = 12.98(2), *b* = 9.359(8), *c* = 3.157(3) Å, β = 111.3(2)° are based on 18 reflections in the X-ray powder pattern performed by 114.6 mm Gandolfi camera. It has a cell volume of 357.3(4) Å^3 with *Z* = 4. Calculated density is 3.351 g/cm^3.

Investigated material has been deposited at the mineral collection of Herman Ottó Museum (Miskolc, Hungary) under catalogue number 2009.90.

A new fluorine-rich phase from Eldfell volcano, Iceland

Garavelli, A.[1*], Balić-Žunić, T.[2], Mitolo, D.[1], Acquafredda, P.[1], Leonardsen, E.[3] & Jakobsson, S.P.[4]
[1]Dept. of Geomineralogy, University of Bari, Italy ([*]a.garavelli@geomin.uniba.it)
[2]Dept. of Geography and Geology, University of Copenhagen, Denmark
[3]St. Karlsmindevej, Denmark
[4]Icelandic Institute of Natural History, Reykjavik, Iceland

A new fluorine-rich phase, with ideal formula $CaAlF_5$, was found among fumarolic encrustations collected in 1988 on the Eldfell volcano (Heimaey, Vestmannaeyjar Archipelago, Iceland). The new phase forms a fine-grained mass of 10-50 μm in size (Fig. 1), which was found on 2-3 cm crust on altered scoria of hawaiite [1] deposited after the eruption started on January 23th 1973.

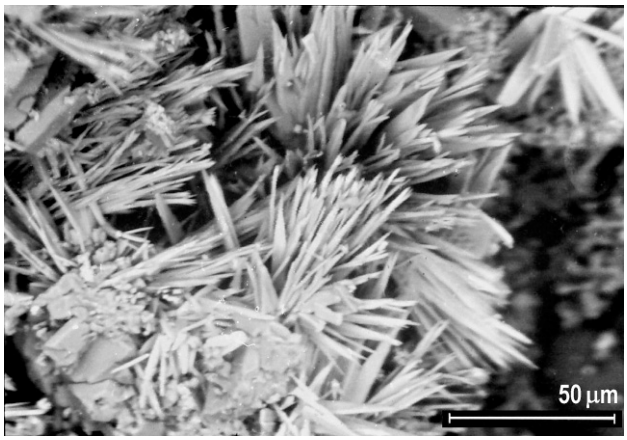

Fig. 1: SEM backscattered image of elongated pointed crystals.

Associated minerals are ralstonite, $Na_xMg_xAl_{2-x}(F,OH)_6 \cdot H_2O$, and another potentially new phase with composition $MgAlF_5 \cdot 1.5H_2O$ [2]. The new phase from Eldfell volcano is colourless to white, transparent, non-fluorescent, has a vitreous lustre and a white streak. The calculated density is 2.79 g/cm^3. SEM-EDS quantitative chemical analysis shows the following range of concentrations (wt.%): Ca 19.15–25.53 (average 21.48), Al 11.42–12.65 (average 11.93), F 52.76–56.30 (average 53.99), O 10.06–14.29 (average 12.24). The empirical chemical formula, calculated on the basis of 7 atoms pfu, is $Ca_{0.84}Al_{0.68}[F_{4.34}(OH)_{1.15}]_{\Sigma=5.49}$. X-ray single-crystal study was prevented by overlapping thin crystals. The X-ray powder diffraction pattern closely resembles that of synthetic α-$CaAlF_5$, which is monoclinic, space group *C*2/*c*. Indexing was performed on the basis of lattice parameters reported for the synthetic analogue (PDF 80-1728). Calculated unit-cell parameters are the following: a = 8.711(5), b = 6.310(4), c = 7.354(6) Å, V = 366.180 Å^3, Z = 4. The strongest reflections in the powder diffraction diagram [d in Å, (I relative to 10)] are: 3.95, (10); 3.17 (9); 3.15, (9); 2.28 (3); 2.01 (1); 1.97, (3); 1.82, (2); 1.77 (2); 1.67 (1).

On the basis of chemical analyses and X-ray data, the new mineral corresponds to the synthetic compound α-$CaAlF_5$ [3] which crystallizes at about 700°C in the system CaF_2-AlF_3 [4].

The new species will be submitted soon for approval to the IMA-CNMNC.

Drobecite, a novel mineral from the Lavrion, Greece, deposit

Giester, G.[*] & Rieck, B.
Inst. für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria ([*]gerald.giester@univie.ac.at)

Ores of the Manto-Type Cu-Pb-Zn deposits of the Lavrion Mining District [1] are locally enriched in Cd, which leads to a rich suite of Cd-bearing minerals. Primary minerals are greenockite and hawleyite, and secondary minerals niedermayrite [2], otavite, keyite and monteponite have been identified. A detailed study of one such occurrence at the Esperanza Mine revealed the existence of three more species thus far unknown or inadequately described. The mineral with the chemical composition $CdSO_4 \cdot 4H_2O$ has been approved as the new species drobecite (IMA 2002-034), whereas the compounds $CdSO_4 \cdot H_2O$ and $3CdSO_4 \cdot 8H_2O$ have so far been found only in insufficient quantities and qualities to complete their description as new minerals.

The similarity of the powder diffraction pattern of drobecite to that of the rozenite-type members indicated close structural relationships [3]. Isotypy of the crystal structure of drobecite was finally proven by a Rietveld refinement: the crystal structure was refined to R = 0.055 (without hydrogen atoms) with cell-parameters: a = 6.586(5), b = 14.329(5), c = 8.571(5) Å, β = 91.51(4)°, Z = 4 in space group $P2_1/n$.

Drobecite occurs as fibrous, colourless to light blue veinlets < 0.1 mm in the hosting rock and as fibrous aggregates in small cavities containing other Cd-bearing species. Sometimes these aggregates are bent ("rams horn"). The individual grains are not suitable for single crystal determination of the crystal structure with maximum dimensions of 5 × 10 × 500 μm^3.

The chemical composition of drobecite varies between $(Cd_{0.97}Cu_{0.03})SO_4 \cdot 3.92H_2O$ and $(Cd_{0.78}Cu_{0.08}Mg_{0.12}Zn_{0.02})SO_4 \cdot 3.87H_2O$ (normalized to 1 SO_4, H_2O by difference to 100%). It is notable, that all samples contain Cu, whereas the other trace elements often are not present. It is yet unknown, if the always observed Cu content in the naturally occurring material is responsible for the stabilization of the phase.

The density was measured by heavy liquids and found to be 2.23(3) g/cm^3, which agrees well with the calculated density of 2.30(2).

Drobecite is colourless to light blue, depending obviously on the Cu-content. It has a white streak, is lustrous and has a Mohs hardness of 2. The optical parameters determined are α = 1.430(3), β = 1.454(3), γ = 1.470(3), 2V = 70° (77° calc.).

Cuproneyite – $Cu_7Pb_{27}Bi_{25}S_{68}$, a new mineral from Băiţa Bihor, Romania

Ilinca, Gh.[1*], Topa, D.[2], Makovicky, E.[3] & Zagler, G.[2]
[1]Dept. of Mineralogy, University of Bucharest, Romania
([*]ilinca@geo.edu.ro)
[2]Dept. of Materials Research and Physics, University of Salzburg, Austria
[3]Dept. of Geology and Geophysics, University of Copenhagen, Denmark

Cuproneyite, with the ideal formula $Cu_7Pb_{27}Bi_{25}S_{68}$, is a new mineral species found in the skarn deposit of Băiţa Bihor, Romania. The mineral occurs in irregular aggregates, nests and veinlets of up to 5 cm, with predominant cosalite, bismuthinite-aikinite derivative $bd_{73\text{-}77}$, and calcite, within the diopside skarn. Cuproneyite is opaque, has a silver-grey color, metallic luster and displays perfect cleavage along crystal elongation. The average Mohs hardness is about 3 (approximated from the average micro-indentation hardness of 222.5 kg/mm^2). Under the microscope, cuproneyite forms irregular or short prismatic grains, 300 μm in length, intergrown with lamellae and irregular patches of cosalite and hammarite-friedrichite. Bireflectance is barely visible in air and moderate in oil immersion, with a grayish white color with faint yellowish tints in the lightest position to grayish white color with faint bluish tints in the darkest position. Between crossed polars, the rotation tints of the most anisotropic grains are dark brownish grey to light brownish grey. Internal reflections are absent. The reflectance data (measured in air) are: 40.4, 47.1 at 470 nm, 39.3, 45.7 at 546 nm, 38.3, 44.3 at 589 nm and 38.1, 43.9 % at 650 nm. The average results of 24 electron-microprobe analyses are Cu 3.36(11), Ag 0.30(3), Pb 40.08(29), Bi 39.55(22), Se 0.12(5), Te 0.12(4), S 16.13(8) wt.%, corresponding to $Cu_{7.1}Ag_{0.38}$-$Pb_{26.03}Bi_{25.47}S_{68}$, calculated on the basis of (S + Se + Te) = 68 atoms per formula unit. The simplified formula (after reconversion of x(Ag + Bi) into 2x Pb) is $Cu_7Pb_{27}Bi_{25}S_{68}$ (Z = 2). It is in agreement with the empirical formula deduced from crystal-structure analysis. The density, 7.14 g/cm^3, was calculated using the structurally derived formula for Z = 1. The unit cell of cuproneyite is monoclinic, with a 37.432(8), b 4.0529(9), c 43.545(9) Å, β 108.803(1)°, V = 6253.62(1) Å^3, space group *C2/m*, and Z = 1. The strongest lines in the calculated X-ray powder pattern (d in Å, (I), *hkl*) are: 3.735, (96), -10.0.3; 3.347, (84), 4.0.10; 2.956, (77), 713; 2.867, (100), 714; 2.027, (81), 020.

Cuproneyite is an isotype of neyite [1]. The defining difference is the fact that the independent Ag position present in neyite is completely occupied by Cu in cuproneyite. Copper has a linear coordination in a flat-octahedral environment, situated in the central portions of the (001) walls of the crystal structure. This site displays a typical Cu-S bond length of 2.239 Å, to be compared with 2.415 Å of the Ag-S bond for silver in this position in neyite. The unit cell dimensions of cuproneyite are reduced against neyite only by 0.1-0.2 Å and the monoclinic angle β is unchanged. The volume of the unit cell is reduced by 65 Å^3. The name of the new mineral reflects this relationship. Both the mineral and its name have been approved by the Commission on New Minerals, Nomenclature and Classification (IMA 2008-053). Neyite has been classified as a typical sulfosalt with a 'box-work' structure (*e.g.*, [1-3]).

The crystal-structural and paragenetic classification of minerals revisited (classes of nitrates, iodates and organic minerals)

Kostov, R.I.
Dept. of Mineralogy and Petrography, University of Mining and Geology "St. Ivan Rilski", Sofia, Bulgaria
(rikostov@gmail.com)

A dual crystal-structural and paragenetic principle introduced by Bulgarian mineralogist Ivan Kostov (1913-2004) has been applied to a rational classification of the classes of minerals [1-6]. Main divisions (associations) are based on geochemically allied metals in the composition of these minerals, and subdivisions (axial, planar, pseudoisometric and isometric types) on their overall structural anisometricity. The latter provides both structural similarity and genetic information, as manner of crystal growth in geological setting under different conditions of crystallization. The structural anisometricity may conveniently be presented by the *c/a* ratio of the minerals with high symmetry and by the $2c/(a+b)$, $2b/(a+c)$ and $2a/(b+c)$ ratios for the low symmetry minerals. The respective ratios are less, nearly equal, equal or above 1.00. The unit cell or sub-cell and the corresponding structures are denoted as axial or A-type, pseudo-isometric or (I)-type, isometric or I-type and planar or P-type, notations which correspond to chain-like, framework and sheet-like structures, respectively ino-, tecto- and phyllo-structures. Crystal chemical approach to the classification of minerals has been applied in general mineralogical works [7]. The basic criteria used for classification of minerals are suitably summarized [8-10].

The notations A, (I) and P offered are further enriched by adding as superscript the direction of structural anisometricity for the low symmetry minerals – A^c, A^b and A^a, $(I)^c$, $(I)^b$ and $(I)^a$, and P^c, P^b and P^a. Use is made of the indices (*hkl*) of the crystal habit form and [*uvw*] symbols for elongation added as subscripts. Combinations of both indicate form and elongation. Such type of systematic has been already applied to almost all mineral classes – oxides [11], silicates [12], sulphides [13], phosphates and related minerals [14], sulphates [15], borates [16], and carbonates [17; for review on different classes of minerals see 5, 6].

New examples are given in the last reviewed classes of minerals: nitrates within the Al-Mg-Fe, Na(K)-Ca-Ba and Cu-Pb-Zn associations, iodates within the Na(K)-Ca-Mg and Cu-Pb-Zn associations and organic minerals within the C-H-(O-N), Al-Mg-Fe, Na-Ca-Ba and Cu-Pb-Zn associations.

Fluoro-micas from Bayan Obo, Inner Mongolia, China: F-analogues of tetraferriphlogopite and kinoshitalite

Miyawaki, R.[1*], Shimazaki, H.[1,2], Shigeoka, M.[1], Yokoyama, K.[1], Matsubara, S.[1], Yurimoto, H.[3] & Yang, Z.[4]
[1]Dept. of Geology and Paleontology, National Museum of Natural Sciences, Tokyo, Japan ([*]miyawaki@kahaku.go.jp)
[2]University of Tokyo, Japan
[3]Dept. of Natural History Sciences, Hokkaido University, Sapporo, Japan
[4]Inst. of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

F-analogues of tetraferriphlogopite ($KMg_3Fe^{3+}Si_3O_{10}F_2$) and kinoshitalite ($BaMg_3Al_2Si_2O_{10}F_2$) occur in metamorphosed carbonate rocks from the South ore body of the East Mine, Bayan Obo, Inner Mongolia, China in association with phlogopite, yangzhumingite ($KMg_{2.5}Si_4O_{10}F_2$) [1], bastnäsite-(Ce), cordylite-(Ce), monazite-(Ce), fluorbritholite-(Ce) and huanghoite-(Ce). They formed during a stage of hydrothermal activity or during a metamorphic event.

The F-analogue of tetraferriphlogopite is brown with a white to pale brown streak. It is transparent showing pearly luster and perfect cleavage on {001}. The hardness is 3-4 on the Mohs scale. The calculated density is 2.966 g cm^{-3}. This mineral is optically biaxial (–) with n = 1.576 (min) - 1.582 (max). It shows reverse pleochroism (Z' = colourless, X' = light brown; Fig. 1).

The F-analogue of kinoshitalite is transparent and colourless with a white streak and pearly luster. Cleavage is perfect on {001}. The calculated density is 3.235 g cm^{-3}. Electron microprobe analyses with SIMS for Li gave the empirical formulae (based on 12 anions); $(K_{0.94}Na_{0.02}Ba_{0.01})(Mg_{2.62}Li_{0.15}Fe^{+2}_{0.14}Mn_{0.01})(Si_{3.33}Fe^{3+}_{0.66}Al_{0.01})O_{10}[F_{1.65}(OH)_{0.35}]$ and $(Ba_{0.56}Na_{0.25}K_{0.06})(Mg_{2.76}Fe^{2+}_{0.14}Ti_{0.01})(Si_{2.73}Al_{1.15}Fe^{3+}_{0.12})O_{10}[F_{1.72}(OH)_{0.28}]$ for the F-analogues of tetraferriphlogopite and kinoshitalite, respectively.

XRD data for the minerals obtained with an IP-Gandolfi camera could be indexed by reference to calculated XRD traces based on the single-crystal structures of tetraferriphlogopite [2, 3] and kinoshitalite [4], respectively. Refined lattice parameters, space group $C2/m$, are a = 5.325(3), b = 9.217(5), c = 10.192(7) Å, β = 100.03(5)º, V = 492.6(5) $Å^3$ (F-analogue of tetraferriphlogopite), and a = 5.316(1), b = 9.2082(2), c = 10.044(2) Å, β = 100.16(2)º, V = 483.96(17) $Å^3$ (F-analogue of kinoshitalite).

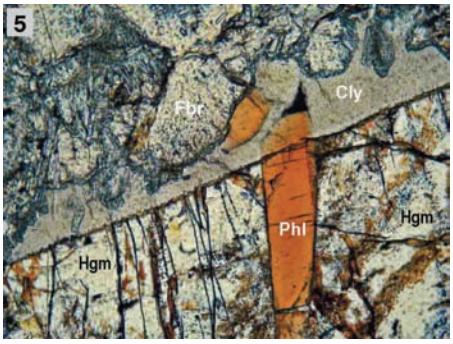

Fig. 1: Photomicrograph of the F-analogue of tetraferriphlogopite with reverse pleochroism taken in plane polarized light. The direction of the polarizer is NS. Width of image is about 1 mm; Phl: F-analogue of tetraferriphlogopite; Fbr: fluorbritholite-(Ce); Hgm: humite-group mineral; Cly: clayey serpentine.

Reinvestigation of orpheite using the type material: is it a valid mineral species?

Mladenova, V.[1*], Kolitsch, U.[2], Kenkman, T.[3], Hecht, L.[3] & Schmitt, R.-T.[3]
[1]Sofia University St. Kliment Ohridski, Sofia, Bulgaria ([*]vassilka@gea.uni-sofia.bg)
[2]Universität Wien Geozentrum, Vienna, Austria
[3]Museum für Naturkunde, Berlin, Germany

Orpheite from the Madzharovo base metal deposit in the Eastern Rhodope Mountains, Bulgaria, was described in 1972. $H_6Pb_{10}Al_{20}(PO_4)_{12}(SO_4)_5(OH)_{40}\cdot 11H_2O$ is an approximate chemical formula [1].

The mineral was approved by the IMA Commission on New Minerals and Mineral Names in 1972. However, in the American Mineralogist abstract of the original description, serious doubts concerning the validity of the species were expressed [2]. Therefore, the species status of orpheite and its chemical formula are noted as being doubtful in many modern data bases. However, orpheite from the Madzharovo deposit has never been reinvestigated and it still retains species status.

In order to obtain new data and to clarify the species status of the mineral, type orpheite and hinsdalite from Madzharovo have been reinvestigated.

The minerals were studied by standard techniques including X-ray diffraction (powders and single crystals), EPMA, SEM-EDS and micro-Raman spectroscopy.

Orpheite and hinsdalite mainly occur as light bluish to colourless, and rarely pale brown, microcrystalline pseudomorphs and perimorphs after hexagonal, prismatic crystals of pyromorphite. Both minerals display simple spindle-like morphology with pointed crystal terminations. Sometimes these terminations are dissolved away, resulting in fibrous forms. Both minerals form the same kinds of penetration twins.

X-ray diffraction studies show close similarities between orpheite and hinsdalite (ICDD-PDF 89-7559), as well as plumbogummite.

Raman spectra of both orpheite and hinsdalite show the same characteristic bands.

BSE analyses reveal strongly zoned crystals of both minerals with widths of different zones varying from less than 1 and up to 10 μm. At the rims of the crystal aggregates an increase in S content and concomitant decrease of P and Al contents is observed, which could be a result of later alteration processes. The highest Pb contents are at contacts with the replaced pyromorphite.

The average chemical formulae of both minerals were calculated on the basis of 2 XO_4, as recommended by Scott for members of the alunite supergroup [3]. For orpheite, the average empirical formula is $Pb_{1.14}Al_{3.00}(PO_4)_{1.91}(SO_4)_{0.09}(H_2O, OH)_6$, and for hinsdalite $Pb_{1.18}Al_{3.22}(PO_4)_{1.87}(SO_4)_{0.13}(H_2O, OH)_6$. Trace amounts of Sr and As (but no Fe) were detected.

According to current nomenclature for the alunite supergroup [3], recalculated microprobe analyses of orpheite and hinsdalite from Madzharovo fit into the plumbogummite field.

Acknowledgements: This study was support by the Synthesys Program (DE-TAF-5203).

A new classification scheme for amphibole group minerals: the matrix model

Nikandrov, S.*, Valizer, P. & Nikandrov, A.
Ilmeny State Reserve of the Urals Branch of the Russian Academy of Sciences, Miass, Russia (*nik@ilmeny.ac.ru)

A new classification scheme for amphibole group minerals using a matrix model is suggested. It is based on the charges of cations in the amphibole structure. The matrix model may be presented in various forms. Thus, one format is based on variations of cations at the C and T sites (Fig. 1). Specific cation balances in the basic units (C and T sites) and in the units of the matrix field (A and B sites) were viewed in terms of isomorphous replacement at these sites according to the so-called "50% rule". It is important that at the C site the "50% rule" is applied for cations of various kinds (L and M) and common border conditions of balances of cations at the sites are applied for all amphiboles. The matrix model may be correlated with the 1997 IMA CNMMN amphibole nomenclature [1], but it differs from it in principle. A special system of concepts and appropriate terminology has been elaborated for the matrix model for normal, anomalous, normative, analogues of normative amphiboles, and so on.

Fig. 1: Matrix model for normative amphiboles (total cationic charge +46).

In comparison with IMA97, the matrix model is stricter and removes a number of logical contradictions. The main feature is the possibility of presenting all minerals of the amphibole group in two-dimensional fields. The problem of dividing total iron from microprobe analyses of amphiboles may be solved by the matrix model with good precision.

The model is convenient for practical use in nomenclature analysis, comparative analysis of different objects, *etc*. [2,3]. Productive application of the model to amphiboles for many years suggests that it represents a real alternative to current nomenclature, including all subsequent corrections and improvements.

The model for amphiboles is described in detail in [2,3].

S-rich apatites in sakenites from southern Madagascar

Ohnenstetter, D.[1*] & Giuliani, G.[1,2]
[1]CRPG/CNRS, Vandœuvre-lès-Nancy, France
(*dohnen@crpg.cnrs-nancy.fr)
[2]IRD, Toulouse, France

Sakenites from Sakeny, North of Ihosy (Madagascar) were defined by Lacroix [1,2] as corundum – spinel – sapphirine – anorthite rocks. Their protholiths are either of metasedimentary origin [2,3], argillaceous limestones [3], or more probably metanorthosites [4,5]. They are metamorphosed under high grade granulitic conditions with a peak at 800°C and 6 to 7 kbar followed by metasomatic alteration under less extreme metamorphic conditions, 700-650°C and 6 kbar [3]. The sakenites studied are composed of sappphirine, anorthite, diopside, amphibole, phlogopite, muscovite, spinel, corundum, Cl-apatite, S-rich apatite, xenotime, zircon, monazite, uraninite, titanite, sulfides and sulfates. In new samples, Raith et al. [3] have also reported magnesiotaaffeite, a boron magnesium aluminosilicate. S-rich apatite with SO_3 contents up to 11 wt.% also have high Na content (Table 1).

Table 1: Analytical data for S-rich apatite (wt.%)

SO_3	10.19	S^{6+}	1.269
P_2O_5	32.72	P^{5+}	4.597
SiO_2	0.23	Si^{4+}	0.038
FeO	0.02	Fe^{2+}	0.002
CaO	50.89	Ca^{2+}	9.044
Na_2O	3.56	Na^{+}	1.152
Cl	1.09	Cl^{-}	0.305
H_2O calc.	1.53	OH^{-}	1.695
O=Cl	-0.25		
Total	99.98		

The S-rich apatite could be a new species belonging to a solid solution between ellestadite, $Ca_{10}(SiO_4)_{3-x}(SO_4)_{3-x}(PO_4)_{6-2x}(OH,F,Cl)_2$, and a new end-member $Na_xCa_{10}(SO_4)_x(PO_4)_{6-x}(OH,F,Cl)_2$.

R-dictionary-catalogue of chemical mineral composition

Petrov, T.G. & Krasnova, N.I.*
Saint-Petersburg State University, Russia
(*nataly_krasnova@rambler.ru)

Our *R*-dictionary-catalogue [1,2] contains the information on a chemical composition of minerals as rank formulas that is sequences of elements on decrease in their concentrations. The structure of the catalogue is based on the development of T.G. Petrov RHA-method [3] according to which the rank formulas are ordered linearly unequivocally hierarchically in a column alphabetically – to numbers of elements in the Periodic table of elements. The lexicographic systematisation principle of the dictionary generates the chemical classification of minerals. The rank formula is identical to result of ordering of chemical elements on decrease of the sums of all their coefficients in crystal-chemical formula, without taking into account the valence of elements or their site position. The present *R*-catalogue of chemical compounds of minerals contains over 4800 inputs; the full version of these data displays the file R-Min-Catalogue-2007.rar on web-site: http://geology.pu.ru/.

For the set up of the *R*-catalogue the crystal-chemical formulas of minerals, as resulting in mineralogical databases (http://www.webmineral.com/ and http://www.mindat.org/), were used. For the majority of mineral species of variable composition by results of real chemical analyses 2-5 rank formulas have been designed. The principle of rank formulas ordering is shown in table 1:

Table 1: Principle of rank formulas

Rank formula	Name	Formula
H F N Si	Cryptohalite	$(NH_4)_2SiF_6$
H F= O Al	Rosenbergite	$AlF_3 \cdot 3(H_2O)$
H= S O= Fe= Cu	Orickite	$CuFeS_2 \cdot (H_2O)$
C= Si	Moissanite	SiC
O H C Ca	Caoxite	$Ca(C_2O_4) \cdot 3H_2O$
O H N S	Mascagnite	$(NH_4)_2SO_4$
O Mg Si	Forsterite	Mg_2SiO_4
O Mg= Si Al	Pyrope	$Mg_3Al_2(SiO_4)_3$
O Mg= Si Cr	Knorringite	$Mg_3Cr_2(SiO_4)_3$
O Fe	Magnetite	$Fe^{2+}Fe^{3+}{}_2O_4$

The *R*–catalogue can be used for solution of following tasks. 1. For express identification of minerals by results of chemical analyses. Identification of minerals with the variable contents of H_2O, F, or other elements is not always unequivocal. 2. For minerals of variable composition, in particular, at multielement type of isomorphism, on *R*-indexes it is possible more proved specify the limits between uses of different species names in isomorphic series. 3. The *R*-catalogue can be used for the improvement of mineral nomenclature, it can help to work out the general recommendations at confirmation of names of new minerals, or updating of limits for application of old terms. 4. On the basis of the *R*-catalogue it is possible to create some more detailed chemical classifications for separate groups of minerals, and to predict existence of new species.

Klajite, a new member of the lindackerite group from Hungary

Szakáll, S.[1*], Fehér, B.[2], Bigi, S.[3] & Mádai, F.[1]
[1]Dept. of Mineralogy and Petrology, University of Miskolc, Hungary (*askszs@uni-miskolc.hu)
[2]Dept. of Mineralogy, Herman Ottó Museum, Miskolc, Hungary
[3]Dept. of Earth Sciences, University of Modena and Reggio Emilia, Modena, Italy

Klajite was found in ore samples collected from the waste dump of the Recsk, Lejtakna ("Inclined adit") area, Lahóca Hill, Mátra Mountains, North Hungary. The ore of the Lejtakna area was discovered in 1969 [1]. It belongs to the Lahóca epithermal high sulfidation Cu-As ore deposit. Primary ore mainly consists of enargite, luzonite and pyrite, with less frequent tennantite, chalcopyrite, galena, and sphalerite [1]. These sulfides usually alter to sulfates, phosphates and arsenates [2].

Klajite occurs in cavities in enargite and quartz, in close association with other secondary minerals including gypsum, jarosite, and an unknown Ca-Cu arsenate which is structurally analogous to the phase Cu-AsO_4-H_2O (3) (ICDD 00-051-1479) described from Jáchymov, Czech Republic [3]. Klajite is a secondary mineral formed by decomposition of enargite and perhaps Mn-rich tennantite.

Klajite forms sheaf-like aggregates made up of lath-like to thin tabular crystals, typically 0.05-0.2 mm in length. Crystals commonly form complex intergrowths. The largest aggregates reach 0.5 mm in diameter. The mineral is translucent, greenish yellow to yellowish green in colour with a white streak and a vitreous lustre. Mohs hardness is 2–3 and the calculated density is 3.213 g cm^{-3}. Klajite has perfect cleavage parallel to {010}, and is very brittle. Its fracture is uneven. Optically klajite is biaxial negative or positive with α = 1.595(30) and γ = 1.665(20). It is weakly pleochroic, colourless to pale green.

The chemical composition of klajite was determined by electron microprobe. After recalculation to 100% the average of seven analyses gave MnO 5.67, CuO 32.03, CaO 0.41, As_2O_5 44.40, H_2O(calc.) 17.49, total 100.00 wt.%. The empirical formula, based on 16 oxygen atoms, is $(Mn_{0.82}Cu_{0.10}Ca_{0.08})_{\Sigma=1.00}$ $Cu_{4.05}As_{3.98}O_{14}(OH)_2 \cdot 9H_2O$, and the simplified formula is $MnCu_4(AsO_4)_2(AsO_3OH)_2 \cdot 9H_2O$.

A powder X-ray diffraction pattern was obtained using Cu*K*α radiation and a Gandolfi camera. The strongest seven lines in the pattern are [d_{hkl} in Å (I_{obs} %, *hkl*)] 10.39 (100, 001), 2.916 (64, 202), 2.708 (29, $\bar{1}$ 13), 3.616 (28, 0 $\bar{2}$ 1), 3.050 (28, 0 $\bar{2}$ 2), 3.956 (27, 020) and 3.110 (24, 122). The mineral is structurally analogous to other lindackerite group minerals; it is triclinic, space group $P\bar{1}$, a = 6.441(3), b = 7.983(4), c = 10.562(3) Å,α = 85.28(4), β = 80.63 (5), γ = 84.80(4)°, V = 532.4(3) Å^3, Z = 1, and $a:b:c$ = 0.807:1:1.323.

Klajite is named after Sándor Klaj (b. 1948), a Hungarian mineral collector. He has found more than 40 mineral species new to Hungary and also provided the samples for this description. The mineral and name have been approved by IMA CNMNC (2010-004). Type material has been deposited at the Herman Ottó Museum, Miskolc, Hungary (catalogue no. 2010.1) and at the Hungarian Natural History Museum, Budapest, Hungary (specimen no. Gyn./1842).

A Sc-Nb oxide from corundum pegmatites of the Krucze Skały in Karpacz (Karkonosze massif, Lower Silesia, Poland) – a potentially new mineral of the $ScNbO_4$ – $FeWO_4$ series

Szełęg, E.[1*], Galuskina, I.[1] & Prusik, K.[2]
[1]Dept. of Geochemistry, Mineralogy and Petrography, Faculty of Earth Sciences, University of Silesia, Sosnowiec, Poland ([*]eligiusz.szeleg@us.edu.pl)
[2]Inst. of Materials Science, University of Silesia, Katowice, Poland

The Sc-Nb oxide occurs as an accessory mineral in a peraluminous corundum pegmatite of the Krucze Skały in Karpacz–Wilcza Poręba, situated within the Karkonosze massif (Lower Silesia, SW Poland). Orthoclase, biotite, muscovite, albite, chamosite and corundum are the main rock-forming minerals of the pegmatite. Schorl, rutile, ilmenite and ferberite are accessories. The Nb-Sc oxide forms xenomorphic, more rarely idiomorphic, grains up to 30 μm in size (Fig. 1), inside rutile, Nb-bearing rutile and ilmenite grains. Grains showing complex zonation are composed of ferberite cores and Sc-Nb oxide in external parts.

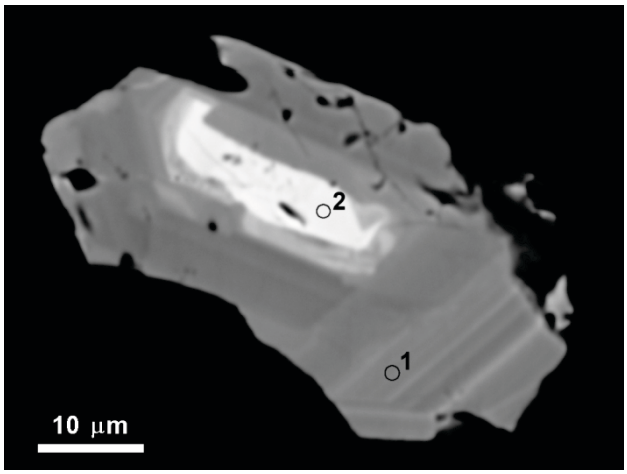

Fig. 1: Idiomorphic zoned grain of Sc-Nb oxides, BSE image; 1 and 2 are analysis sites.

The chemical formula of the zoned external part of a grain (Fig. 1) with maximum concentrations of Sc (1) is $(Sc_{0.55}Fe^{2+}_{0.15}Ti_{0.12}Fe^{3+}_{0.08}Mn_{0.05}Zr_{0.03})_{\Sigma 0.98}(Nb_{0.86}W_{0.07}Sn_{0.06}Ta_{0.03})_{\Sigma 1.02}O_4$. The core (Fig. 1) shows an intermediate composition, belonging to the $ScNbO_4$ – $FeWO_4$ series, with composition (2) $(Fe^{2+}_{0.39}Sc_{0.35}Mn_{0.13}Ti_{0.08}Fe^{3+}_{0.05}Zr_{0.02})_{\Sigma 1.02}(Nb_{0.48}W_{0.47}Ta_{0.01}Sn_{0.01})_{\Sigma 0.97}O_4$. The Sc-Nb oxide has a wolframite-type structure according to EBSD data. All analytical data point to the Sc-Nb oxide being a new mineral species with end-member composition $ScNbO_4$. Recently, the new mineral heftetjernite, $ScTaO_4$, was described [1], and is a Ta-analogue of the mineral from Krucze Skały. After detailed studies the new species will be submitted for approval to the IMA CNMNC.

Ammineite, $CuCl_2(NH_3)_2$ – the first mineral containing an ammine complex

Walter, F.[1*], Bojar, H.-P.[2], Baumgartner, J.[3] & Färber, G.[4]
[1]Inst. of Earth Sciences (Mineralogy and Petrology), University of Graz, Austria ([*]franz.walter@uni-graz.at)
[2]Dept.of Mineralogy, Universalmuseum Joanneum Graz, Austria
[3]Inst.of Inorganic Chemistry, Technical University of Graz, Austria
[4]Gunnar Färber, Samswegen, Germany

The type locality of ammineite, $CuCl_2(NH_3)_2$, is Caleta Pabellon de Pica, Tarapaca, south of Iquique, Chile. It has been accepted as new mineral by CNMNC (2008-32).

Ammineite occurs as intense sky blue xenomorphic grains up to 4 millimetres in size in solution cavities in halite together with atacamite and darapskite. Ammineite is a reaction product of guano with copper mineralisation.

For ammineite Cu (37.60 wt.%) and Cl (41.67 wt.%) were analysed by EMP, N (16.54 wt.%) and H (3.32 wt.%) by CHNS analyser. O, S and C are below the detection limits. FTIR spectra give exclusively NH_3 frequencies at 3316, 3241, 3160, 1594, 1245, 711, 660 and 480 cm^{-1}.

Ammineite is orthorhombic, space group *Cmcm*, with a = 7.688(1), b = 10.645(2), c = 5.736(1) Å, V = 469.4(2) $Å^3$ and Z = 4. The crystal structure was solved by direct methods and refined with SHELX-97 [1] to R = 0.024 [$F_o > 4\sigma(F_o)$] for 231 unique reflections.

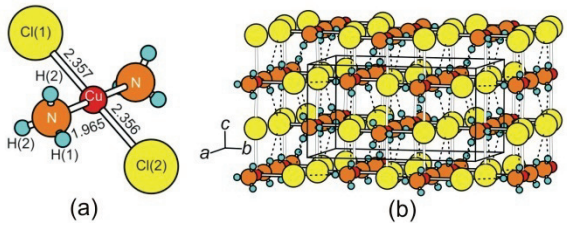

Fig. 1: The crystal structure of ammineite: (a) basic unit, (b) layers of $CuCl_2(NH_3)_2$ parallel (001). Dotted lines indicate hydrogen bonds.

The basic structural unit consists of a central Cu site with *trans* planar coordination of two NH_3 molecules and two Cl ions with Cu-N 1.965(3) Å and Cu-Cl distances of 2.356(2) and 2.357(2) Å (Fig. 1a). In the unit cell the complex forms layers parallel to (001) and oriented by Cl(1)-Cu-Cl(2) parallel to [010] (Fig. 1b). Along [001] Cu is connected to parallel layers nearly perpendicular by two long bonds (Cu-Cl(2) 2.868(1) Å), building orthorhombic dipyramids connected by shared edges to form zigzag chains running along [001]. Some H···Cl distances ranging from 2.69(3) to 2.79(4) Å indicate the presence of weak hydrogen bonds, which connect the complexes within the (001) layers and also from one layer to the next.

X-ray powder data for ammineite and *trans*-diamminedichloro-copper(II), which was synthesized for comparison, are nearly identical. However, calculated powder data using parameters taken from the structure determination of synthetic $Cu(NH_3)_2Cl_2$ reported in [2] are completely different from our data.

A thermal analysis study of chromium oxyhydroxide nanoplates synthesised under different pH conditions

Frost, R.L.[*] & Yang, J.
Chemistry Discipline, Faculty of Science and Technology, Queensland University of Technology, Brisbane, Australia
([*]r.frost@qut.edu.au)

As a transition metal oxide, chromia (Cr_2O_3) has attracted special attention because of its importance in specific applications, such as in high-temperature resistant materials, solar energy collectors, catalyst, and so on [1]. Chromium oxyhydroxide CrO(OH) is a principal precursor for chromium oxides Cr_2O_3, since the original size and morphology of CrO(OH) precursor can be retained after calcination. Three naturally occurring chromium oxyhydroxides are bracewellite (orthorhombic CrO(OH)), guyanite (orthorhombic CrO(OH)) and grimaldiite (trigonal CrO(OH)) [2]. Nanoscaled grimaldiite material has been successfully synthesised in different pH environments through a simple hydrothermal route. Plate-like CrO(OH) crystals with average diameter of 11 nm were observed from transmission electron microscopy (TEM). Thermogravimetric analysis [3,4] was applied to study the thermal decomposition process for the synthesis CrO(OH) nanomaterials (Table 1). The thermal properties of CrO(OH) nanomaterials and the influence of pH to the crystal growth was deduced from this thermal study.

Table 1: Summary of peaks shown in dTG curves for CrO(OH) nanomaterials synthesised in various pH conditions

CrO(OH)-5.0	*CrO(OH)-5.0*	*CrO(OH)-10.0*
45°C, 84°C, 109°C	45°C, 84°C, 109°C	50°C, 80°C
	276°C	238°C
315°C		318°C
	396°C	
444°C, 463°C	438°C	436°C, 458°C
	643°C	

The thermal gravimetric study indicated that synthesised CrO(OH) nanomaterials decomposed at ~ 450°C (Fig. 1). All products after heated to 1000°C were well crystalline Cr_2O_3 nanomaterials, which were confirmed by X-ray diffraction (XRD).

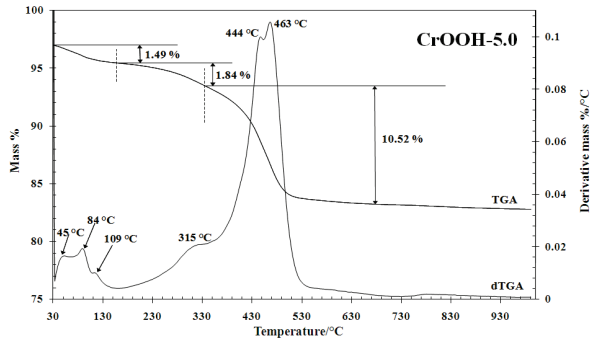

Fig. 1: Thermalgravimetric analysis (TGA) of CrO(OH) nanomaterials synthesised at pH=5.0.

Cr-rich alunite nodules in acid sulfate alteration zones overlying bentonites at Milos, Greece: evidence for Cr transport by acidic fluids

Gilg, H.A.[1*], Riehl, M.[1], Hattori, K.[2], Takahashi, Y.[3] & Vennemann, T.[4]
[1]Lehrstuhl für Ingenieurgeologie, TUM, Munich, Germany
([*]agilg@tum.de)
[2]Dept. of Earth Sciences, University of Ottawa, Canada
[3]Dept. of Earth and Planetary System Sciences, Hiroshima University, Hiroshima, Japan
[4]Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland

Nodular alunite concretions occur at the base of acid sulfate alteration zones in Upper Pliocene to Middle Pleistocene pyroclastic rocks overlying bentonites at Siskinos and Aspro Chorio, Milos, Greece. The white concretions with diameters of up to 50 cm consist of euhedral to partly corroded alunite crystals (1-3 µm, 89-99 vol.%) with minor amounts of halloysite, opal-A, and quartz. The alunites at Siskonos, SE Milos, are characterized by intermediate atomic Na/(Na+K) ratios (0.43-0.73) and high Cr (840-1250 ppm), V (240-580 ppm), moderate Sr (520-650 ppm) and Ba (300-730 ppm) and low Zn (<5 ppm) contents. In contrast, an alunite nodule from Aspro Chorio in the NW of Milos has a very low atomic Na/(Na+K) ratio (~ 0.16) and no detectable Cr (<5 ppm), but high Ba (2580 ppm) and Zn content (140 ppm).

Selective leaching experiments using sulfuric acid and ammonia show that Cr in nodules from Siskinos is not adsorbed to clays and not present as discrete chromite, but most probably located in the alunite crystals. EXAFS studies indicate that all Cr is present in a trivalent state. The calculated Cr-O distance is 1.965Å, which is consistent with an octahedral coordination. The Cr in alunites cannot be derived from the andesitic to dacitic protoliths (<20 ppm Cr [1]), but must have been introduced by hydrothermal sulfate-rich fluids. We suggest that Cr was leached by strongly acidic fluids from ultramafic/mafic rocks in the metamorphosed accretionary wedge in the SE part of the island. We note that steam condensates with a pH 1.7 and temperatures of 90°C at Paleochori Bay, SE Milos, contain up to 3.0 µM Cr [2]. The low Cr contents in alunites at Aspro Chorio in the NW part of Milos are probably related to the absence of ultramafic bodies in the basement. The tabular acid-sulfate alteration zones at Siskinos require input of magmatic fluids. Preliminary stable S, O, H, isotope data of alunites are consistent with this interpretation.

On the plutonities of the subduction regime (Southern Sinai, Egypt): discrimination and modeling

Ghoneim, M.F.[1*], Lebda, E.M.[2], Abdel-Karim, A.M.[3] & Nasralla, N.[3]
[1]Geological Dept., Faculty of Science, University of Tanta, Egypt ([*]ghoneimf@yahoo.com)
[2]Geological Dept., Faculty of Science, Kafr El-Sheikh University, Kafr El-Sheikh, Egypt
[3]Geological Dept., Faculty of Science, Zagazeg University, Zagazeg, Egypt

Petrological, geochemical and mineralogical characteristics of both calc-alkaline granites and their counterpart gabbros of southern Sinai (Egypt) have been carried out. The rocks are considered to pertain to the island arc regime. The study includes Nesren, Shahera and Minader outcrops as case example.

The granite composition includes diorite, tonalite and granodiorite. The gabbros are pyroxene, pyroxene/hornblende, hornblende gabbros and diorite. Opaque mineral contents are relatively enriched in gabbroid rocks and represented by magnetite, hematite and ilmenite with few sulphides.

From geochemical point of view, the granitic rocks are peraluminous, calc-alkaline and of I-type syncollision volcanic arc. The gabbros exhibit transitional calc-alkaline/tholeiite magma type of island arc setting. Microprobe data of amphiboles indicate that the amphiboles from gabbros are calcic-type and have the composition of actinolite, actinolitic hornblende with subordinate of magnesio-hornblende. They crystallized under medium (Minader and Shahera) to low pressure (Nesren). Amphiboles from the granites have the composition of actinolitic hornblende (Minader), ferroedenite to ferroedenitic hornblende (Nesren). They crystallized under low pressure. Plagioclase from the study rocks varies in composition from oligoclase to andesine. Biotites of the granites are Mg-rich (Minader), Fe-rich (Nesren), and lepidomelane of calc-alkaline and magmatic origin. Plagioclase favours temperature of formation at 1100°C (Minader gabbro), 750 to 850°C (Shahera gabbro) and 900 to 1000°C (granitic rocks) under general pressure of 2 Kbs.

Modeling and thermobarometric calculations elucidate magma generation at a depth of about 30 km for granite and from 15 to 35 km for gabbros. The later rocks have achieved 25% fractional melting of mantle lherzolite.

Origin of rapakivi texture: a case study of the rapakivi-textured granitoids in the Qinling orogen (China)

Wang Xiaoxia[1*] & Wang Tao[2]
[1]Institute of Mineral Resource, Chinese Academy of Geological Sciences, Beijing, China ([*]xiaoxiawang@hotmail.com)
[2]Institute of Geology, Chinese Academy of Geological Sciences, Beijing, China

Rapakivi texture (ovoidal alkali feldspar megacrysts with and/or without plagioclase mantle) is a key marker of rapakivi granitoids. The origin of the rapakivi texture has interested petrologists for more than 100 years. The main models for the origin of the rapakivi texture are (1) hybridization between granitic and more mafic magmas; (2) sub-isothermal decompression of the crystallizing magma; and (3) exsolution of albitic plagioclase from the original alkali feldspar and migration to the grain boundaries. However, each model could not interpret the origin of all rapakivi textures. For instance exsolution model is unable to explain the shape of ovoidal alkali feldspar and oligoclase to andesine mantle. Mixing model is difficult for such huge volumes of homogeneous rapakivi granites in the Wiborg batholith.

The Qinling rapakivi-textured granitoids intruded into the Qinling orogen (central China) at 211–217 Ma. The rapakivi texture is characterized by ovoid or rounded alkali feldspar megacrysts. Some of the megacrysts are surrounded by one or, occasionally, two plagioclase mantles. This study indicates that magma mixing is a major reason for the origin of the texture.

The granitoids contain many mafic to intermediate magmatic enclaves with fine-grained sinuous margins against the granitoids or transitional contacts with the granitoids and disequilibrium textures and mineral assemblage, suggestive of mingling and mixing of mafic and felsic magmas. The *P–T* conditions of crystallization have been determined for early mineral assemblages (inner parts of alkali feldspar megacrysts and their plagioclase, quartz, amphibole and biotite inclusions) and late assemblages (matrix minerals) of the rapakivi-textured granitoids. Al contents in amphibole from the early and late mineral assemblages yield pressures of 1.2–3.0 and 0.7–3.0 kbar, respectively, and indicate only minor pressure change between the crystallization of the early and late assemblages. Amphibole–plagioclase thermometry gives temperatures mainly from 600 to 730°C for both the early and late assemblages indicating nearly isothermal conditions, and it appears that locally the temperature of the late assemblages was even higher. Feldspar thermometers yield lower temperatures. Relative abundances of minerals and their chemical compositions indicate that the late mineral assemblages tend to be richer in MgO, Na_2O and CaO than the early assemblages. Rapakivi texture is interpreted in this case mainly as a result of compositional changes and isothermal temperature related to the hybridization between granitic and more mafic magmas. Another possibility is that a small release of pressure during crystallization of the magma chamber was able to stabilize plagioclase instead of alkali feldspar and produce the rapakivi texture.

LA-ICP-MS measurements on K-feldspar megacrysts of Mórágy granite, Hungary

Király, E.[1*], Chenery, S.[2], Bartha, A.[1], Bertalan, E.[1] & Dobosi, G.[3]
[1]Geological Institute of Hungary, Budapest, Hungary
([*]kiraly@mafi.hu)
[2]British Geological Survey, Keyworth Nottingham, UK
[3]Institute of Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary

The variscan (~320 Ma) Mórágy Granite (SE–Transdanubia, Hungary) — belonging to Tisza megaunit — is formed by mixing and mingling of a felsic and mafic magma [1]. Microcline megacrysts of both monzogranite and mafic microgranular enclave were analysed by LA-ICP-MS and electron microprobe to characterise trace element (Ba, Rb, Sr, Cs, REE, Pb) profiles in two types of microcline megacrysts for reconstruction of petrogenetic mechanisms. Both types of microcline megacrysts are well ordered, low temperature microcline [2]. There are only very few trace elements built in the lattice. Ba as an index of magma mixing plays the most important role in microcline exchange reaction. In monzogranite the megacryst has some thousands or hundreds ppm of Ba, Sr, Rb and Pb content and only very few ppm of Cs, La and Eu content aside from the main elements of potassium, sodium and calcium. The trace element distributions of the megacryst from monzogranite reveal no systematic zoning however Ba seems to be decreased from zone to zone from core to rim in agreement with the normal magmatic crystallisation. In addition, patchy enrichments in Ca, Sr and Pb couple sometimes with Ba-rich domains however Ba enrichments are commonly independent from the concentrations of the above mentioned trace elements.

In contrast, Ba is clearly enriched at the rim in microcline megacryst of mafic microgranular enclave but the inner part of the megacryst shows more complicated structure. Ba, Sr (compatible elements) and Pb vary together in contrast to the changes in Rb and Cs (incompatible elements) in microcline megacryst.

The linear trends of different trace element substitutions of potassium in microcline suggest similar magma conditions for both megacrysts of the monzogranite and mafic enclave in agreement with the whole rock geochemistry. It means the same source of the microcline formation and close relationship to the two coeval magmas, where the megacrysts developed. Enrichment in Ba at the rim of microcline megacryst from mafic enclave reflects the appearance of the mafic melt during the microcline formation. Ba is enriched in zone, where plenty of plagioclase inclusions are developed illustrating rapakivi-like texture. Both support the granitoid formation by mixing and mingling.

New U-Pb and Lu-Hf isotopic constraints on the age and origin of the Mórágy Granite (Mecsek Mountains, South Hungary)

Koroknai, B.[1*], Gerdes, A.[2], Király, E.[1] & Maros, Gy.[1]
[1]Geological Institute of Hungary, Budapest, Hungary
([*]koroknai@mafi.hu)
[2]Institute of Geosciences, Frankfurt am Main, Germany

The Mórágy Granite — located in the south-eastern hilly foreland (Mórágy Hills) of the Mecsek Mts., Hungary — represents the volumetrically most important surface outcrop of the crystalline basement in the northern part of the Tisza mega-unit. The crystallization age of the microcline megacryst-bearing biotite-monzogranites and its mafic enclaves of predominantly monzonitic composition is in dispute. Radiometric dating both by conventional (multi-grain) and single grain U-Pb analyses of zircon yielded controversial results (ages between 339 and 405 Ma, [1–4]). In this study we present new U-Pb and Lu-Hf isotope data obtained on oscillatory zoned domains of zircon grains both from microcline megacryst-bearing monzogranites and its mafic monzonitic enclaves (4 samples, 64 analyses) using the LA-SF-ICPMS (laser ablation-magnetic sector field inductively coupled plasma mass spectrometry) technique.

The results deriving from the monzogranitic rock group imply an age of around 337 Ma for the emplacement and magmatic crystallization of the Mórágy Granite. This result is unambiguously confirmed by the concordia (339±3 Ma) and mean $^{207}Pb/^{206}Pb$ ages (343±9 Ma) of zircons from cogenetic mafic enclaves (monzonite) dated now for the first time. Rarely preserved, internal domains of zircons from monzogranites show U-Pb ages around 355–359 Ma, suggesting also an early stage of zircon crystallisation. On the other hand, no relic, old cores were found in the investigated samples, presumably due to complete resetting of U-Pb isotopic system during the main magmatic event, suggested also by the surprisingly uniform Hf isotopic data of zircons. Eight concordant analyses on single titanites from a hybrid monzonite resulted in a concordia age of 332±3 Ma, which is in accordance with the lower closure temperature of titanite, and indicates moderate cooling of the pluton. The presented ages clearly confirm the assignment of the Mórágy Granite to the Variscan orogeny and exclude a pre-Variscan origin.

Fairly homogeneous Hf isotopic data of zircons both from monzogranite and its mafic enclave suggest considerable equilibration within and between the main rock types of the Mórágy Granite. This is in accordance with the quite uniform main, trace and REE element patterns from the different rock types of the pluton. However, a few internal zircon domains record an earlier event of zircon formation (~357-359 Ma) with distinct, less radiogenic Hf isotope composition. These relics support the idea that the initial isotope heterogeneity was almost completely reset.

Morphology, types and internal zoning of zircon from Mecsek Mountain granitoids resemble very much that of the ultrapotassic durbachites and associated rocks from Bohemian Massif. These rocks most likely formed by melting of metasomatised and enriched lithospheric mantle and all were emplaced shortly after the granulite-facies metamorphic peak in the Bohemian Massif (ca. 340 Ma).

Geochemistry of magnetite from Cu-Mo porphyry + skarn, and Climax Mo deposits in the western United States

Nadoll, P.[1*], Mauk, J.L.[1], LeVeille, R.[2] & Koenig, A.[3]
[1]School of Environment, The University of Auckland, New Zealand ([*]p.nadoll@auckland.ac.nz)
[2]Freeport-McMoRan Copper and Gold Inc., USA
[3]U.S. Geological Survey, Denver, USA

Magnetite (Fe_3O_4) is a common and widespread accessory mineral in many host rocks and mineral deposits. Major- and trace element contents in magnetite are highly susceptible to geologic factors like temperature, oxygen fugacity, silica activity and melt composition. The ability to incorporate a large number of foreign cations in its spinel structure makes magnetite sensitive to hydrothermal processes and therefore an ideal target for geochemical investigations. The ongoing development of analytical techniques such as laser ablation inductively coupled mass spectrometry (LA-ICP-MS) are proven assets in determining even subtle variations in the geochemistry of magnetite from different geological settings. We used electron microprobe (EPMA) and LA-ICP-MS analyses, in combination with petrographic observations and factor analysis, to test whether magnetite from major Cu-Mo porphyry + skarn, and Climax Mo deposits of the western United States has distinct geochemical signatures. Our results show that the large variety of geological settings found in these deposits is reflected in the magnetite geochemistry. For example, in most places, hydrothermal and igneous magnetite can be discriminated by their respective trace element compositions. Furthermore, magnetite from different types of igneous rocks can be distinguished. The best overall discriminators for the trace element geochemistry of magnetite from igneous, porphyry, and skarn deposits are Mg, Al, Ti, V, Co, Mn, Zn, and Ga. These elements commonly occur in magnetite at concentrations above the LA-ICP-MS detection limits, and show characteristic variations across different geological settings. For example, Ti values can range from a few parts per million to several weight percent; higher values typically occur in igneous magnetite. Aluminium and V display a similar trend, although the overlap between hydrothermal and igneous magnetite is more pronounced for these elements. Hydrothermal magnetite hosted in skarn has the highest Mg concentrations, but igneous magnetite typically has higher Mg concentrations than magnetite from porphyry deposits. In contrast, Mn commonly has higher concentrations in hydrothermal magnetite. Factor analysis can help reveal relationships among trace elements that help fingerprint and characterize magnetite from specific geological settings. Although preliminary, our work suggests that three main factors are responsible for most geochemical variation in magnetite from the examined deposits: (1) Mg, Al, Ti, and Ga, reflecting an igneous signature, (2) Mn, Co, and Zn, suggesting hydrothermal control, and (3) V with a negative correlation to Mn. Factor analysis is also helpful for screening the data for analyses that were affected by inclusions. Our research demonstrates that rigorous petrographic examination, EPMA, LA-ICP-MS, and factor analysis can successfully fingerprint magnetite from different geological settings, including plutonic igneous rocks, and porphyry and skarn deposits.

Hungarian Variscan granitoids and their correlation with surrounding granitoids

Buda, Gy.[1*], Koller, F.[2], András, E.[3] & Nagy, G.[4]
[1]Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary ([*]buda@ludens.elte.hu)
[2]Dept. of Lithospheric Research, University of Vienna, Austria
[3]Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Hungary
[4]Inst. of Geochemical Research, Hungarian Academy of Science, Budapest, Hungary

The Tisia Composite Terrane (TCT) consists of various high-grade metamorphic series and Variscan granitoids. The TCT forms the basement of South Hungary, NE Croatia, N Serbia and W Transylvania (W Romania), and is surrounded by orogenic belts and faults. In TCT, few Variscan granitoid occurrences are known. The Mecsek granitoids are between the oldest ones (340-354 Ma). They are of I-type, metaluminous, calc-alkaline, high-K and high-Mg, bearing large intrusion with lamprophyre-derived, ultrapotassic, Mg-rich intrusions and/or enclaves (durbachite). The whole intrusion formed in a post-collisional zone. The magma originated from the uplifted and partially melted mantle and continental crust due to extension after the continent-continent collision. The large granitoid intrusion contains microcline megacrysts, zoned plagioclases (An_{60-35}), quartz, actinolitic hornblende, calc-alkaline-type biotite. The basic intrusions/enclaves contain the same mineral assemblages but enriched in Mg-rich amphibole and biotite, the zoned plagioclases are richer in An, and microclines have lower triclinicities. Both contain allanite, apatite, zircon and titanite as accessory minerals, but some of basic enclaves contain chromites. The intrusive bodies belong to the calc-alkaline K-rich monzonitic series. The other intrusions (Papuk, Psunj, Battonya, Muntele Mare [1], Codru) are mostly two micas, peraluminous, monazite-type younger (310-290 Ma) S or S/I-type granitoids. The granitoid melts originated from the partially melted continental crust after collision. The TCT belonged to the Moldanubicum zone of the Variscan orogenic belt. Later the TCT was disconnected by eastward movement of S Alps (Pelso unit) containing peraluminous/peralkaline, S/A-type small intrusions of Permian age (280-275 Ma), indicating the initial rifting.

Archean Lithospheric mantle: its formation, composition and today's remnants

O'Reilly, S.Y.* & Griffin, W.L.
GEMOC, Earth and Planetary Sciences, Macquarie University, Sydney, Australia (*sue.oreilly@mq.edu.au)

Archean subcontinental lithospheric mantle (SCLM) is distinctive in its highly depleted composition, commonly strong stratification, and the presence of rock types absent in younger SCLM. Was the Archean mantle formed in a different way in a distinctive tectonic regime? What is the composition of original Archean mantle and how much persists today?

The "typical" Archean mantle composition used in geochemical/geophysical modelling is depleted garnet lherzolite, derived mainly from peridotite xenoliths in kimberlites from the SW Kaapvaal Craton, and a few from Siberia. However, most such "typical" Archean xenoliths have experienced repeated metasomatism, leading to a progression from dunite/harzburgite through "depleted" lherzolite to "fertile" lherzolite, mirroring the secular evolution of the SCLM. Similar refertilisation processes can be studied *in situ* in peridotite massifs (eg Western Norway, Lherz), showing the lherzolites to be the product of melt infiltration into magnesian dunite/harzburgite protoliths. The most depleted rocks are poorly represented in the published xenolith record; the bias partly reflects the collecting of rocks useful for P-T studies, but also has a geological basis. High-resolution seismic tomography of Archean cratons shows high-Vs volumes surrounded and dissected by zones of lower Vs. The low-Vs parts can be modelled using the "typical" garnet lherzolite compositions, while the higher-Vs volumes require much more depleted rocks. In detail, kimberlites avoid the high-Vs volumes to preferentially follow older zones of fluid passage and metasomatism, hence biasing our "mantle sample" toward the metasomatic products. Seismic tomography suggests that this material still underlies the bulk of Archean cratons to depths of 150-200 km, but is poorly sampled by kimberlites. Relict Archean mantle is also imaged as buoyant high Vp blobs in oceanic regions, a likely source for reported "recycled" geochemical signatures in some ocean island basalts and providing evidence of mechanisms of continental breakup

Hf-isotope data on zircons show that much Proterozoic crust, especially in cratonic areas, has Archean protoliths, suggesting that the underlying SCLM also was originally Archean. Seismic tomography shows high-Vs roots, requiring depleted compositions and low geotherms, under many of these areas; clearly juvenile Proterozoic belts (eg SW Scandinavia) do not have such roots. Re-Os isotopic data for the underlying mantle record similar events, indicating a linked tectonic history. These observations suggest that much of the observed secular evolution in SCLM composition reflects progressive reworking of buoyant Archean SCLM, rather than secular changes in the mechanisms of SCLM production. Seismic tomography suggests that≥50% of existing continental crust is underlain by relict Archean SCLM, modified to varying degrees. This implies a much larger volume of originally Archean crust than currently accepted, and hence very high early crustal growth rates.

Melt-modelling exercises that treat "typical" Archean peridotites as simple residues are invalid, and cannot be used to support "lithosphere stacking" models for SCLM formation. The "primitive" Archean dunites/harzburgites are best modelled as restites/cumulates from high-degree melting at 3-6 GPa, in ascending plumes/mantle overturns. This uniquely Archean regime may have coexisted with a more modern plate-tectonic regime, which produced weakly depleted residues similar to Phanerozoic SCLM. This "modern" SCLM would be inherently unstable, easily recycled and lost to the modern record.

Deformation and melt localization in the subcontinental mantle: a case study from the plagioclase tectonite zone of the Ronda peridotite massif (South Spain)

Hidas, K.[1*], Garrido, C.J.[1], Booth-Rea, G.[2], Gervilla, F.[1], Bodinier, J.-L.[3], Tommasi, A.[3] & Marchesi, C.[3]
[1]Instituto Andaluz de Ciencias de la Tierra, CSIC-UGR, Granada, Spain (*karoly.hidas@gmail.com)
[2]Dept. of Geodynamics, Universidad de Granada, Spain
[3]Geosciences Montpellier, CNRS-Université de Montpellier-2, Montpellier, France

The processes that take place during the transport of melts through the convecting mantle are the least understood and, therefore, state-of-the art problems among a series of processes of formation and evolution of mantle magmas. It is widely accepted that, dunite channels might be pathways by which mantle melts easily pass through the overlying mantle (e.g. [1]). The role of shear strain during the formation of dunite bodies in ophiolites was considered in details by [2]. It was also shown that the stress field can control the melt migration paths marked by dunite bodies occurring oriented regularly relative to the hinge and axial plane of a harzburgite fold [3]. The localization of melt flow and formation of channels under mechanical instability during the formation of dunites is expected to lead to a stronger olivine crystallographic preferred orientation (CPO) in these rocks than in their surroundings. However, accepted models explain formation of dunitic lithology mostly in oceanic environment, but one would face several challenges trying to apply them to the subcontinental lithospheric mantle.

The Ronda massif (southern Spain) is the largest (*ca.* 300km^2) of several orogenic peridotite massifs exposed in the Betic and Rif (northern Morocco) mountain belts in the westernmost part of the Alpine orogen that was tectonically emplaced during early Miocene times. One of the most remarkable features of the Ronda massif is the 'recrystallization front' that represents the transition from the spinel-tectonite to the coarse granular peridotite domain corresponding to a narrow boundary of a partial melting domain caused by thinning and coeval asthenospheric upwelling formed at the expense of former subcontinental lithospheric mantle and associated with melting and kilometer-scale migration of melts by diffuse porous flow through the 'asthenospherized' domain [4, 5, 6]. In the vicinity of the recrystallization front, coarse granular peridotites pass into layered granular peridotites with a typical layered structure composed of plagioclase lherzolites, harzburgites and dunites.

The main scientific goals of this study are to test new mechanism(s) for the formation of dunites and dunite-harzburgite-lherzolite layered bodies in the subcontinental lithospheric mantle on the example of Ronda peridotite massif (Spain), and to introduce new processes that are expected to lead the evolution of the subcontinental lithospheric mantle in extensional settings.

Petrogenesis of olivine clinopyroxenites from Sorkhband ultramafic complex, Southern Kerman, Iran: constraints on mineral and whole rock chemistry

Najafzadeh, A.R.[1*], Arvin, M.[2], Pan, Y.[3] & Ahmadipour, H.[2]
[1]Dept. of Geology, Payame Noor University, Kerman, Iran
([*]najafzadeh@pnuk.ac.ir)
[2]Dept. of Geology, Shahid Bahonar University of Kerman, Iran
[3]Dept. of Geological Sciences, University of Saskatchewan, Saskatoon, Canada

The Ordovician Sorkhband ultramafic complex lies in southern Kerman Province of Iran. The wedge shape complex covers an area of more than 100 km^2 and is divided into: lower part, comprises of dunite, largest podiform chromitite deposits in Iran (Faryab mine), massive and dyke like olivine clinopyroxenite, wehrlite and olivine websterite dykes; and an upper part of foliated porphyroclastic diopsidic harzburgite with subordinate lenses and dykes of dunite, massive and dyke like olivine clinopyroxenite and minor orthopyroxenite dykes with no significant chromitite mineralization.

Petrographically the massive and dyke like olivine clinopyroxenites have granular to subgranular textures and modally consist mainly of 80-85% diposidic clinopyroxene ($En_{45}Fs_6Wo_{49}$), 5-20%, olivine (Fo_{90-92}), 1-10% bronzitic orthopyroxene ($En_{81}Fs_{18}Wo_1$), and <0.5% chromite ($Cr^{\#}$=53-87, $Mg^{\#}$=48-67). Clinopyroxenes often exhibit exsolution lamellaes of orthopyroxene with a triple junction boundary.

Mineral chemistry of olivine clinopyroxenites reveals a mantle origin for the Sorkhband ultramafic complex. Moreover, their chondrite normalized rare-earth element (REE) patterns show flat medium REE (MREE) and heavy REE (HREE) patterns, [$(Gd/Yb)_N$~1], and highly light REE (LREE) depletions. Their platinum group element (PGE) patterns also show highly differentiated pattern with a positive slope and high Pd/Ir ratio (0.85-11.49).

The mineral and whole rock chemistry along with REE and transition elements (TE) patterns in Sorkhband olivine clinopyroxenites are quite similar to those reported from pyroxenite of Nan-Uttardite ophiolites in Thailand [1], Leka ophiolites in Norway [2] and San Jorge in Solomon Islands [3]. So, it is most likely that Sorkhband olivine clinopyroxenites have been crystallized from a CaO rich boninitic melt in a supra-subduction zone environment.

Textural mapping by SEM in amphiboles and biotites from alkaline rocks: identification of inclusions and implication for Ar-Ar dating

Borges, W.N., Vargas, T. & Geraldes, M.C.[*]
Faculdade de Geologia, Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brasil ([*]geraldes@uerj.br)

The alkaline complexes which occur in south-southeast of Brazil comprise basically a series of syenitic associations composed of trachyte, tinguaite and nepheline syenite. These rocks yielded K-Ar ages from 80 Ma to 65 Ma. The geodynamic models for the origin of these rocks consider the intrusions lineament of NW-SE direction originated by mantle plume magmatism.

The biotite and amphibole samples obtained from 10 alkaline intrusions (Tinguá, Marapicu, Tanguá, Nova Iguaçu, Itatiaia, Morro de São João, Morro Redondo, Ilha de Cabo Frio, Soarinho and Passa Quatro) were studied by Scanning Electron Microscope (SEM). The sample from Morro Redondo (Fig. 1A) shows apatite intrusion and iron oxide in the biotite. Tanguá sample (Fig. 1B) shows agglomerates of small grains of biotite. In Fig. 1C, the biotite grain has no fractures. In the samples from Morro de São João (Fig. 1D), intrusions of apatites and biotite in the amphybole grains are observed. Locally the amphibole shows a lighter texture, possibly indicating a change to biotite. In Tinguá sample we can see pyrite and amphybole inclusions in the biotite grains (Fig. 1E). In Mendanha sample we notice biotite developed at the borders of amphibole grains. We can also notice a round inclusion of biotite within an amphybole grain (Fig. 1F).

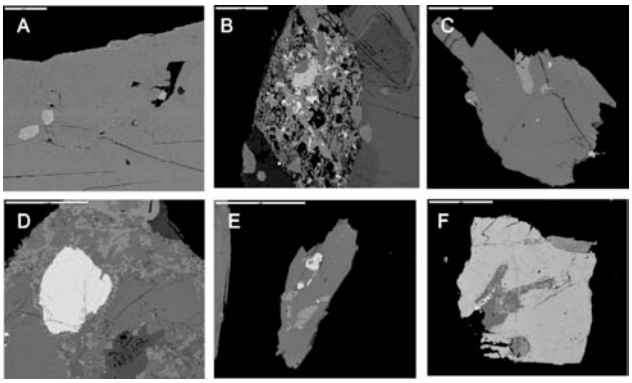

Fig. 1: Images obtained in SEM for biotite and amphibole from alkaline rocks.

The usage of SEM was very useful due practical, economic and accessible procedures. The use of the BSE signal was very useful in the identification of mineral phases, which allows greater accuracy in the interpretations of Ar-Ar age patterns, obtained by step-heating technique. In this sense, the possible age anomalies may be related to solid intrusions not observable in the optic petrography. For these reasons, the use of SEM becomes of fundamental importance to Ar-Ar analysis in mineral grains.

Dilution of a volcanic rare earth element signature in ancient active margin sedimentary basins

Ryan, K.M.[*] & Williams, D.M.
Dept. of Earth & Ocean Sciences, National University of Ireland, Galway, Ireland ([*]kieran.mryan@gmail.com)

The western Ireland Caledonides record the deposition of sediments and tuff bands in a number of depositional settings including: (1) alluvial plain and delta fans [1] and (2) submarine fan environments [2], along an Ordovician active continental margin. The REE profiles from both settings exhibit the typical uniform profile for sandstones [3], however, the medium-coarse grained sandstones in each setting display REE enrichment during post eruption deposition. In the case of the submarine fan sandstones, post-eruption REE concentrations display an average enrichment of 27% compared to the pre-eruption sandstones. The alluvial plain sandstones record a similar profile with 10% post-eruption REE enrichment.

The difference in the level of enrichment between the submarine fan and the alluvial plain sandstones (27% and 10% respectively) can be attributed to two main factors: (a) differences in the mineralogy of the volcanic deposits and (b) differences in surface processes at each setting. In relation to the mineralogy, the volcanism in the alluvial plain setting is represented by rhyodacitic ignimbrites, with embayed quartz and feldspar crystals in a glassy matrix. In contrast, the volcanism in the submarine fan setting is characterised by andesitic-rhyodacitic, coarse-grained, alkali feldspar rich crystal tuffs with glass fragments.

The second factor that may contribute to the difference in the REE enrichment is related to surface processes. The alluvial plain sandstones were deposited rapidly and in close proximity to the source region [1], with limited time for mechanical breakdown and sorting of the sandstone fraction. Therefore, significant chemical differences would not be expected in the pre and post eruption sediments. In contrast the submarine sandstones were deposited as gravity flow sediments in large submarine fans [2], this suggests a greater degree of mechanical reworking to breakdown a less stable volcanic component.

In both environments the erosion of the volcanic deposits results in a short term elevation of the volcanic component in sediment derived from the source region with a return to pre-eruption REE concentrations as sedimentation continued in the basin. The REE profiles from the ancient sedimentary basins support previous studies (e.g. [3]), which identified the difficulty in using the uniform signatures as provenance indicators, but they highlight the potential to use changes in the REE concentrations to indicate volcanic events within sandstone sequences and to decipher localised surface processes.

Metamorphic evolution in the Khetri Complex, India

Kaur, P.[1], Zeh, A.[2,3], Okrusch, M.[2*], Gerdes, A.[4] & Chaudhri, N.[1]
[1]Panjab University, Chandigarh, India
[2]Universität Würzburg, Germany ([*]okrusch @würzburg.de)
[3]Freie Universität Berlin, Germany
[4]Universität Frankfurt am Main, Germany

The NE-SW trending Proterozoic Khetri Complex is part of the Aravalli Orogen, an important constituent of the Indian Plate. The northern part of the complex consists predominantly of metasedimentary rocks that were metamorphosed under greenschist to amphibolite facies conditions in Paleoproterozoic times [1]. The metamorphic sequence was intruded at 1.71–1.66 Ga by A-type, alkali feldspar granites [2,3]. These were widely affected, together with their metamorphic country rocks, by a regional sodic metasomatic event leading to albitisation of plagioclase and microcline [4]. Representative mineral assemblages in the metamorphic rocks are:

And–Grt ($Alm_{0.9}Prp_{0.1}$)–Bt (X_{Fe} 0.65)–Chl (X_{Fe} 0.6)

And/Ky–Bt (X_{Fe} 0.5)–Chl (X_{Fe} 0.4)–Ms (Si 3.1 pfu)–Qtz

Grt ($Alm_{0.66}Prp_{0.06}Grs._{0.05}Sps_{0.23}$)–Bt ($X_{Fe}$ 0.4)–Ms (3.1 Si pfu)–Pl (An_{6-12})–Qtz

Ath (X_{Fe}0.55)–Ged (X_{Fe} 0.55)–Bt (X_{Fe} 0.5)–Chl (X_{Fe} 0.5)–Scp (Me_{34-38})–Pl (An_{12-17}),

Ged (X_{Fe} 0.5)–Crd (X_{Fe} 0.3)–Bt (X_{Fe} 0.55)–Chl (X_{Fe} 0.4)–Scp (Me_{26-34}).

From a pseudosection, calculated in the model system KNCMnFMASH for a metapelitic schist, peak P-T conditions at c. 3.5 kbar and 550°C were derived. The timing of regional metamorphism is not well constrained. However, it is bracketed by LA-SF-ICP-MS U-Pb ages of 1.74-1.73 Ga obtained from the youngest detrital zircons grains from a quartzite sample, and the emplacement age of the A-type granites at 1.71 – 1.66 Ga.

Mineralogical and chemical characteristics of chrysotile veins from Semail Ophiolite, Wadi Daftah, United Arab Emirates

Heikal, M.Th.S.[1], Hassan, A.M.[1], El Nashar, E.S.R.[2*] & Lebda, E.M.L.[3]
[1]Geology Dept., Faculty of Science, Tanta University, Tanta, Egypt
[2]Geology Dept., National Research Centre, Dokki, Cairo, Egypt ([*]saidnashar@hotmail.com)
[3]Dept. of Biological and Geological Sciences, Faculty of Education, Kafr El Sheikh University, Kafr El Sheikh, Egypt

Twelve selected sites of chrysotile-hosted serpentinized peridotite in Wadi Daftah across Masafi –Al Fujairah paved road, eastern coast, UAE, have been carefully sampled and collected samples investigated by different techniques of mineralogy and chemistry.

Field data reveal three modes of occurrence and stages of chrysotile; namely: slip-fiber (splintery form), cross-fiber and mass-fiber. Structural control of chrysotile formation is suggested by discontinuous occurrences of the mineral along tight cracks and shear fractures, mostly trending NW and NE.

Petrographically, chrysotile has partly and/or completely replaced olivine and/or pyroxene. On the other hand, the appearance of talc which has subsequently replaced the serpentine and/or pyroxene during retrograde talcification has recorded in few sites.

On the mineralogical basis, differential thermal analysis (DTA) and thermogravimetry (TG) indicate that the process of the thermal decomposition of chrysotile leads to the formation of olivine. The infra-red (IR) absorption technique applied for end products of some selected samples showed that the spectra of the end products are similar and the absorption bands assigned in the range of 1100-800 cm^{-1} and 700-200 cm^{-1} correspond to Si-O and Mg-O vibration modes. The chemical data revealing the similarity in chemical behaviours of chrysotile veins, implies that a close cogenetic relationship among three modes of chrysotile and removal of some major elements occurred during serpentinization; Mg, Fe and Si were removed in solution from the peridotite and precipitated in tension and shear fractures to form fibrous chrysotile and magnetite. The chrysotile serpentinization process is due to metasomatic replacement of peridotite during ocean floor early episode and later due to an episode of ophiolite obduction.

Do the mineralogical and geochemical characteristics of Camlidere Volcanic Rocks (Galatean Volcanic Province), Central Anatolia, Turkey, verify the magma mixing event in its evolution?

Varol, E.[1*], Temel, A.[1] & Gourgaud, A.[2]
[1]Dept. of Geological Engineering, Hacettepe University, Beytepe, Ankara, Turkey ([*]elvarol@hacettepe.edu.tr)
[2]OPGC, UMR-CNRS 6524 'Magmas et Volcans', Blaise Pascal University, Clermont-Ferrand, France

The Camlıdere district, located in Galatean Volcanic Province, NW of Ankara, Turkey, consists mainly of lacustrine sedimentary deposits, pyroclastic deposits, volcanic lava flows, domes and small dikes. The pyroclastic units are rhyolitic fall and flow deposits. The volcanic rocks are rhyolitic, andesitic, trachytic, dacitic and locally basaltic in character from older to younger. All these rocks exhibit hypocrystalline porphyritic textures. The rhyolitic lavas contain plagioclase + biotite + quartz, the andesitic lavas clinopyroxene + orthopyroxene + plagio-clase + amphibole, the trachytic lavas clinopyroxene + orthopyroxene + plagioclase + amphibole + biotite and the dacitic lavas clinopyroxene + orthopyroxene + plagioclase + amphibole + biotite ± quartz. The youngest basaltic rocks crop out as dikes and consist of olivine + clinopyroxene + plagioclase ± orthopyroxene. Oxides occur as accessory minerals or inclusions in the phenocrysts in all type of rocks. The mineralogical characteristics, mineral chemistry and whole-rock geochemistry reveal that magma mixing is an important process on the evolution of these rocks. Some features can be interpreted as evidences of magma mixing process, features such as:

-orthopyroxene surrounded by clinopyroxene,

-normally and reversely zoned, reacted amphiboles,

-coexistence of normally and reversely zoned, sieved and unsieved plagioclase and pyroxene in the same rock,

-having a wide compositional range of An% from core to rim of plagioclase,

-major element modelling using least-square mass balance calculations.

Low-temperature wollastonite: evidence for carbonate reduction around serpentinite

Malvoisin, B.[1], Chopin, C.[1*], Brunet, F.[1], Galvez, M.[1] & Beyssac, O.[2]
[1]Ecole normale supérieure–CNRS, Paris, France
([*]chopin@geologie.ens.fr)
[2]IMPMC, Université P. et M. Curie–CNRS, Paris, France

Siliceous marbles immediately overlying a serpentinite body above Patrimonio, in the Alpine blueschist- to eclogite-facies meta-ophiolitic units of northern Corsica, are remarkable in two respects. i) In a calcite ± quartz matrix, they preserve aragonite inclusions in grossular garnet. The aragonite fibres are oriented perpendicular to the garnet growth surface and impart the garnet porphyroblast a very uncommon, radial to sectoral microtexture [1]. ii) The refolded contact between serpentinite and marble shows a very continuous reaction zone, with a conspicuous, weathering-resistant centimetre-thick selvage of pale 'nephrite' (diopside ± andradite/grossular ± perovskite) on serpentinite side, followed toward the impure marble by a 1 to 5 cm thick, light grey and easily weathered zone of wollastonite (± grossular), followed by a 5 to 20 cm thick, dark zone forming like a dark halo around the serpentinite in the overlying series and consisting essentially of wollastonite + quartz + carbonaceous material (± grossular ± diopside), with no carbonate. The transition to the overlying wollastonite-free, calcite+quartz-bearing layers is sharp.

Considering the stability of calcite + quartz throughout all the regional series, this low-temperature (< 500°C) occurrence of wollastonite is paradoxical. A clue to its origin is the abundance of carbonaceous matter along with wollastonite within a few decimetres of the serpentinite body. We interpret this observation as evidence for local reduction of the carbonate to form carbon and wollastonite (in the presence of quartz), probably by diffusion of/in a highly reducing fluid (< FMQ –1) equilibrated with the serpentinite. The implication is that serpentinite bodies may preserve a reducing redox potential throughout subduction and metamorphism.

Preliminary geochemical characteristics of Variscan granitoids from Apuseni Mountains (Romania)

András, E.[1], Pál-Molnár, E.[1*] & Buda, Gy.[2]
[1]Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Szeged, Hungary ([*]palm@geo.u-szeged.hu)
[2]Dept. of Mineralogy, University of Eötvös L., Budapest, Hungary

The Tisia Composite Terrane [TCT] is built up from Variscan metamorphic series and granitoids. The TCT forms the basement of South Hungary, NE Croatia, N Serbia and W Romania and it is surrounded by mobile zones and fault lines.

In order of correlation studies between granitoid suits from the Tisia Composite Terrane, an extended field survey is being carried out in the Apuseni Mountains (Romania). The Apuseni Mountains consist of four Alpine tectonic units: the Bihor Unit, the Codru Nappe System, the Biharia Nappe System and the Mureş zone. Its basement is built up from three pre-Alpine Godwanan terranes: Someş, Biharia and Baia de Arieş. These units are built up by metamorphic sequences, most of them contain Variscan granitoid intrusions. The present study focuses on different granitoid occurrences from the Someş Terrane: Şiria granitoid [SG] (presumably the same age as CG), Codru granitoid [CG] (372 Ma), Codru migmatite [CM] (516 Ma), Muntele Mare granitoid [MMG] (both main pluton and satellite branches) (297-291 Ma).

The composition of the suits is more or less heterogenic, many structural and compositional variations are present within a group. The MMG suite contains: equigranular two mica granitoids, biotite granitoids, k-feldspar megacryst bearing granitoids, leucogranites, leucogranites with gneissic texture. The CM suite is mostly metatexite, where both paleosome (~70%) and neosome are present (~30%). The SG and CG are two mica granites with or without feldspar megacrysts.

Petrogenetic and geotectonic interpretations were elaborated based on whole rock geochemical compositions (major and trace elements). Modal and geochemical classifications show granodiorite to monzogranite compositions for MMG, granitic (monzo- and syeno-) for CG and SG, and granodiorite to tonalite for CM.

The studied samples have a calc-alcaline and moderately peraluminous character. The only exceptions are framed by the CM, which are calcic. The samples from MMG, CG and SG show syn-collison and post orogenic origin, while the CM samples are mantle fractionates.

Acknowledgements: Research supported by NRF No. 67787.

Sr-Nd isotope evidence for mixing in the mafic rocks from the Reguengos de Monsaraz Variscan Pluton (Ossa Morena Zone, Portugal)

Antunes, A.[*], Santos, J.F. & Azevedo, M.R.
GeoBioTec, Dep. Geociências, Universidade de Aveiro, Aveiro, Portugal ([*]ana.antunes@ua.pt)

The late-post-kinematic Reguengos de Monsaraz pluton is located in the Ossa Morena Zone, one of the major geotectonic units of the Iberian Variscan Belt. At the presently exposed level, the intrusion is dominated by tonalite-granodiorite rocks, spatially associated with minor bodies of gabbro-diorite composition, particularly in the central part of the area. Field evidence shows that the different intrusive facies define mixing/mingling contact relationships, suggesting a coeval emplacement for mafic and felsic magmas. The Rb-Sr age obtained for the pair amphibole-feldspar in one granodiorite sample (297.5 ± 2.9 Ma, initial $^{87/86}$ Sr = 0.70766 ± 0.00011) provides a minimum estimate for the time of original crystallization [1].

Petrographic and geochemical studies reveal that the different members of the suite have compositions ranging from metaluminous to slightly peraluminous and a distinctive calc-alkaline signature. Furthermore, the occurrence of systematic rectilinear correlations in Harker variation diagrams supports a mixed provenance for this sequence [1].

The εSr_{300}-εNd_{300} co-variation displayed by the least evolved members of the suite indicates that these rocks do no longer represent the mafic mixing end-member. Their relatively low εNd_{300} values [εNd_{300}=-5.1 to -7.8; $^{87}Sr/^{86}Sr_{300}$= 0.70871 to 0.71037] point to a significant interaction with time-integrated LREE-enriched upper crustal source components, comparable to the Late Proterozoic metasediments of the "Série Negra" (Fig. 1).

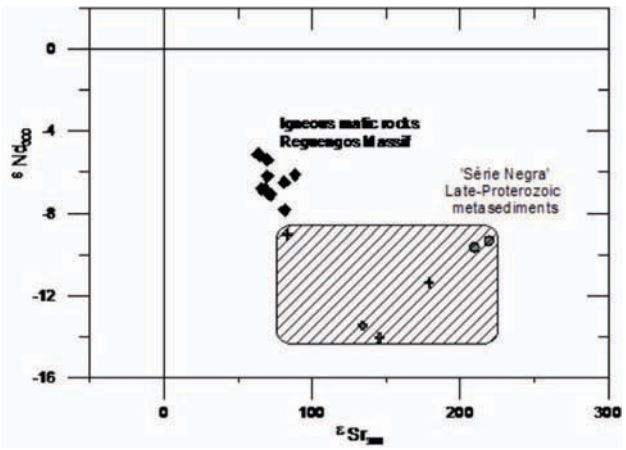

Fig. 1: εSr300-εNd300 diagram for the mafic rocks of the Reguengos de Monsaraz intrusion. Sr-Nd compositions of the "Série Negra" metasediments from Schäfer (1990) [2] and Beetsma (1995) [3].

A scenario where the gabbro-diorite magmas from Reguengos de Monsaraz correspond to contaminated basic liquids is therefore proposed. Further hybridization of mafic magmas with anatectic crustal melts would have generated the entire range of granitoid types present in the massif.

Geochemistry of biotite as a petrogenetic indicator for the Castelo Branco granitic pluton, Central Portugal

Antunes, I.M.H.R.[1,2*], Neiva, A.M.R.[3] & Silva, M.M.V.G.[3]
[1]Polytechnic Institute of Castelo Branco, Castelo Branco, Portugal ([*]imantunes@esa.ipcb.pt)
[2]Geoscience Centre, University of Coimbra, Coimbra, Portugal
[3]Department of Earth Sciences, University of Coimbra, Coimbra, Portugal

The reversely zoned pluton of Castelo Branco consists of five concentric late-tectonic Variscan granitic rocks (310 ± 1 Ma), which intruded the Cambrian schist-metagraywacke complex [1]. A muscovite>biotite granite (A) in the pluton's core is surrounded successively by biotite>muscovite granodiorite (B), porphyritic biotite>muscovite granodiorite (C) grading to biotite≈muscovite granite (D) and finally by muscovite>biotite granite (E). The contact between granite A and granodiorite B is sharp, such as the contact between granites D and E. All granitic rocks are peraluminous with A/CNK ratio ≥ 1.1, normative corundum ≥ 2.8 % and of S-type. These granitic rocks are mainly classified as magnesian and alkali-calcic [2]. They contain quartz, microperthitic microcline, plagioclase, biotite, muscovite, tourmaline, monazite, apatite, zircon, ilmenite and rutile. Biotite crystals are euhedral to subhedral, with pleochroism from γ and β – dark reddish brown to α – pale yellow. They are Fe-biotites [3] and have compositions similar to those of biotites from aluminium-potassic rock series [4]. Variation diagrams for major and trace elements and trace/major element ratios of the biotites plotted against whole-rock % total FeO define curvilinear trends between granodorites B and C and granite D. The general increases in Al, Nb, Zn, Sn, Li, Rb, Cs and Ta contents and Rb/K and Li/Mg values and decreases in Mg, Cr, Ni, Co, Sc, Ga and Ba contents and $Mg/(Mg+Fe^{2+})$, Ba/K, Ni/Fe^{2+} and Sc/Fe^{2+} values from biotite of granodiorite B to biotites of granodiorite C and granite D suggest a magmatic differentiation process. The biotites of granites A and E do not fit these trends and are not related, supporting that these granites represent two distinct pulses of granite magma. The granodiorite C and granite D are the products of in situ fractional crystallization of granodiorite magma B by separation of plagioclase, quartz, biotite and ilmenite, which took place outwards in maximum two million years [1].

Crystal structural characterization of calcite in low-grade metamorphic rocks of the Szendrő Mountains (NE-Hungary)

Bajnóczi, B.[*], Tóth, M. & Árkai, P.
Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary ([*]bajnoczi@geochem.hu)

It is well known that the average grain size of carbonate rocks increases with increasing (peak) metamorphic temperature (e.g., [1,2]). However, the grain size is not suitable for a reliable determination of metamorphic grade because there are several factors (e.g., modal composition and textural characteristics of rocks) that control grain growth. The amounts and distributions of associated fine-grained clay minerals and organic matter, strongly related to the original depositional environment and diagenetic history of the rock, display significant influences on the main grain size of metacarbonates (e.g., [3]).

The structural changes in phyllosilicates (mostly illite and chlorite) are well known and widely used empirical indicators for expressing differences in diagenetic and low-T metamorphic (anchi- and epi-) zones. For this purpose the full width at half maximum (FWHM) values of the basal XRD reflection(s) of phyllosilicates is a widely applied method. Changes in average size of submicroscopic crystallites (i.e., in the mean size of domains that scatter coherently the X-ray) of carbonate minerals during metamorphism may provide also a useful empirical tool to differentiate between metamorphic zones.

To test the applicability of FWHM of calcite in metamorphic research, the present study attempts to compare crystal structure characteristics of different metacarbonate rocks originated from a given metamorphic unit. Recrystallized limestones and marbles of the Szendrő Mountains from NE-Hungary were investigated, for which epizonal character based on the FWHM of phyllosilicates is well-known from earlier studies [4, 5]. The studied metacarbonate formations, originated from protoliths from various sedimentary environments, have distinct grain sizes, clay and organic matter contents. In addition to microtextural characterisation, differences among formations were revealed by comparing FWHM values of the maximal intensity X-ray reflection (d_{104} = 3.03 Å) of the bulk (matrix) calcite. In addition single line profile analysis of the maximal intensity reflection was applied to determine mean crystallite size of calcite in each formation.

In the studied formations the average crystallite size correlates fairly well with the grain size. Coarse-grained (0.1 to 0.5 mm), "pure" platform limestone (Rakaca Marble) has lower FWHM and higher crystallite size (0.149 to 0.167 °2theta, 730 to 830 Å) than fine-grained (< 0.05 mm), clayey, basin facies limestone (Verebeshegy Limestone) (0.163 to 0.192 °2theta, 600 to 690 Å). Previously Abod Limestone (metatuffitic, recrystallized limestone rich in phyllosilicates) was regarded as having the highest metamorphic grade (biotite zone) among formations of the Szendrő Mts. The FWHM (0.155 to 0.197 °2theta) and crystallite size (610 to 920 Å) of the Abod Limestone, however, overlaps with that of the Rakaca Marble and the Verebeshegy Limestone in accordance with its medium grain size (0.05 to 0.3 mm).

The FWHM and mean crystallite size of bulk calcite in the Szendrő metacarbonate rocks seem to especially depend on the lithology. To compare the metamorphic grade of different units these parameters can only be evaluated for similar lithological types of carbonate-rich rocks.

First report of Mg-rich chloritoid + staurolite assemblage from the Sanbagawa belt, Japan

Banno, Y.
Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan (y-banno@aist.go.jp)

Mg-rich [Mg/(Mg + Fe^{2+}) = 0.37 to 0.49] chloritoid associated with staurolite was found in a corundum-bearing zoisite rock from the Besshi area (N 33°52', E133°24') in the Sanbagawa metamorphic belt, Japan. Chlorotoid is a rare mineral that occurs in the Sanbagawa belt, which is a high-*P*/*T* metamorphic belt [1]. This is the first report of chloritoid + staurolite assemblage from the Sanbagawa belt. The zoisite rock consists mainly of coarse-grained zoisite, corundum, garnet, and pargasite. These minerals are considered to be stable at the peak metamorphic stage under eclogite facies condition. Garnet belongs to the almandine-pyrope series (X_{Alm}: 0.28-0.40, X_{Prp}: 0.38-0.50) and is poor in Mn (X_{Sps}: 0.01) and rich in Ca (X_{Grs}: 0.19-0.24). Corundum was retrogressively replaced by fine-grained secondary chloritoid, zoisite, clinozoisite, chlorite, and paragonite. Staurolite [Mg/(Mg + Fe^{2+}) = 0.27 to 0.35] rarely occurs in aggregates of the secondary phases (chloritoid, chlorite, and paragonite), which occur along the cracks in corundum, and is surrounded by chloritoid (Fig. 1).

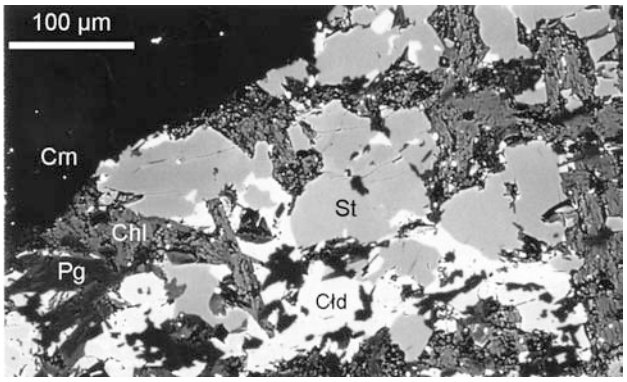

Fig. 1: Backscattered electron image of chloritoid growing into staurolite. Abbreviations: Cld, chloritoid; Crn, corundum; Chl, chlorite; Pg, paragonite; St, staurolite.

This texture indicates that chloritoid was formed by the following retrogressive reaction: 7chlorite + 8corundum + 4staurolite + 15H_2O → 51chloritoid. The *P*-*T* condition during the retrograde stage can be determined using the chloritoid-staurolite-chlorite-corundum assemblage. The mineral equilibrium is calculated using the THERMOCALC program (ver. 3.21) [2] with coexisting compositions of chloritoid, staurolite, and chlorite. The estimated temperature for the above univariant reaction in the MASH system is 637 ± 30 °C at 10 kbar and 744 ± 34 °C at 20 kbar. The temperature obtained from the calculation using the FASH system is approximately 130 °C lower than that obtained from the MASH system at 10-20 kbar. The process of formation of staurolite is not clear. One of the possible reactions for the formation of staurolite at an early stage of retrograde metamorphism is as follows: garnet + corundum + H_2O → staurolite + chlorite. The textural evidence and the estimated temperature suggest that chloritoid formed during the exhumation stage from eclogite to epidote-amphibolite facies conditions.

Geological studies on Pleistocene rubble of Palaeo Danube in Carpathian Basin

Bors, V., Giber, A., Józsa, S., Lévai, E., Micsinai, D.*, Molnár, M., Szabó, Zs., Varga, M. & Vígh, Cs.
Dept. of Petrology and Geochemistry, ELTE, Budapest, Hungary (*dani9@tvnetwork.hu)

At the end of last Glacial the Palaeo Danube stepping out from the Eastern Alps and from the Visegrád-Pilis-Budai Mts. has been depositing its bedload in two large gravel funs: west of Pozsony (Bratislava) on Little Hungarian Plain and south of Budapest on Csepel Plain. These late Pleistocene terraces are mostly covered by thin holocene sediments and consist of gravels with few sporadically embedded angular blocks both containig wide variety of partly exotic rock types. We give summarised petrographic and grain morphologic description of this debris to know more about the environment of the late Pleistocene Palaeo Danube.

1400 pebbles were collected from one gravel pit in Dunavarsány, Csepel Plain to determine rock type distribution and main grain morphological parameters. Beside the dominating quartzite (43%), 40 main rock types were detected. Ostrea bearing conglomerate pebbles and bored limestone pebbles refer about redeposition of some pebbles from miocene marine conglomerate layers. Traces of aeolian erosion were also examined and counted. 64.97% of the whole collection, mainly the hard rock types showed at least partly bright surface. Not so the soft or weathered rock types as andesites and limestones some of which have only special tortoiseshell shape.

Rock type distribution of boulders is similar in the 2 areas, exept miocene andesites occuring only in Dunavarsány. Surface of many blocks have also been formed or/and polished by the wind. Significant group of exotic chrystalline rocks (e.g. granites, granulites, gneises, amphibolites) could be distinguished. Some special rock types were selected for more detailed examinations.

Few blocks of graphic granite with large sheaf shaped muskovite have been found in Dunavarsány. It has macroscopically well visible very special texture.

The andalusite bearing two micas mostly fine grained granite is a very frequent rock type in the whole study area. Short lathy grains of microscopic andalusite often show pale pink pleochroism and surrounded by muskovite. In some of these blocks turmaline and garnet also appear.

Latites and related rocks appear in both areas and form a well distinguishable group. They are dark, very hard, finegrained rocks and contain large (1 cm long) sanidine porphyres, different amount of plagioclase, kinked biotite, finer grained green hornblende and rarely augite.

Felsic granulites from the two main areas were investigated even more detailed. Three main types can be distinguished. Grt-Ky granulites contain HP/HT peak mineral assemblage: garnet-kyanite-ternary feldspar-quartz. In Grt-Sil granulites kyanite is commonly replaced by sillimanite while biotite appears as a stable phase. Some sample show well developed foliation and mylonitic texture. Orthopyroxene-bearing granulite also presents.

The crystalline rock assamblage, the andalusite bearing granites, the latites and the granulite boulders are very similar to those known from certain areas of Bohemian massif. Special textured graphic granite occur on Zerge Hill near Pozsony (Bratislava). Miocene andesites found only south of Budapest have been related to those of Visegrád and Börzsöny Mts.

We suppose as a conclusion that studied boulders were picked up by the Palaeo Danube from the above mentioned areas and transported mainly by pack ice. Before burial most pebbles and boulders of the debris were effected by wind erosion.

Hybridization events in the Tatra Granite, Western Carpathians, Poland

Burda, J.[1*], Gawęda, A.[1] & Klötzli, U.[2]
[1]Faculty of Earth Sciences, University of Silesia, Sosnowiec, Poland ([*]jolanta.burda@.us.edu.pl)
[2]Dept. of Lithospheric Research, University of Vienna, Austria

Mafic magma has long been recognized to play an important role in the granitoid melt generation. The processes of felsic and mafic magma interactions can be observed in different scales: from outcrop scale to micro-chemical and trace by isotopic signatures. The fundamental features that unequivocally prove the presence of mixing – mingling processes are textural ones.

It is currently believed that no single texture can be used to undoubtedly prove the presence of hybridization in granitic rocks, so the term "textural assemblage" was proposed to define the combination of textures, forming together good evidence for mixing – mingling phenomena [1].

In the Variscan Tatra Granite, both in western and eastern parts, the mixing and mingling phenomena can be observed at the contact of mafic precursors of dioritic composition with more felsic granite. The textural assemblage include: 1) plagioclase–K-feldspar–sphene ocella; 2) boxy-cellular plagioclase (An_{20-30}) crystals with spike zonation (An_{40-50}); 3) inversely zoned K-feldspar crystals (Cn_{2-4} in the cores and Cn_{5-9} at rims); 4) mafic cloths, composed of biotite, hornblende, magnetite, zoned allanite, locally pyroxene; 5) poikilitic plagioclases and quartz crystals with micro-inclusions of hornblende, biotite and apatite; 6) mixed apatite morphologies, including prismatic, chemically zoned apatites and unzoned acicular apatites; 7) chemically zoned K-feldspar phenocrysts, with inclusion zones; 8) "hydrogenic" biotite of blade-shape morphology.

The apparent pressure range of the magma hybridization event was calculated at 6.1 kbar to 4.6 kbar, whiles the temperature, calculated by independent methods, is in the range of 810°C -770°C.

U-Pb age data of the hybrid rocks were obtained by in-situ LA-MC-ICP-MS analysis of zircon. Most zircons are characterized by well-developed oscillatory zoning, from fine to broad, displaying variable CL intensities. Some crystals exhibit homogeneous to weakly growth-zoned cores with bright luminescence. Cores are sub-rounded and the contacts with surrounding growth-zoned rims are irregular. Eleven measurements on seven crystals were made. All data points are concordant within the assigned error. Nine analyses from the oscillatory-zoned zircon crystals yield a weighted average age of 368.4 ±7.7 Ma (MSWD= 1.07), interpreted here as the age of igneous crystallization. Two inherited cores give an age of ca. 540 Ma, providing evidence for the assimilation of zircons derived from Ediacaran/Early Cambrian sources.

The occurrence of ages around 368 Ma could be interpreted as an age of magma hybridization and timing of formation of the magmatic precursors for the granitoid magmatism event in the Tatra Mts.

Spinel and orthopyroxene exsolution in clinopyroxene from gabbro, southwest Tianshan Mountains: an indicator of fO_2 decrease during cooling in post-collision environment

Chen, J.[1*], Zhu, Y.F.[2] & Christy, A.G.[3]
[1]School of Physics, Peking University, Beijing, China ([*]jchen@pkjchen@pku.edu.cn)
[2]School of Earth and Space Sciences, Peking University, Beijing, China
[3]Research School of Earth Sciences, Australian National University, Canberra, Australia

We report new data for oriented spinel rods and orthopyroxene lamellae exsolved from clinopyroxene in the Haladala gabbro, southwest Tianshan Mountains Xinjiang, NW China. Our study is based on optical, TEM and EDX analyses. Several diffraction patterns of the same microphase were obtained by tilting the sample in the double-tilt stage. The results show that the rods are crystals of a spinel-group mineral. The spinel rods (110) are parallel to their host clinopyroxene $(11\bar{1})$. The TEM images show that the Opx lamellae (010) are strictly parallel to their host clinopyroxene $(11\bar{1})$. The Haladala gabbro intruded into Carboniferous arc segments in the southwest Tianshan mountains. Exsolution of the cation-rich spinel phase from clinopyroxene implies a decrease in fO_2 during cooling, and that the pyroxene started with substantial contents of Fe^{3+}, tetrahedral Al and (Mg,Fe^{2+}) on the M2 site, all consistent with an igneous origin in a relatively oxidized arc environment.

Textural and mineralogical evidences for magma mixing and mingling: the example of a late-tectonic Variscan granite intrusion from Central Portugal

Costa, M.M.[1*], Neiva, A.M.R.[2] & Azevedo, M.R.[1]
[1]Dept. of Geosciences, University of Aveiro, Aveiro, Portugal ([*]mmcosta@ua.pt)
[2]Dept. of Earth Sciences, University of Coimbra, Coimbra, Portugal

The Touro pluton is a late-kinematic coarse- to medium-grained porphyritic biotite-muscovite granite hosting abundant fine-grained mafic microgranular enclaves from tonalite to granodiorite composition. Both the granite and the mesocratic microgranular enclaves (MME) show a series of textural and mineral assemblages typical of hybrid rocks produced by the interaction of magmas with contrasting compositions. The granite has plagioclase and microcline phenocrysts and its matrix is composed by quartz, microcline, plagioclase, biotite, muscovite, zircon, monazite, apatite, ilmenite and rutile. The MME have higher plagioclase and biotite contents than the host granite. K-feldspar and muscovite are absent in the tonalitic enclave. At the outcrop scale, the MME display round, ellipsoidal and discoid shapes and sizes varying between a few centimeters and one meter long . Their contacts against the host granitoid range from sharp to diffuse suggesting contemporaneous flow and mingling of partly crystalline felsic-mafic magmas. Mechanical transfer from the felsic host to the enclave magma is also documented by the presence of corroded minerals (xenocrysts) within the MME. Petrographic and mineral chemistry studies on both the MME and their host rocks indicate that magma mixing / mingling between granite and evolved mafic melts played a key role during the evolution of the batholith. Disequilibrium textures include: plagioclase crystals with oscillatory zoning, cellular structures (boxy-cellular and/or spongy-cellular), anorthite-rich 'spikes' and resorbed surfaces, acicular apatite with high aspect ratios and quartz *ocelli* rimmed by thin biotite flakes. Plagioclase chemistry is a helpful tool to decipher the complex processes involved in the petrogenesis of these granitoids. As expected from their xenocrystic character, the large plagioclase crystals of the MME exhibit a significant degree of compositional overlap with those of the host granite (An_{20-38} to An_{21-40}). The matrix plagioclase crystals are generally more sodic but tend to define a bimodal distribution pattern, with peaks at An_{15-20} and An_{30-35}, suggesting abrupt changes in the chemistry of the enclave magma. The observed compositional discontinuities appear to reflect variations in the conditions of feldspar nucleation and crystallization during mixing / mingling processes. In contrast, the biotites from the MME and the host granite are compositionally uniform (Fe/Fe+Mg = 0.45 – 0.74) possibly as a consequence of re-equilibration after magma mixing.

The occurrence of tonalite and granodiorite compositions within the MME provides evidence for multiple mixing events involving relatively evolved basic melts, which may themselves correspond to hybrids. Mixing should therefore have occurred under different conditions and at different times in the history of the Touro intrusion. These conclusions are supported by field observations, whole-rock and isotopic geochemistry.

Noble gases in peridotite xenoliths from Tasmania: implications for interaction with the host basalts

Czuppon, Gy.[1*], Matsumoto, T.[2], Matsuda, J.[1], Everard, J.[3] & Sutherland, L.[4]
[1]Dept. of Earth and Space Science, Osaka University, Osaka, Japan ([*]gyorgy.czuppon@univie.ac.at)
[2]Institute for Study of the Earth's Interior, Okayama University, Okayama, Japan
[3]Mineral Resources Tasmania, Rosny Park, Australia
[4]Australian Museum, Sydney, Australia

In order to better understand the evolution of the subcontinental lithospheric mantle (SCLM) beneath Tasmania, spinel peridotite xenoliths were analyzed for elemental and isotopic compositions of noble gases. The noble gas isotopic compositions indicate contributions of radiogenic and MORB-like components to the xenoliths. The typical features of the radiogenic component include (1) lower $^3He/^4He$ ratios than those in MORB (8.75±2.14Ra, [1]); (2) excesses in ^{136}Xe relative to the MORB composition. The MORB-like component is characterized by $^3He/^4He$ ratios between 7-9Ra. The deconvolved argon isotopic ratios also support the presence of these noble gas components. The identified radiogenic component in xenoliths from Tasmania may stem from subduction events, during which the mantle wedge and subcontinental SCLM were metasomatised by U- and Th- rich fluids. As subduction processes have played important role in the evolution of Eastern Australia during the Paleozoic, the radiogenic component is probably associated with this event. The contributions of MORB-like noble gas component to the xenoliths indicate such a component in SCLM beneath Tasmania. This happened in Eastern Australia when extensional rifting in the Late Mesozoic and Cenozoic opened the Tasman Sea. The identified noble gas components are consistent with the geochemical character of the host basalt. This agreement and the petrographic observations indicate that fluids (noble gases, CO_2) most likely propagated from the host basalts to the xenoliths forming fluid inclusions.

The petrogenetic meaning of schorl-dravite transition and apatite association in peri-amphibolitic tourmalinites – Northern Portugal

Dias, P.A.* & Leal Gomes, C.
CIG-R – DCT, Universidade do Minho, Braga, Portugal
(*patriciasdias@gmail.com)

In opposite sides of the massif of Serra de Arga, meta-volcanic to meta-sedimentary formations in Monteiro and Verdes include complex suites of amphibolitic rocks with unusual phosphate tourmalinites, mafic and felsic porphyroid proto-tuffs, stratiform tourmalinites, epidotites with graphite levels and phosphate meta-cherts. These rocks are interbedded with regional andalusite phyllitic formations.

The amphibolite lenses are small and have been transported by over-thrusting in structures lately reactivated as strike-slip shear zones. Amphibolite paragenesis holds anorthite, Fe-hornblende, F-rich sphene, fluorite, Cr-rich epidote, F-apatite, scheelite and sulphides. The peri-amphibolitic tourmalinites mainly located at the roof of amphibolite lenses may show distinctive textures and habits of tourmaline aggregates: T1 - massive monomineralic tourmaline and spindle-shaped agglomerations of tourmaline crystals; T2 - cataclastic aggregates with matrix phosphate; and disseminations in the amphibolites matrix and in altered mafic tuffs (Fig. 1). Different generations of tourmaline (schorl compositions and scarce dravite) were identified: G1 - early tourmaline (Fe, Al and□ X richer) affected by micro-displacements; G2 - crystals with oscillatory zoning; G3 - diffuse substitutions of G2 generation; G4 - dravite bands perpendicular to the c axis of G2; G5 - veinlet and micro-fracture remobilizations. F and Ti contents mark well the evolution between early compositions poor in Ti and F till late compositions with oscillatory enrichments.

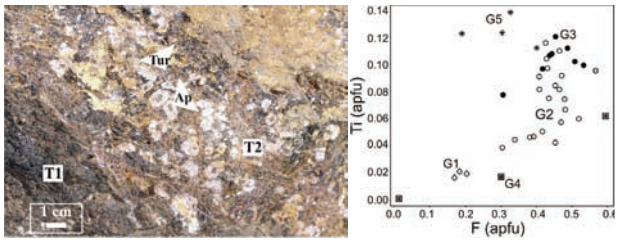

Fig. 1: Tourmaline / apatite textures and Ti/F constituents from T2 tourmalines (crystals G1 to G5).

The amphybolitic facies are interpreted as remnants of alkaline basalt compositions, which could evolve locally to intermediate or felsic end - members. Primary and proto - lithic boron enrichment might be related to proto - exhalitic and/or evaporite activity (compare to [1]), lately remobilized by hydrothermal fluids and contaminated by the various surrounding metassomatized rocks. Hypothetically, a fluid/magma P-saturated phase would be released from the alkaline trend, producing apatite enrichment. Textural relations between tourmaline and apatite seem to be remnants of an ancestral hydraulic breccia of "roof- rock" clasts.

Similarities between tourmaline compositions, here studied, and those occurring in neighbour stratiform tourmalinites, may suggest the introduction of B (± P) in volcanic spots, associated with deep faults, and the spread of metasomatism to adjacent, previously seated, sedimentary sequences.

Geothermometry of volcanic rocks from SW Shahrood, N Iran

Ghorbani, G.
School of Earth Sciences, Damghan University of Basic Sciences, Damghan, Iran (ghasemghorbani@yahoo.com)

The study area is located southwest of Shahrood town in Semnan Province (northern Iran). This region is characterized by the presence of a magmatic belt consisting of extrusive and intrusive igneous rocks. Middle Eocene volcanics are the most important rocks of this unit; they are represented by basalt, basalt with olivine, basaltic andesite, andesitic basalt, dacite and equivalent pyroclastic rocks.

Based on their petrographical and geochemical features, these rocks show an alkaline-subalkaline nature. The studied basalts have average Ce/Pb and Nb/U ratios lower than the value for average oceanic basalts (OIB and MORB), but close to the average values of sub-continental lithospheric mantle (SCLM). The chondrite-normalized REE patterns of the basalt samples plot as steep lines, suggesting that the rocks might have been generated via slow melting processes affecting a garnet-enriched peridotitic mantle source.

Amphiboles are present in the rocks cropping out in the northern part of the study area; they are Ca-rich, and show pargasite and ferropargasite compositions**.** Pyroxenes are represented by augite, diopside (as cpx) and enstatite (opx).

Based on previous studies, geobarometry of basaltic andesites located in the northern part of the study area based on the Al-content of hornblende and calculated by using the formula of Schmidt: $P(\pm 0.6Kbar) = -3.01+4.76Al^{tot}$ [1] indicated values ranging from 8.64 to 9.70 and from 3.48 to 4.47 Kbar (at depth of 32-36 and respectively 13–16 km).

Equilibration temperatures of cpx and opx pairs in andesitic basalts rocks were also previously calculated by means of different thermometers; the obtained values range from 709 to 900°C for the rocks in the northern part, while for the southern part they range from 900 to 1100°C.

In the present study, geothermometry information retrieved from olivine and clinopyroxene compositions [2] of basalts suggests that these rocks were crystallized at relatively higher temperatures, ranging from 850 to 1270°C.

Peridotite nodules and xenoliths in the Paleogene alkali basalts from the Muncelu Mare - Muncelu Mic area (Poiana Ruscă Mts., Romania)

Giurgiu, A.M.* & Grindean, R.A.
Dept. of Geology, Babeș-Bolyai University, Cluj Napoca, Romania (*alexa.giurgiu@yahoo.com)

The magmatic activity occurred in the Poiana Ruscă Mountains (the western part of Romania) during late Cretaceous to Paleogene. Mârza & Egri [1] describe the peridotite xenoliths beared by these rocks as autoliths, while Savu et al. [2] describe them as mantle xenoliths. In fact, these igneous rocks contain both nodules and xenoliths.

In the peridotite nodules olivine and pyroxenes are the main participants while the chlorite and magnetite participate as secondary phases. These nodules are consanguine with the basaltic magma, eventually becoming small centers of crystallization in the differentiated magma (Fig. 1).

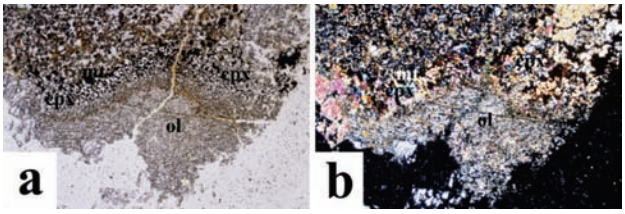

Fig. 1: Granular texture of nodule consisting of coarse grains of clinopyroxene (cpx) and olivine (ol) in alkali basalt (a-1N, b-N+; 35x).

The peridotite xenoliths from the Poiana Ruscă alkali basalts represent unmelted remnants of the primary alkaline magma source [2]. The core of these xenoliths consists of euhedral clinopyroxenes, partially altered to greenish aegirine, and colourless olivine. The matrix is represented by nepheline and alkaline zeolites. Pockets or veinlets of chlorite may support the theory of Na_2O rich melts influx. The rim consists in pyroxenes which are not associated with opaque magnetite minerals (Fig. 2).

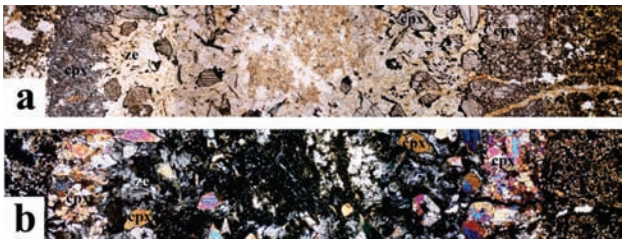

Fig. 2: Microscopic of peridotitic xenolith found in the alkali basalts from Muncelu Mare-Muncelu Mic area (a-1N, b-N+; 35x); cpx-clinopyroxene, ze-zeolite.

Based on the mineralogical and textural differences between the peridotitic terms, and also on the relation of these peridotitic terms to the igneous alkali host rocks, we consider that the alkali basalts from the Muncelu Mare-Muncelu Mic area carry both peridotite nodules − developed from a basaltic magma, and xenoliths − of mantle origin.

Corundum-quartz, Zn-bearing spinel and staurolite inclusions in garnet, and their implications for metamorphic evolution of the Sor Rondane Mountains, East Antarctica

Hokada, T.[1,2*], Adachi, T.[2,3], Osanai, Y.[3], Nakano, N.[3], Toyoshima, T.[4] & Baba, S.[5]
[1]National Institute of Polar Research, Tokyo, Japan
[2]The Graduate University for Advanced Studies, Tokyo, Japan
(*hokada@nipr.ac.jp)
[3]Kyushu University, Fukuoka, Japan
[4]Niigata University, Niigata, Japan
[5]University of Ryukyus, Okinawa, Japan

Neoproterozoic to Cambrian age magmatic and high-temperature metamorphic terranes comprise the area more than 1000 km along the coast or the inland of Dronning Maud Land in East Antarctica [1]. Among those, the Sor Rondane Mountains consist of greenschist-facies through amphibolite-facies to granulite-facies metamorphic rocks from which quite complicated P-T trajectories including two-stages of heating accompanied by two-stages of decompression have been estimated [2]. The Sor Rondane Mountains can be subdivided into at least two areas - the NE and the SW Terranes [3], and the attempt to unravel the metamorphic records in each area has been made by several authors.

In this paper, we provide some new consideration of metamorphic evolution based on the corundum-quartz, Zn-bearing spinel and staurolite inclusions of garnet in garnet-sillimanite-cordierite and garnet-orthoamphibole-cordierite gneisses from the Austkampane area where is the granulite-facies part of the Sor Rondane Mountains. The metamorphic rocks also suggest the following petrograhical constraints: (1) Garnet in the garnet-sillimanite gneiss commonly includes Zn-bearing spinel (up to 24wt% ZnO) which is commonly associated with sillimanite, cordierite and biotite. Other inclusions in garnet are quartz, biotite, sillimanite, rutile, ilmenite, biotite+rutile, biotite+sillimanite, biotite-staurolite, biotite+quartz and biotite+corundum+quartz aggregates. (2) Porphyroblastic garnet crystals in the garnet-sillimanite-cordierite gneiss are commonly surrounded by cordierite corona with or without quartz and biotite. Cordierite also occurs replacing biotite+sillimanite aggregates. (3) Orthoamphibole (anthophylitic) in garnet-orthoamphibole-cordierite gneiss has Al_2O_3 content commonly less than 4-5 wt% down to 1-2 wt% in the rim.

We will discuss the inferred clockwise P-T trajectory started with the prograde staurolite break down reaction in the sillimanite-stability field followed by the decompression of garnet(+sillimanite) to form cordierite(+quartz+biotite) that are also combined with the corundum-quartz, Zn-bearing spinel and staurolite inclusions in garnet. Metastability of the natural association of corundum and quartz has been discussed by several authors [4]. The mode of occurrence of the corundum and quartz associated with biotite in this study provides some insight for the process to form the natural corundum-quartz metastable association.

Geology, petrochemistry of trachyte and rhyolite magmas, Inshiel alkaline volcanics, Southern Sinai Egypt

Imbarak, S.H.[1*], Bilik, I.[2] & Weiszburg, T.G.[3]
[1]Geology Dept., Suez Canal University, Ismailia, Egypt
([*]imbarak25@yahoo.com)
2Dept. of Geochemistry, Eötvös Loránd University, Budapest, Hungary
3Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary

The Inshiel Acidic volcanics represented a small volcanic caldera within Kathrina ring dykes (6-7 km diameter). The rocks occur as lavas, ash-flow, welded tuffs and ignimbrites peralkaline quartz trachyte, rhyolite, and high-silica rhyolite.

They tend to be fine-grained, containing small amounts of phenocrysts. Plagioclase (andesine–oligoclase), anorthoclase or occasionally sanidine coexist with some microenclaves minerals such as augite, fayalite, pigeonite, orthopyroxene and magnetite. Quartz phenocrysts are exceedingly rare. Zoning of phenocrysts is limited and the pattern is variable.

They represent the silicic end member of a bimodal suite, between 57 and 62 wt% SiO2); the mafic end member (Rutig volcanics) consists primarily of basic and intermediate lavas.

The rocks classified as dacites, trachytes, low-alkali rhyolites and alkalic rhyolites. Some of the trachytes and alkalic rhyolites are peralkaline

The rocks are relatively Fe-rich and Ca-poor indicating low water pressure in the source. Trace element concentrations follow similar patterns in most central volcanoes. Exceptions are some samples where silicic rocks display a negative correlation of Ba to Th and unusually high Th-contents. The ratios of different high field-strength elements are generally similar within each central volcano or region, which probably reflects different ratios in the source materials. Isotope systematics indicates that the silicic rocks are derived from older basaltic rocks similar to those from the same volcano, and that meteoric water has played a role in the genesis of the silicic rocks.

High-silica rhyolite is not cogenetic with the quartz trachyte-rhyolite suite, and can be best explained as the result of ~5% partial melting of a mafic granulite in the deep crust under the fluxing influence of fluorine. Variation within the high-silica rhyolite is most likely due to fractional crystallization of alkali feldspar, quartz, magnetite, biotite, and monazite. Lavas and tuffs form A-type rhyolite suites, and are broadly similar to rock series described in anorogenic settings both in terms of petrology and petrogenesis.

The caldera is interpreted to have developed in a post-orogenic tectonic setting, or an early stage of continental rifting, and represents the earliest evidence for continental extension in the area.

Neogene quartz andesites from the Oaş-Gutâi Mts. (Romania): new geochemical data

Jurje, M.[1,2*], Ionescu, C.[2] & Hoeck, V.[3,2]
[1]Mineralogical Museum, Baia Mare, Romania
([*]jurjemaria@yahoo.com)
[2]Babeş-Bolyai University, Cluj-Napoca, Romania
[3]Paris Lodron University, Salzburg, Austria

Lava flows, volcaniclastics and subvolcanic bodies of quartz andesites quantitatively represent one of the most important volcanics in the Oaş-Gutâi Mts. This area belongs to the northwesternmost part of the Neogene volcanic chain in the Eastern Carpathians. The volcanics have a calc-alkaline geochemistry and range in principle from basalts and basaltic andesites to dacites and rhyolites. The age of the whole volcanic activity in the Oaş-Gutâi Mts. is Badenian-Pannonian i.e. 15.4 – 7.0 M.a. [1]. Quartz andesites are restricted to Pannonian, i.e. 11.5-10.7 M.a. in the Gutâi Mts., and 10.3-9.5 M.a. in the Oaş Mts. respectively.

Quartz andesites consist of quartz, plagioclase, orthopyroxene, clinopyroxene and amphibole phenocrysts, in a hyalopilitic to intersertal texture or holocrystalline groundmass. From the whole volcanic association, a number of 25 samples were analysed geochemically (ICP-MS) and by Electron Microprobe (EMP).

Geochemically, the volcanics range from andesites to dacites (56 to 65 wt% SiO_2). Major element oxides such as TiO_2, MgO or CaO are negatively, Na_2O and K_2O are positively correlated with SiO_2. The K_2O content classifies andesites as calc-alkaline to high K-calc-alkaline. A significant negative Nb, Ta and TiO_2 anomaly can be observed. The distribution of TiO_2, Zr, Nb and Y argues for crystal fractionation dominated by plagioclase, pyroxene, amphibole and magnetite.

The composition of plagioclases ranges from An_{90} to An_{40} reflecting the partly recurrent zoning from core towards the rim. Ortho- and clinopyroxenes show a wide range of Fe# and Ca-Tschermaks molecule, but little Na, Ti or Cr contents. Amphibole is predominantely magnesiohornblende with a wide range of Al^{IV}. More pargasitic or edenitic compositions are rare. Ilmenite and Ti-magnetite occur as oxides. The Si and K-rich groundmass is glassy or microcrystalline. It contains variable amounts of K-feldspar microliths.

The presence of amphibole as well as An-rich plagioclase argues for a relatively high amount of water present in the melt. The presence of at least two plagioclase generations and their complex zoning suggests magma mixing and an open system with repeated supply of less fractionated magma.

Ye'elimite and fluorellestadite as new indicators of ultrahigh-temperature–ambient pressure metamorphism

Kokh, S.N.
V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (zateeva@uiggm.nsc.ru)

Numerous fossil mud volcanoes (so-called the "Mottled Zone" complexes) cover Upper Cretaceous carbonate strata at the Middle East. Mottled Zone complexes are composed of brecciated sediments of the underlying Cretaceous sequence. Location of high-temperature combustion metamorphic (CM) foci annealed by methane jets ignition was fixed within Nabi Musa fossil mud volcano dome. At the base of the section, CM rocks occur as rounded clasts composed of larnite rocks, spurrite and brownmillerite marble formed at 700 – 900ºC. The foci of the ultrahigh-temperature (T_{min} = 1170 – 1200°C) CM rocks and paralavas are localized within conduits and were related by breccia zones [1]. The uncommon rocks sample depleted in CaO (17.0 wt.%) and enriched by (in wt.%): MgO–14.9, Al_2O_3–9.8, Fe_2O_3–4.5, TiO_2–0.5 and Na_2O–1.6 was found here. It mainly consists of primary minerals such as larnite, fluorellestadite, and brownmillerite with minor ye'elimite, bredigite, Cr-spinel and melilite and accommodated by retrograde spurrite, calcite, aragonite.

Ye'elimite $Ca_4Al_6O_{12}(SO_4)$ occurs as irregular interstitial patches (<300 μm) between melilite, fluorellestadite and bredigite. Ye'elimite is colorless and has specific atypical brownish hues in thin section. Major oxides are in the ranges of 43.03-43.63 Al_2O_3, 35.12-35.35 CaO, 12.46-12.98 SO_3, 4.01–5.82 Fe_2O_3, 0.35-1.86 SiO_2, 0.26-0.70 Na_2O, 0.10-0.28 MgO, 0.07-0.26 K_2O, 0.07-0.20 P_2O_5 (in wt %). The empirical formula is $Ca_{3.910}Al_{5.637}Fe^{3+}_{0.312}Si_{0.036}S_{1.007}O_{16.}$

Bredigite $Ca_7Mg[SiO_4]_4$ forms lath-like crystals (300 μm). Fresh bredigite is colorless in thin section and distinctly pleochroic: X = pale violet; Y = Z = colorless to pale blue, has intense blue fluorescence under the electron beam and contains inclusions of apatite. Bredigite shows little variation in CaO (57.80-58.98), SiO_2 (34.13-35.07), MgO (5.70-5.84), P_2O_5 (0.44-0.62), Na_2O (0.27 – 0.32), Fe_2O_3 (0.23 – 0.26 wt), TiO_2 (0.18-0.25 wt.%). BaO, MnO, SO_3 and K_2O are negligible. Its empirical formula is $Ca_{6.920}Mg_{1.010}Si_{3.946}Al_{0.015}P_{0.032}O_{16}$.

Fluorellestadite $Ca_{10}[(PO_4),(SiO_4),(SO_4)]_6F_2$ occur as <2mm single "pencil-like" crystals, with abundant larnite, spinel, and melt inclusions. Mineral is colorless or grayish and has survived hydrothermal alteration. Fluorellestadite has little variation in CaO (56.91-58.47), P_2O_5 (7.25-9.72), SO_3 (15.81-17.48), and SiO_2 (14.79-15.63 wt.%); F is 3.37-4.19 wt % and Cl is less than < 300 ppm. P, S, Si, and F vary slightly and irregularly from core to rim.

Ye'elimite, together with larnite, fluorapatite, and brownmillerite, were synthesized at 1000-1200ºC and ambient pressure [2], while the upper temperature limit of ye'elimite stability is 1300-1350ºC. The larnite-spurrite-spinel association and the absence of rankinite, imply a minimum of 975°C where $P_{total} = P_{CO2}$ [3]. Bredigite was found to be stable between 979-1381ºC [4]. So, the thermal alteration that produced the assemblage of bredigite, P-bearing larnite, ye'elimite, fluorellestadite, brownmillerite, and spinel with retrograde spurrite, calcite, and aragonite) occurred between 975-1000ºC and 1300-1380ºC.

Petrologic and geochemical study on mantle xenoliths and their multi-phased sulfide inclusions from Paleozoic lamprophyre dikes from Tuva (South Siberia, Russia)

Konc, Z.[1,2*], Hidas, K.[1], Szabó, Cs.[2], Sharygin, V.V.[3] & Garrido, C.J.[1]
[1]Instituto Andaluz de Ciencias de la Tierra, CSIC-UGR, Granada, Spain ([*]zoltankonc@ugr.es)
[2]Lithosphere Fluid Research Lab, IGES, Eötvös University Budapest, Budapest, Hungary
[3]Institute of Mineralogy and Petrology, UIGGM, Siberian Branch of the Russian Academy of Science, Novosibirsk, Russia

The main aim of this study is to describe petrographic and geochemical features of upper mantle xenoliths and their sulfide inclusions, hosted in 440-435 million years old lamprophyre dikes in Tuva Region (South Siberia). The study area is located between southern Siberia and northern Mongolia in Central Asia where one of the oldest members of the Calenodines has been exposed due to the tectonic processes from accretion (late Vendian), through collision (Cambrian) to transform faulting (Ordovician). The lamprophyre melts formed and brought up the xenoliths in the last stage of the tectonic period dominated by transform faulting.

The studied xenoliths are frequently poikilitic textures orthopyroxene-rich lherzolites, harzburgites, olivine-websterites and orthopyroxenites which suffered a 10-15% partial melting and their rock forming silicates have common mg# (0.90). The orthopyroxene-rich character of the studied xenoliths can be the result of interaction between subducted slab-derived SiO_2-rich melt and the peridotitic wall rock. The primary sulfide assemblages occur as 1) interstitial phases among mantle silicates (Fig. 1 & 2) enclosed blebs mostly in orthopyroxenes. Both interstitial and enclosed sulfide inclusions have rounded and irregular shape. The size of interstitial sulfide inclusions ranges between 75-300 μm, whereas the enclosed sulfide blebs are generally smaller (30-175 μm). Based on microscopy, X-ray mapping and SEM study, the primary sulfide inclusions consist of maximum four phases. The primary sulfide minerals are pentlandite, chalcopyrite, pyrite and millerite (Fig. 1). Using mass-balance calculation, the bulk composition of the studied sulfide assemblages is mostly plotted in the MSS (monosulfide solid solution) and MSS+$L_{Ni,Cu}$ fields (above 1000°C) in the S-Cu-Fe-Ni systems. The calculated KD_3 values, based on the Fe and Ni content of coexistence sulfides and olivines, suggest equilibrium between the sulfide assemblages and the silicates.

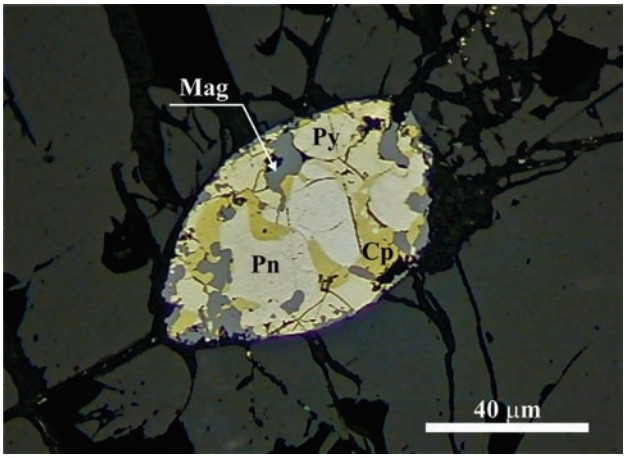

Fig. 1: Microphotograph of a multi-phased interstitial sulfide inclusion among mantle silicates (Cp - chalcopyrite, Pn - pentlandite, Py - pyrite and Mag - magnetite).

Deformation study on upper mantle peridotite xenoliths in relation with their petrographic and geochemical features from SE Iberian Volcanic Province (Spain)

Konc, Z.[1,2*], Garrido, C.J.[1], Tommasi, A.[3], Hidas, K.[1], Szabó, Cs.[2] & Marchesi, C.[3]
[1]Instituto Andaluz de Ciencias de la Tierra, CSIC-UGR, Granada, Spain ([*]zoltankonc@ugr.es)
[2]Lithosphere Fluid Research Lab, IGES, Eötvös University Budapest, Budapest, Hungary
[3]Géosciences Montpellier, Université Montpellier II & CNRS, Montpellier, France

We present here a detailed study on lithospheric mantle beneath SE Iberian Volcanic Province (SEI-VP, Spain) based on petrographic, geochemical and olivine LPO (lattice preferred orientation) analysis of upper mantle xenoliths. The volcanic activity in SEI-VP is the surface expression of magmatism in a complex geodynamic setting during the Cenozoic, which was characterized by a sequence of transpressional and transtensive stages in a "Mediterranean-type" back-arc system. The last stage in this geodynamical evolution was the Neogene alkaline basalt volcanism erupted at 2-3 Ma [1], which sampled the upper mantle beneath SEI-VP providing a unique possibility to study the lithospheric mantle beneath this region.

The studied samples came from the "Cabezo Negro" de Tallante and Los Perez (Murcia). The locality is one of the major xenoliths occurrences within SEI-VP. The xenoliths are spinel peridotites (lherzolite and wehrlite) with textures ranging from fine-grained equigranular to coarse-grained granular. In many samples (~30%) tiny plagioclase and/or amphibole appear mostly interstitially. The LPO of olivine is similar in all samples; it displays a strong [100] maximum, implying dominant activation of high temperature [100] {0kl} slip systems. The strength of the LPO varies in function of the xenolith texture and modal content of clinopyroxene. In coarse-grained peridotites, from lherzolite to wehrlite, the olivine LPO ranges from strong to a weak LPO. The stronger olivine LPO is characterized by alignment of [100] axes close to the lineation and a girdle distribution of [010] with a maximum normal to the foliation. Whereas, the weaker olivine LPO with a [100] maximum is still preserved close to the lineation and [010] one normal to the foliation. Altogether, stronger olivine LPO are observed in the coarse-grained peridotites. Modal enrichment in clinopyroxene and development of fine-grained equigranular texture are both accompanied by a dispersion of the olivine LPO. Based on these results, we suggest that the coarse-grained samples are representative of a primary subcontinental lithospheric mantle that was later affected by re-fertilization reaction that led to dispersion of the LPO, as well as an increase in the clinopyroxene content. This textural evolution may record thermal and chemical erosion of the subcontinental mantle during Cenozoic extension of western Mediterranean region.

Magma mingling and mixing as key processes in the petrogenesis of the Laleaua Albă Neogene composite igneous complex, Gutâi Volcanic Zone, Northern Romania

Kovacs, M.[1*], Fülöp, A.[1], Cook, N.J.[2,3], Kovács-Pálffy, P.[4] & Pécskay, Z.[5]
[1]North University of Baia Mare, Baia Mare, Romania ([*]marinelkovacs@yahoo.com)
[2]University of Adelaide, S.A., Australia
[3]South Australian Museum, Adelaide, S.A., Australia
[4]Hungarian Geological Institute, Budapest, Hungary
[5]Institute of Nuclear Research of the Hungarian Academy of Sciences, Debrecen, Hungary

The Laleaua Albă Neogene igneous complex (8.5-8.0 Ma) was emplaced at the end of volcanic activity in the Gutâi Volcanic Zone, Eastern Carpathian inner volcanic chain. The complex consists of sanidine dacites (hosting abundant mafic microgranular enclaves/MME, of ~50 wt% SiO_2) enveloped by aphyric andesites.

Chemistry and textures of the mineral assemblages from dacites, andesites and MME show constraints on the main magma-mingling and -mixing rock-forming processes. Characteristic features include: disequilibrium textures of the two populations of plagioclase phenocrysts (strongly oscillatory zoned, An_{26-44} and sieve-textured with resorption zones, An_{60-90}); similar high Mg# (79-95) clinopyroxene, mainly chromian diopside (as abundant clusters in dacites and andesites) and high Mg# (71-84) amphibole (Ti-magnesiohastingsite) in the MME, dacites and andesites; clinopyroxene coronas on the quartz phenocrysts exclusively within the andesites; resorption embayments displayed by the large-sized (up to 5 cm) sanidine phenocrysts.

Abundant and evenly distributed MME, disequilibrium phenocryst assemblages and textures of host rocks and enclaves suggest complex open-system processes, mainly magma-mingling and -mixing between a basaltic magma and a silicic one.Geochemical data show a mixing evolution trend from a basaltic composition similar to those of the MME (possible mafic end member) to a silicic composition similar to those of the dacite granophyric groundmass in equilibrium with sodic plagioclase, quartz, biotite and sanidine (possible silicic end member). A multistage magmatic evolution related to multiple replenishment events with hot basaltic magma in a evolved and probably zoned magma chamber, or more likely in a shallow level silicic reservoir, could be invoked in the genesis of the Laleaua Albă magmatic rocks. The andesite envelope represents a hybrid product from a first mingling and mainly mixing stage between the mafic magma corresponding to MME (storage and crystallization at as much as 18-25 km based on Al-in-hornblende and amphibole-plagioclase barometers) and silicic magma. The sanidine dacite formed from a second silicic and more alkalic magma batch during a further mingling stage with MME components.Multistage and complex evolution in the open-magmatic system constrained also by the composition and texture of the MME.

The mineralogical and geochemical similarities between the MME and the Firiza basalts (small basaltic dykes of 8.1-7.0 Ma from the vicinity) suggest the involvement of that basaltic magma as the mafic end member in the multistage magma-mingling and -mixing processes responsible for the genesis of the Laleaua Albă igneous rocks.

Geochemical and isotopic studies of mafic-ultramafic complex, NE Vietnam

Lan, C.Y.[1*], Tri, T.V.[2], Tran, T.A.[3], Usuki, T.[1] & Yang, T.F.[4]
[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan ([*]kyanite@earth.sinica.edu.tw)
[2]Vietnam National Committee for IGCP, Hanoi, Vietnam
[3]Institute of Geological Sciences, Vietnamese Academy of Science and Technology, Hanoi, Vietnam
[4]Dept. of Geosciences, National Taiwan University, Taipei, Taiwan

Mafic-ultramafic complexes outcrop along the Song Lo in NE Vietnam. They occur as blocks in the mélange with groundmass being metamorphosed fine-grained turbidites of lower Paleozoic age. They consist of serpentinite, amphibole gabbro and basalt. The serpentinites show high degree of serpentinization (LOI 11.8-13.8%) and have low SiO_2 (39.8-40.6%), TiO_2 (0.05-0.09%), Al_2O_3 (1.5-2.2%), TFe_2O_3 (7.8-10.5%) and CaO (0.1-1.1%) but high MgO (34.3-37.3%) and $Mg^{\#}$ value (87-9090). Chondrite-normalized REE patterns are U-shaped. They are characterized by high compatible elements of Cr (2439-5781 ppm), Ni (1184-3240 ppm) and Co (120-156 ppm). The amphibole gabbros and basalts are all basaltic in composition with silica contents ranging from 43.3 to 51.1 %. Magnesium content is moderate (6.0-7.8%) and $Mg^{\#}$ value range from 43 to 64. On the discrimination diagrams, basaltic rocks fall in the fields of N-MORB+IAB and WPA in the Zr/Y vs Zr diagram and ternary plots of Ti/100-Zr-3Y and 2Nb-Zr/4-Y. Chondrite-normalized REE patterns are different and show slightly LREE-depleted ($(La/Yb)_N$=0.8-0.9) and LREE-enriched ($(La/Yb)_N$=1.9-11.9), respectively. In the trace-element spidergram, the N-MORB+IAB rocks display slightly negative Nb, Ta and Ti anomalies suggesting the presence of a subduction component. Some WPA basaltic rocks exhibit significantly higher TiO_2 content (2.8-3.4%) when compared with other basaltic rocks (1.1-1.8%). The present εNd and Sr isotopic compositions are +6.2 to +9.1 and 0.70471 to 0.70571 for N-MORB+IAB and -2.9 to +7.5 and 0.70412 to 0.70653 for WPA rocks. The coexistence of serpentinite and N-MORB+IAB and OIB basaltic rocks suggests that the mafic-ultramafic complex represents a remnant of Paleo-Tethys in NE Vietnam.

Granitic pegmatites from the Banabuiú region (Central Ceará Domain, NE Brasil)

Lima, M.N.[1*], Azevedo, M.R.[1], Nogueira Neto, J.A.[2] & Valle Aguado, B.[1]
[1]GeoBioTec, Dept. of Geosciences, University of Aveiro, Aveiro, Portugal ([*]marthageolima@yahoo.com.br)
[2]Dept. of Geology, Federal University of Ceará, Brazil

The Banabuiú pegmatites intrude both a syn-collisional S-type granite pluton emplaced at around 580 Ma and basement rocks of Paleoproterozoic age, extensively transformed into gneisses and migmatites during the Brazilian/Pan-African orogeny (≈ 600 Ma). Most of the pegmatites bodies associated with the granite are barren, homogeneous and occur as fracture-filling dykes and veins, less than 1 m thick. Their main mineralogical assemblage consists of quartz + K-feldspar + albite + muscovite + tourmaline ± garnet.

In contrast, the basement pegmatites range from homogeneous to heterogeneously zoned, show conformable to cross-cutting relationships with the country rocks and vary from barren to transitional (beryl- and beryl-columbite–tantalite-phosphate types) to complex pegmatites (albite + K-feldspar + quartz + muscovite + lepidolite ± columbite – tantalite ± spodumene). Tourmaline is present in all pegmatite types. The development of a zonal sequence from the granite outwards appears to reflect a continuous fractionation trend, extending from the least evolved granite facies to the most geochemically specialized pegmatites.

Petrographic and mineral chemical data for feldspars and muscovites from two heterogeneously zoned pegmatites from the Banabuiú region show that: (1) K-feldspar ($Or_{90}Ab_{10}$ – $Or_{94}Ab_{06}$) is a major rock-forming mineral in these pegmatites, occurring mainly as large, euhedral to subhedral megacrysts in blocky K-feldspar zones. However, much of this phase was converted to sacchroidal albite and cleavelandite by late-stage sodium metasomatism; (2) Plagioclase is present as a fine-grained sacchroidal textured type or as platy to acicular cleavelandite crystals. Both varieties display nearly pure albite compositions ($Ab_{98.2}$ – $Ab_{99.5}$); (3) Muscovite can have primary or secondary origin. The former is light brown to silvery coloured and occurs as coarse books, whereas secondary muscovite is generally associated with albitized zones either after blocky K-feldspar or in beaded quartz texture or as fracture coatings. As seen in the M^{2+}-Al-Si ternary plot of Monier and Robert (1986) [1], they exhibit close to end-member compositions with minor Fe (< 2.3 wt. % FeO) and Na (< 0.3 wt % Na_2O), suggesting high temperature equilibration (≈ 600° C) (Fig. 1).

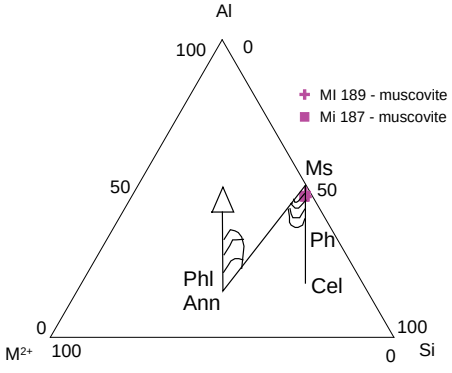

Fig. 1: Electron microprobe muscovite analysis plotted in the ternary diagram of [1]. Cel- celadonite; Ph-phengite; Ms-muscovite; Ann-annite; Phl- phologopite.

Magmatic lithic clasts of ignimbrite as messengers of the magma reservoir: a study from the Bükkalja Volcanic Field (Hungary)

Lukács, R.[1*], Harangi, Sz.[1] & Ntaflos, T.[2]
[1]Dept. of Petrology and Geochemistry, Eötvös University, Budapest, Hungary ([*]lrekuska@freemail.hu)
[2]Inst. of Lithosphere Studies, University of Vienna, Austria

Lithic clasts are accidental or accessory components of pyroclastic flow deposits. They represent rock fragments picked up by the pyroclastic flow accidentally from the surface or they derived from the basement torn down by the uprising magma. Magmatic accessory lithic clasts either derived from the magma reservoir or from the wall rock of the vent area. In the former case the magmatic lithic clasts are messengers of the magma reservoir, and their study can help us to understand the pre-eruptive petrogenetic processes.

In the Bükkalja Volcanic Field, Szomolya locality exhibits a lithic clast rich (up to 15vol %) rhyolitic ignimbrite. 90% of the lithic clasts are magmatic and they are mainly andesites, subordinately rhyolites. The bulk rock geochemistry ($^{87}Sr/^{86}Sr$ isotope, and main and trace element data) of the andesite lithic clasts and pumices of the ignimbrite suggests their genetic relationship. The andesite lithic clasts have fresh or variably devitrified rhyolitic matrix glass. Based on their mineral assemblage at least three lithic types can be recognised. The main mineral phases in each group are plagioclase and orthopyroxene accompanied by clinopyroxene or/and amphibole or/and biotite. Textures of the matrix glass and the phenocrysts suggest rapid quenching of the interstitial melt. The detailed textural investigations combined with in-situ microprobe and La-ICP-MS analyses of the andesite lithic clasts are consistent with a crystal-mush origin, i.e. they represent different parts of the complex crystal-mush zone of the magma reservoir generating the ignimbrite.

The high Mg-orthopyroxenes and high Ca-plagioclases of lithic clasts (Fig. 1) imply the role of mantle derived basaltic magmas in the petrogenesis of the ignimbrite. The mineral geochemical data revealed that the mineral assemblage is not in equilibrium. They were formed from different magmas at different stages of magma evolution. The mineral phases of the andesite lithic clasts are in fact antecrysts and overall they do not represent a true andesitic magma, but rather a mixture of crystals crystallized from basaltic and dacitic/rhyolitic magmas. The distinct origin of the mineral phases suggests that they were mobilised from different parts of the crystal-mush zone probably as a result of an intrusion of fresh magma in the magma reservoir.

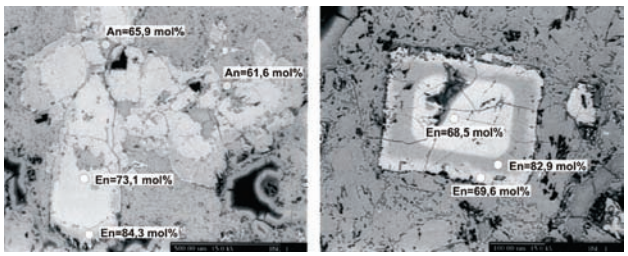

Fig. 1: BSE images of an orthopyroxene-plagioclase cumulate (left) and an oscillatory zoned othopyroxene (right) of an andesite lithic clast. The compositions of different zones are marked with the enstatite (En) or anorthite (An) contents of orthopyroxene and plagioclase, respectively.

The presence of two mutually immiscible melts during the late-stage crystallization of the Kymi topaz granite stock, Finland: evidence from melt and fluid inclusions

Lukkari, S.[1*] & Thomas, R.[2]
[1]Dept. of Geosciences and Geography, University of Helsinki, Finland ([*]sari.lukkari@helsinki.fi)
[2]GeoForschungsZentrum, Potsdam, Germany

The crystallization of the late-stage, F-enriched Kymi topaz granite stock has been investigated by remelting and analyzing crystallized melt inclusions as well as fluid inclusions in quartz and topaz grains from porphyritic and equigranular topaz granites and marginal pegmatite. The melt inclusion compositions show that the topaz granites and the stocksheider pegmatite of the Kymi stock crystallized from very F and H_2O-rich melts (up to 14 wt % F and 29 wt% H_2O), and that Li and B were present in the granitic melt at high concentrations [1].

Previous melt inclusion studies on other granite-pegmatite complexes (Ehrenfriedersdorf, Zinnwald, Königshain) have demonstrated that a late-stage liquid immiscibility and a formation of two separate melt fractions were crucial for the formation of these pegmatites [2]. Although the melt inclusions in this study show only peraluminous compositions, and isolated and preserved peralkaline pegmatite patches are not found in the Kymi stock, the melt and fluid inclusions contain evidences for two mutually immiscible melts, one of these being relatively H_2O- and alkali-poor and the other extremely H_2O- and alkali-rich. Quartz from the granites and pegmatite contains two coexisting melt inclusion types, varying in vapour content. Quartz from the equigranular granite contains also melt inclusions composed of two coexisting silicate glasses, one of which contains chiolithe ($Na_5Al_3F_{14}$) (Fig. 1). The observed chiolithe in the silicate glass nodules of the melt inclusions as well as cryolite (Na_3AlF_6) and $LiAlF_4$ daughter minerals from equigranular granite and zabuyelite (Li_2CO_3) daughter mineral in fluid inclusions in topaz from pegmatite are remnants of the peralkaline character of the melt and mineral-forming fluid.

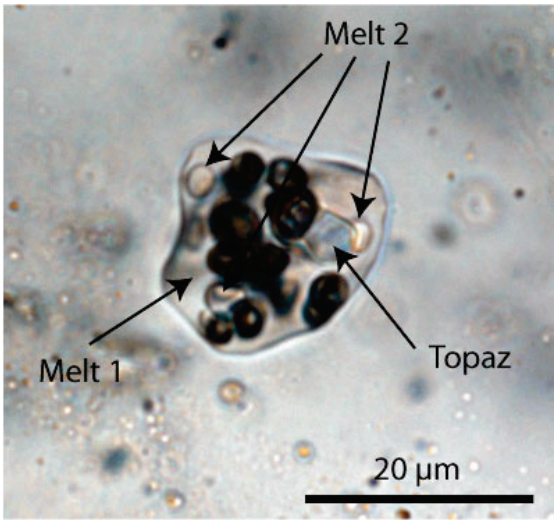

Fig. 1: A melt inclusion in quartz from the equigranular granite composed of two coexisting silicate glasses, topaz daughter crystals and several vapor bubbles after homogenization at 700 °C, 300 MPa and 24 h. The small glass nodules are H_2O-, F- rich silicate glass showing remnants of chiolithe ($Na_5Al_3F_{14}$).

Metasomatic titanates associated with Cl-rich amphibole and phlogopite in a multiply metasomatized garnet lherzolite from Letseng-la-Terae, Lesotho

Mair, P.[1*], Konzett, J.[1] & Hauzenberger, Ch.[2]
[1]Institute of Mineralogy, University of Innsbruck, Austria
([*]P.Mair@uibk.ac.at)
[2]Institute of Earth Sciences, University of Graz, Austria

The Letseng-la-Terae diamondiferous kimberlite contains a complex suite of upper mantle peridotites and pyroxenites, some of which showing evidence for multi-stage metasomatism [1]. Here we present major and trace element data on a garnet-lherzolite containing an unusually complex suite of Cr-rich oxides consisting of crichtonite + armalcolite + ilmenite + chromite + rutile which have formed by two different metasomatic events. Crichtonite is present as tiny (<10 µm) inclusions in Cr-rich clinopyroxenes which form a narrow vein crosscutting the lherzolite. Unlike almost all crichtonites from other Kaapvaal craton localities [2] which are mostly lindsleyite-mathiasite solid solutions, those from the present study are virtually free of K and Ba but rich in LREE (1.6-1.7 wt% Ce_2O_3, 2.4-3.0 wt% La_2O_3), U, and Th (~0.6 wt% UO_2 and 0.4 wt% ThO_2) indicating significant loveringite and davidite components. The crichtonites are associated with inclusions of Cr-rich spinel and Cr-Zr-rich rutile (0.7-1.6 wt% Cr_2O_3, 0.3-0.4 wt% ZrO_2) calcic amphibole and phlogopite. Both phlogopite and pargasitic calcic amphibole are unusually Cl-rich with up to 0.25 wt% Cl in amphibole und up to 0.4 wt% Cl in phlogopite. Phlogopite and Cr-rich spinel is also present as large matrix grains several hundred microns in diameter. The crichtonite-rutile-amphibole-phlogopite association is thought to have formed by infiltration of a hydrous fluid rich in K-REE-U-Th and Cl. A second metasomatic event most likely involving a hydrous melt caused (1) a partial to complete pseudomorphic replacement of garnet by Al-rich spinel + clinopyroxene + orthopyroxene; (2) replacement of Cl-rich phlogopite-I by F-Ti-Fe-rich and Cl-poor phlogopite-II containing up to 1.0 wt% F and 9.9 wt% TiO_2; (3) modification of the composition of primary clinopyroxene and orthopyroxene along a network of narrow veins to produce Na-Al-poor clinoyproxene and Ca-Al-rich orthopyroxene and (4) formation of Cr-rich armalcolite and ilmenite associated with Na-Al-poor clinoyproxene. The composition of the armalcolite is very similar to that reported from metasomatic xenoliths of the Kimberley area [2]. The application of various geothermobarometers involving major- and trace element exchange between the primary lherzolite phases yields consistent P-T conditions of ~850°C and ~3 GPa. These are significantly lower than conditions of 1100°C and 4.5 GPa reported for other garnet-lherzolites from Letseng affected by multi-stage metasomatism [1] and indicate a considerable depth interval over which metasomatism affected the Kaapvaal lithosphere in the Lesotho area. The xenolith of this study also provides rare evidence for the presence of significant amounts of Cl in hydrous metasomatizing fluids of the shallow Kaapvaal lithosphere.

Plagioclase phenocrysts and their alteration in rhyodacitic porphyries from Zalas near Cracow (Poland)

Marszałek, M[*] & Czerny, J.
Dept. of Mineralogy, Petrography and Geochemistry, AGH-University of Science and Technology, Krakow, Poland
([*]mmarszal@agh.edu.pl)

The Upper Palaeozoic porphyries of Zalas form a classic laccolith 3-4 km long. These rocks were subjected to complex postmagmatic alterations, expressed mainly in their enrichment in potassium [1,2]. Plagioclase phenocrysts occurring in five colour varieties of the porphyries (black, grey, green, red and white) have been studied. Analyses included SEM, EDS, WDS, XRPD.

The tabular plagioclase phenocrysts with sizes from a fraction of mm to 8 mm make up fifteen or so vol.% of the rocks. They reveal complex, mainly albite and Carlsbad and less frequent pericline twinning; zoning is common. In the smaller crystals zoning is normal, in bigger ones it is recurrent, usually 2-3-fold, with a narrow, inversion outer zone. The chemistry of plagioclases varies from An_{52} to An_{21}, being most often between An_{40} and An_{30}.

The degree of alteration of the plagioclase phenocrysts is variable. In the black variety they are generally fresh, in the grey one only some grains are slightly altered. In the green and red porphyries the phenocrysts are mostly replaced by secondary minerals, and in the white ones only pseudomorphs after plagioclases occur, a few of them with relics of the original feldspar.

The phenocrysts studied were subjected to two types of alterations, usually overlapping. Replacing of plagioclases by secondary minerals is one of them, the other includes leaching of the phenocrysts with subsequent filling empty spaces with the minerals crystallizing from hydrothermal solutions. In metasomatic changes plagioclases are replaced first by albite and next by adular (albitization directly preceded adularization). These alterations are developed along the network of irregular, small veins and concentrate in the form of nests. They are accompanied in places by aggregates of calcite and clays (close to illite). Hydrotherma precipitation has resulted in adular with characteristic rhombohedral habit, rosettes of chlorite overgrown by illite, and occassional quartz. In the white porphyries, pseudomorphs after plagioclases are composed of adular and kaolinite (+/- calcite) with subordinate albite and illite; celadonite instead of chlorite is the clay mineral in the leached out spaces of these phenocrysts.

New insights into the significance of gneisses and tourmalinites in the Nevado-Filabride complex (western Sierra Nevada, Spain), from U-Pb zircon and $^{40}Ar/^{39}Ar$ tourmaline geochronology: geological implications

Martínez-Martínez, J.M.[1], Torres-Ruiz, J.[2], Pesquera, A.[3*] & Gil-Crespo, P.P.[3]
[1]Depto. de Geodinámica e Instituto Andaluz de Ciencias de la Tierra (IACT) , Facultad de Ciencias, Universidad de Granada, Granada, Spain ([*]alfonso.pesquera@ehu.es)
[2]Depto. de Mineralogía y Petrología, Facultad de Ciencias, Universidad de Granada, Granada, Spain
[3]Depto. de Mineralogía y Petrología, Universidad del País Vasco, Bilbao, Spain

The Nevado-Filabride complex, the lowest one in the Betic hinterland, forms a stack of Alpine nappes. The tectonic units consist of metasedimentary sequences whose ages are not well constrained. Gneiss bodies included in the sequences have been one of the few sources of geochronological data in this metamorphic complex. New radiometric data from U-Pb zircon dating on gneisses from the western Sierra Nevada confirm the presence of upper Carboniferous intrusive rocks in the Betic hinterland. These results, combined with available data from the literature and a detailed structural analysis, suggest that the gneisses represent an only late Hercynian magmatic event. Evidence for a close genetic relation between gneisses and tourmalinites is provided by field and petrographic observations, in conjunction with U-Pb zircon (314 ± 7 and 304 ± 23 Ma) and ^{40}Ar-^{39}Ar tourmaline dating (319.85 ± 5.81 and 317.85 ± 3.67 Ma). A pre-upper Carboniferous age for the basal formation of the Nevado-Filabride sequence can be inferred. The gneiss protolith and the graphite schist are considered to be the boron source and the precursor of the tourmalinites, respectively. Superposed tectonically units rather than a continuous Palaeozoic sequence is supported by the occurrence of Palaeozoic rocks at the top of the Nevado-Filabride complex. The nappe tectonics, as evidenced from the contractive character of the unit boundaries and the superposition of more on less metamorphic rocks, is additionally supported by the older on younger rocks superposition.

Olivine and clinopyroxene in tholeiites as indicators of ocean magmas origin

Migdisova, N.A.[*], Sushchevskaya, N.M., Sobolev, A.V. & Kuzmin, D.
Institute for Geochemistry and Analytical Chemistry RAS, Moscow, Russia ([*]nat-mig@yandex.ru)

A study of clinopyroxene and olivine phenocrysts from the basalts of complex geodynamic setting of the Southern Ocean provided insight into the specific conditions of magma formation and origin. The new results on primary melts are reported.

The region of investigation is situated at the western end of the Southwest Indian Ridge (SWIR) near the Bouvet triple junction (BTJ). The Bouvet Triple Junction (BTJ) consists of three main structures of the oceanic floor: Mid Atlantic Ridge (MAR), American Antarctic Ridge (AAR) and Southwest Indian Ridge (SWIR). These three oceanic ridges which constitute the BTJ have been changing their positions in the space and time relatively each other. Clinopyroxene and olivine phenocrysts were separated from the basalts of two SWIR segments: directly opposite Bouvet Island and in the Spiess Ridge, which is the westernmost part of the SWIR. The most abundant basalts of these segments are oceanic tholeiites enriched in lithophile elements and radiogenic isotopes. The basalts of both segments are similar in the character of enrichment. The Spiess Ridge is the largest structure of the Bouvet triple junction. Morphologically it is a large volcanic rise oriented at a low angle to the structures of the Mid-Atlantic Ridge (MAR).

Numerical modeling based on the dependency of clinopyroxene composition on pressure and temperature of crystallization allowed us to estimate the depth of melt fractionation in transitional magma chambers. The pressures of magma fractionating are supposed to be from 1 to 5 kbar defining the level of transit chamber under the ridge.

Ni excess over Mg and Mn deficiency over Fe in olivine phenocrysts suggest the presence of olivine-free pyroxenite lithologies in the sources of primary melts. The lowest amounts of pyroxenite component (X_{PX} Mn/Fe = 0-10%) were recorded for the samples from the station S18-63, located in the MAR valley. The greatest range (X_{PX} Mn/Fe = 0-90% in the single rock) was observed in samples from the station G96-10 situated on the western slope of the Spiess Ridge. Obtained results suggest the participation of recycled crustal component in the generation of primary melts.

BTJ isotopic signatures (Sr, Nd, Pb) and trace element patterns are similar to those in the alkaline basalts of Antarctic Peninsula. These features imply melting of enriched constituent in the mantle source common to the western Antarctica and SWIR. The long-term enrichment of mantle is seen in the more radiogenic Pb and Sr and less radiogenic Nd of basalts. It likely indicates contamination by oceanic crust. Such global mantle heterogeneities could have been formed during various and complicated stages of South Ocean geodynamic evolution.

Mineral chemistry of Kamtal Skarn (Eastern Azarbaijan, NW Iran)

Mokhtari, M.A.A.[1*], Moinvaziri, H.[1], Ghorbani, M.R[1], Mehrpartou, M.[2], Padashi, S.M.[3] & Baburek, J.[4]
[1]School of Science, Tarbiat Modares University, Tehran, Iran
([*]mokhtari1031@gmail.com)
[2]Geosciences Research Center, Geological Survey of Iran, Tehran, Iran
[3]Geological Survey of Iran, Tehran, Iran
[4]Czech Geological Survey, Prague, Czech Republic

Kamtal intrusion is a part of Qaradagh batholith. This batholith with an area more than 1500 km^2, crops out in NW of Iran and republics of Azerbaijan and Armenia. Kamtal intrusion with an area about 25 km^2, is located in southwestern part of Qaradagh batholith in eastern Azarbaijan province, NW of Iran, near the Armenia border.

Compositionally, this intrusion consists of monzogranite, quartz- monzonite and gabbro [1]. Kamtal intrusion is intruded into Cretaceous flysch type rocks. This intrusion leads to formation a wide contact aureole (Kamtal skarn) around the Kamtal body. These rocks characterized by garnet, clinopyroxene and calcite [1]. Epidote, actinolite, quartz and albite are the accessory minerals.

Garnets are the more abundant mineral in these rocks. Many part of skarn aureole have very high concentration of garnet (more than 90%), therefore we can call these rocks as garnetite. Main parts of garnets have grossularitic composition (Ad_{33-35}). Along the fractures, andraditic compositions (Ad_{71-73}) become dominant component. The rims of garnets have intermediate composition between andradite and grossularite ($Ad_{53-55.5}$). Overall, the EPMA data show that the garnets are mainly andraditic–grossularitic (grandite) with negligible amounts of the almandine and spesartine component, varying slightly in composition as follows:

$Na_{(0-0.01)}Ca_{(2.73-3.06)}Mg_{(0.002-0.03)}Fe^{2+}_{(0.05-0.64)}Fe^{3+}_{(0.32-1.57)}Mn_{(0.02-0.1)}Al_{(0.002-0.22)}Ti_{(0.001-0.13)}Si_{(2.78-3)}O_{12}$

Clinopyroxene is common mineral after garnet. Its frequency rarely reaches to 50%. EPMA data from clinopyroxenes indicate that they are mainly salite, and belong compositionally to the hedebergite-diopside series ($Di_{74.5-99.8}$). The rims of clinopyroxenes have more diopsidic component. Johannsenite component have negligible amounts. Overall, clinopyroxenes varying slightly in composition as follows:

$Na_{(0.005-0.024)}Ca_{(0.98-1.03)}Mg_{(0.63-0.9)}Fe^{2+}_{(0.025-0.23)}Fe^{3+}_{(0-0.11)}Mn_{(0.01-0.055)}Al_{(0.002-0.11)}Si_{(1.89-2.04)}O_6$

On the basis of EPMA data, it's concluded that early formed crystals of garnets have high grossularitic component (rich in Ca). This is because of concentration of Ca in marbles. By progressing of metamorphic reactions and consuming of Ca in the structure of early formed garnets, the rim of these crystals and fractures have low grossularitic component (poor in Ca) and high andraditic component (rich in Fe).

Discovery of meta-komatiites in the Archaean high-grade polymetamorphic Central Zone of the Limpopo belt, South Africa: remnants of oceanic crust and evidence of cryptic suture?

Mouri, H.[1*], Maier, W.[2], Andreoli, M.[3], Brandl, G.[4] & Rebay, G.[5]
[1]Dept. of Geology, University of Johannesburg, South Africa
([*]hmouri@uj.ac.za)
[2]Dept. of Geology, University of Oulu, Finland
[3]Nuclear Energy Corporation of South Africa, South Africa
[4]Council for Geoscience, Limpopo Unit, Polokwane, South Africa
[5]Dept of Geology, University of Pavia, Italy

Komatiites have been described from many Archaean greenstone belts where they were subjected to greenschist and upper amphibolite facies metamorphic conditions. So far, komatiites have not been reported from high to ultra-high metamorphic grade environments (upper granulite facies conditions). Here we report the discovery of komatiites in the Archaean high to ultra-high grade polymetamorphic terrain of the Central Zone of the Limpopo Belt in South Africa. These rocks have relatively high MgO (26-31%), Cr (2800-3800 ppm) and Ni (1400-1800 ppm), but low SiO_2 (41-46%) and Al_2O_3 (5-7%). These geochemical characteristics, including the unfractionated Rare Earth Element (REE) and the platinum group element (PGE) patterns, are most consistent with late Archaean or Proterozoic aluminum (Al)-undepleted Munro-type komatiites.

Thermodynamic calculations combining classical conventional methods as well as modern techniques such as THERMOCALC, in conjunction with textural relationship and mineral chemistry, indicate that the studied rocks went through upper granulite facies metamorphic conditions reaching a temperature of up to 900°C and an intermediate pressure of up to 10 kbar.

Although the emplacement age of the komatiitic rocks is not yet known, geochemical evidence such as PGE concentrations seem to be consistent with a late Archaean or early Proterozoic age [1].

The discovered rocks might add important insight into our understanding regarding the geological evolution of the Limpopo Belt. According to Light [2] the Kaapvaal and Zimbabwe Cratons may have been separated by a distance of more than 1000 km of oceanic crust before 3350 Ma. This author suggested that the collision between the two cratons was initiated during Palaeo-archaean times (3350Ma) and terminated in the late Neo-archaean (2500Ma). Since komatiites can be potential candidates for Archaean oceanic crust [3], the rocks studied here might represent an ophiolitic remnant of obducted oceanic crust indicating the presence of a hidden suture zone in the Central Zone of the Limpopo Belt.

Geochemistry and petrology of mantle xenoliths from Poiana Ruscă (W Romania)

Nédli, Zs.[1*], Princivalle, F.[2] & Szabó, Cs.[1]
[1]Lithosphere Fluid Research Lab, Dept. of Petrology and Geochemistry, Eötvös University Budapest, Hungary
([*]nedlizs@yahoo.com)
[2]Dept. of Earth Sciences, University of Trieste, Italy

Recently collected mantle xenoliths from Late Cretaceous - Paleogene alkali basic rocks from the Poiana Ruscă (W Romania) show new petrologic and thermobarometrical aspects of the pre-Neogene subcontinental lithospheric mantle. The xenoliths widely vary among wehrlite, lherzolite and olivine websterite in composition. The most distinctive feature of the modal composition is the high variability in orthopyroxene content (1-45 vol%). Texturally 2 main groups can be distinguished: transitional porphyroclastic-equigranular texture and poikilitic texture xenoliths.

Clinopyroxene has high Al_2O_3 (6-7 wt%) and Na_2O (1.5-2 wt%) content. Spinel is always Al-rich, cr# are low (0.08-0.18). Mg# of pyroxenes varies between 0.89-0.91. The major element chemical composition of minerals shows rather fertile composition and low degree of basaltic melt extraction. Apart from different textures and modal composition, clinopyroxenes generally have enrichment in REE content approx. 10x relative to the chondrite, showing rather flat patterns (Fig. 1). Slight LREE-depletion is typical as a result of basaltic component extraction. Some samples are different with steeply downward REE patterns and in a few samples with notable LREE enrichment.

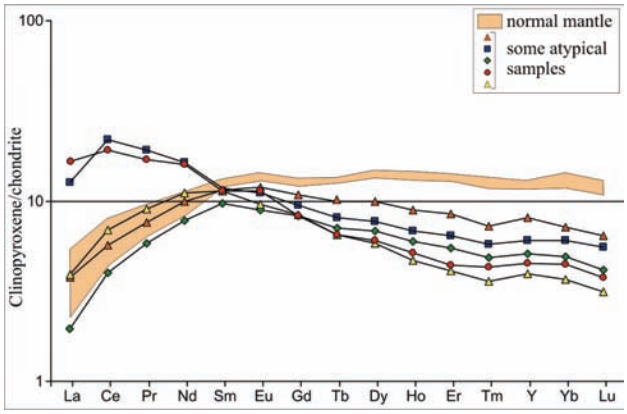

Fig. 1: Chondrite normalized REE diagram for Poiana Ruscă xenolith clinopyroxenes.

Clinopyroxene single crystal X-ray diffraction measurements show low cell (432.9-433.6 $Å^3$) and M1, M2 site volumes. Their structural data are similar to those from garnet-bearing lherzolites worldwide therefore we suggest that they can be equilibrated at high depths near to garnet stability field. Thermometry indicates a homogeneous equilibrium temperature between 950-1010°C.

Chemistry and textural evidences suggest that the mantle might have undergone interaction with a Si-rich melt. Such a metasomatic agent is different from any metasomatism described previously from orthopyroxene-rich xenoliths from the Carpathian-Pannonian Region (e.g. [1]) and from the Dacia block (e.g. [2]) and show a particular metasomatism without significant incompatible element enrichment.

Mineralogical composition of Kamtal intrusion (Eastern Azarbaijan, NW Iran)

Padashi, S.M.[1], Mokhtari, M.A.A.[1,2], Moinvaziri, H.[2], Ghorbani, M.R.[2], Mehrpartou, M.[3], Abedian, N.[1] & Baburek, J.[4]
[1]Geological Survey of Iran, Tehran, Iran
([*]sm_padashi@yahoo.com)
[2]Iran School of Science, Tarbiat Modares University, Tehran, Iran
[3]Geosciences Research center, Geological Survey of Iran, Tehran, Iran
[4]Czech Geological survey, Prague, Czech Republic

Kamtal intrusion is a part of Qaradagh batholith. This batholith with an area more than 1500 km^2, crops out in NW of Iran and republics of Azerbaijan and Armenia. Kamtal intrusion, with an area about 25 km^2, is located in southwestern part of Qaradagh batholith in eastern Azarbaijan province, NW of Iran, near the Iranian-Armenian border.

Compositionally, this intrusion consists of monzogranite, quartz- monzonite and gabbro. Gabbros can be seen as small lenses within the quartz- monzonite. Quartz- monzonites have been intruded by the monzogranite. Both monzogranites and quartz- monzonites are high-K calk alkaline and metaluminous in character and can be classified as I-type granitoids, while the gabbros have tholeiitic nature [1].

Electron-probe micro-analysis (EPMA) was used for determining the composition of some silicate minerals, such as pyroxenes, amphiboles, plagioclases and olivine. These analyses were carried out at Czech geological survey.

Monzogranites outcrop as a small stock. They are microgranular in texture and characterized by quartz, alkali feldspar, plagioclase (An28-30) with some hornblende (magnesio- hornblende) and biotite.

Quartz- monzonites form the main part of the Kamtal intrusion. They are coarse grained and light gray to dark gray in color. They are characterized by alkali feldspar, plagioclase (An29-39), quartz, Hornblende (magnesio- hornblende), biotite (composition between annite and phlogopite) and clinopyroxene (augite). Titanite, apatite, magnetite, rutile and zircon are the accessory phases and epidote, actinolite, chlorite and sericite are the secondary minerals.

Gabbros are coarse grained and dark in color. They have gradational contact with quartz- monzonite. Gabbros characterized by plagioclase (An50-79), clinopyroxene (diopside) and Amphibole (magnesio- hastingsite). Most of the clinopyroxenes have been altered to actinolite. Biotite present as a minor phase in these rocks that mainly altered to chlorite. Olivine present in some samples that has chrysolite composition. Magnetite is a frequent minor phase in these rocks. In some samples, xenomorphic magnetite (wormy shape) can be seen in the groundmass of other minerals. This indicates that magnetite crystallized at end of crystallization. Also, in some samples, wormy shape magnetite aggregation present with small crystals of plagioclase and clinopyroxene. These aggregations may be result of immiscibility.

Mineralogy of nepheline syenite dykes from the Ditrău Alkaline Massif, Romania

Pál-Molnár, E.*, Ódri, Á. & Batki, A.
Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Szeged, Hungary (*palm@geo.u-szeged.hu)

The Ditrău Alkaline Massif (DAM) is a Mesozoic alkaline igneous complex situated in the S-SW part of the Giurgeu Alps belonging to the Eastern Carpathians (Romania). It outcrops right east of the Neogene-Quaternary Călimani-Gurghiu-Harghita calc-alkali volcanic belt by breaking through the pre-Alpine metamorphic rocks of the Bukovina Nappe. According to our present knowledge, the DAM is an intrusive rock body with an eastern, north eastern tilt, built up by several tectonic blocks providing the massif a complex form. Great number of different rock types appears on the surface (ultrabasites, gabbros, diorites, monzonites, syenites, nepheline syenites, granites, lamprophyres, etc.). Based on K/Ar data [1] originating from various mineral fractions of different rock types has shown that the DAM is the result of a long lasting (Middle Triassic – Lower Cretaceous) two phase magmatic process, which started during the Triassic by the opening up of the Tethys and the detachment of the Getida-Bukovina Microplate from the Eurasian Plate.

Nepheline syenite aplites (tinguaites) are very rare in the DAM, form thin dykes and are in connection with white nepheline syenites which they are also chemically related to [2]. Nepheline syenite dykes chemically belong to the group of foidsyenites however by their texture they are determined as tinguaites [3]. This paper reports new results on the mineralogy of the nepheline syenite dykes which were not discussed yet in former works of the DAM.

Mineral chemistry analyses were determined by Cameca SX-50 elecron microprobe at the Department of Earth Sciences, University of Uppsala, Sweden. Operating conditions were probe current of 15 nA and acceleration voltage of 20 kV.

Nepheline syenite dykes are light grey coloured rocks of small grain size with a porphyric texture. Both groundmass minerals and the phenocrysts are hipidiomorphic to xenomorphic. The phenocrysts of tinguaites are andradite-grossular $[Ca_3Fe^{3+}_{1-1.4}Al_{0.5}(Al_{0.1}Si_{2.9}O_4)_3]$, aluminian sodian ferroan diopside $[Ca_{0.9}Na_{0.1}Mg_{0.5}Fe^{2+}_{0.1}Fe^{3+}_{0.2}(Al_{0.2}Si_{1.8}O_6)]$ and aegirine-augite $[Ca_{0.4}Na_{0.6}Mg_{0.1}Fe^{2+}_{0.3}Fe^{3+}_{0.5}(Al_{0.1}Si_{1.9}O_6)]$. Based on Ti- and Al-content of the pyroxenes the diopsides crystallised under high pressure, while the aegirin-augites formed under low pressure. The groundmass minerals are eckermannite $[Na_{2.8-3.5}Fe^{2+}_{3-3.5}Mg_{0.3-0.7}Al_{0.3-0.4}(Si_8O_{22})(OH)]$, albite ($Ab_{98-99}$), orthoclase and muscovite. Accessories are titanite, zircon and magnetite. Secondary minerals are annite-phlogopite (mg#=0.57-0.76), chlorite, epidote, calcite and sericite.

The mineral composition of nepheline syenite dykes occurring in the DAM confirms their alkali character and largely contributes to the understanding of their petrogenesis.

Mineralogy of syenites from the Ditrău Alkaline Massif, Romania

Pál-Molnár, E.[1*], Sogrik, E.[1], Batki, A.[1] & Dobosi, G.[2]
[1]Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Szeged, Hungary (*palm@geo.u-szeged.hu)
[2]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary

The Ditrău Alkaline Massif (DAM) is a Mesozoic alkaline igneous complex situated in the S-SW part of the Giurgeu Alps belonging to the Eastern Carpathians (Romania). It outcrops right east of the Neogene-Quaternary Călimani-Gurghiu-Harghita calc-alkali volcanic belt by breaking through the pre-Alpine metamorphic rocks of the Bukovina Nappe. According to our present knowledge, the DAM is an intrusive rock body with an eastern, north eastern tilt, built up by several tectonic blocks providing the massif a complex form. Great number of different rock types appears on the surface (ultrabasites, gabbros, diorites, monzonites, syenites, nepheline syenites, granites, lamprophyres, etc.). Based on K/Ar data [1] originating from various mineral fractions of different rock types has shown that the DAM is the result of a long lasting (Middle Triassic – Lower Cretaceous) two phase magmatic process, which started during the Triassic by the opening up of the Tethys and the detachment of the Getida-Bukovina Microplate from the Eurasian Plate.

The S-SW part of the DAM is formed mainly by syenites. There are several hypotheses on their genesis [2-4] but it is still not complete and clearly understood. We present new results on the mineralogy of the syenites which can contribute to a better understanding of their origin.

Mineral chemistry analyses were determined by JEOL JCXA-733 electron microprobe equipped with WDS and EDS at the Geochemical Research Institute of Hungarian Academy of Sciences, Budapest.

The syenites are holocrystalline, hypidiomorphic and medium-grained (1.9-3.5 mm). The main rock forming minerals are K-feldspar, amphibole, biotite and subordinately plagioclase. The amphiboles are Ca-amphiboles, hastingsite $[Na_{0,7-1,2}K_{0,3-0,4}Ca_{1,6-1,8}Fe^{2+}_{2,1-2,8}Fe^{3+}_{0,2-0,9}Mg_{1,2-2,0}Mn_{0,1-0,2}Al_{0-0,3}(Al_{1,8-2,2}Si_{5,8-6,2}O_{23})]$, pargasite $[Na_{0,8}K_{0,3}Ca_{1,8}Fe^{2+}_{2,1}Fe^{3+}_{0,1}Mg_{2,3}Mn_{0,04}Al_{0,1}(Al_{1,9}Si_{6,1}O_{23})]$ and ferropargasite $[Na_{0,8}K_{0,3}Ca_{1,8}Fe^{2+}_{2,2}Fe^{3+}_{0,1}Mg_{2,0}Mn_{0,1}Al_{0,2}(Al_{1,9}Si_{6,1}O_{23})]$. The biotites are annites (mg# = 0.29-0.48). Perthitic orthoclase and microcline are the dominant feldspar phases, but albite-oligoclase ($An_{0,8-16,5}$) appears as well. Accessories are titanite, apatite, magnetite, rutile and zircon.

The estimated crystallisation pressure based on Al-in-hornblende barometry [5] for hastingsites, pargasites and ferropargasites are approx. 6.9-7.5 kbar which signs the starting of the crystallisation process of syenites. The presence of several secondary minerals such as sericite, chlorite, epidote and calcite assume metasomatic effects on syenites.

Mafic plutonic rocks from south of Gorgan (NE Iran) – mineralogical and geochemical data

Rahimi-Chakdel, A.* & Raghimi, M.
Dept. of Geology, Faculty of Science, Golestan University, Gorgan, Iran (*rahimiaz@yahoo.co.uk)

Gorgan schists, exposed as discontinuous outcrops in the southern part of Gorgan town, Eastern Alborz Mountain Ranges, Northern Iran, represent metamorphic relicts of the PaleoTethyan collision in lower Palaeozoic [1]. Consisting of low-grade metamorphic rocks, Gorgan schists are intruded by mafic plutonic rocks, the largest exposed mafic dike having 1 m width and 4 km length.

A total of 7 samples were collected from various locations along the exposed mafic bodies for mineralogical investigations, whole-rock major and trace element analysis.

The mafic dikes are coarse grained and the texture varies from ophitic to intergranular. The mineralogy of the gabbros is dominated by large crystals of clinopyroxene, plagioclase and hornblende. The clinopyroxene displays prominent hornblende coronas in most samples.

The compositional ranges of the major elements are SiO_2 49.75-51.67 wt%, Al_2O_3 11.37-12.65 wt%, Fe_2O_3 10.17-10.65 wt%, MgO 6.66-8.48 wt%, and TiO_2 <2 wt%. All samples show an increase in total Fe_2O_3, K_2O and TiO_2 concentrations with decreasing MgO abundances, whereas Al_2O_3 content decreases with increasing MgO.

Minerals observations and laboratory analysis studies show that these rocks have low to medium K_2O contents, and are of tholeiitic type (Fig. 1). The major and trace element geochemistry suggests that the gabbroic dikes were generated by partial melting of enriched lithospheric mantle with garnet in the residue [2].

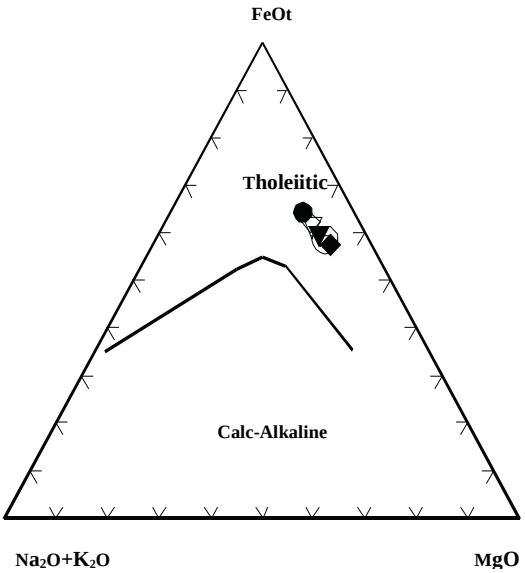

Fig. 1: Samples from the mafic dykes of southern Gorgan, Northern Iran, plotting in the tholeiitic field of AFM diagram.

Metamorphic history of late Neoproterozoic Dokhan-type volcanics in the Meknas area, SE Sinai, Egypt

Sadek Ghabrial, D.[1*] & Ren, M.[2]
[1]Geological Dept., National Research Centre, Dokki, Cairo, Egypt (*dghabrial@yahoo.com)
[2]Geological Sciences Dept., University of Texas, USA

The mineralogical and metamorphic features of the Neoproterozoic Meknas volcanics in southeastern Sinai, Egypt, have been studied. These volcanics developed during the late stage of the Pan-African event and occur as successive sheets ranging in composition from andesite to rhyolite. Their mineral assemblages and mineral chemistry indicate these rocks underwent two metamorphic phases; an early contact phase, which is characterized by the assemblage actinolitic hornblende + hornblende + biotite + oligoclase + quartz suggesting amphibolite facies metamorphism, with PT conditions at 550±50°C and <2-3 kbar. This metamorphism was followed by a late hydrothermal phase under the greenschist and sub-greenschist facies conditions as evidenced by formation of actinolite + chlorite + albite in andesite and dacite and chlorite + muscovite in rhyodacite and rhyolite.

Geochemistry of titanomagnetite in rocks and ores of Medvedevskoe deposit, Southern Urals

Shagalov, Ev.S.* & Holodnov, V.V.
Institute of Geology and Geochemistry UB RAS, Ekaterinburg, Russia (*shagalov@igg.uran.ru)

Medvedevsky gabbro massif and associated deposit is attributed to northern abyssal group as a part of Middle-Riphean riftogenic Kusinsko-Kopansky gabbro-granite complex in South Urals [1].

Several genetic types of ore mineralization are revealed in Peredovoy quarry of Medvedevskoe deposit: basic magmatic titanomagnetite (Ti-Mt) ores in stratificated gabbroids and skarn connected with xenolites of host carbonate rocks. Magmatic ores are impregnated and can be rich impregnated in ore melanogabbro; Ti-Mt is an accessory mineral in anorthosites and dyke complex. Solid Ti-Mt-chlorite ores are found in tectonic zone. Second outcrop of solid ores is connected with gabbro and calcareous skarn contact zone of Praskovie-Evgenievskaya mine situated in the central part of the massif [2]. Thickness of layer ores on the contact between gabbroids and skarns is 1-40 cm. Ores are composed of chlorite and magnetite, comprising a great amount of thin (5 μm) ilmenite lamells. Gabbroids in the contact with skarn are dramatically depleted with ore minerals. Magnetite accumulations up to 20 cm in diameter are observed in mine's marbles away from the contact, and on the contact between marble and intrusive diabase dyke Mg-ludwigite is developed [2].

Microelement ICP-MS analysis of basic types of rocks and ores and comprising Ti-Mt was carried out in order to study the chemical composition of sorted out genetic types of Ti-Mt ore mineralization. Titanium content in Ti-Mt is quite consistent in different types of magmatic ores and makes from 6.2 wt% TiO_2 in solid ores up to 8.0 wt% in ore gabbroids (rich impregnated ores). In anorthosites magnetite is depleted with TiO_2 (1.5%). Ti-Mt in near-skarn gabbroids is enriched in TiO_2 up to 14.4%, and magnetite in marbles situated away from contact contains significant amounts of Mn and Mg upon almost total absence of Cu, Eu and Ti. Ti/V ratio in Ti-Mt is also unstable: in solid ores 10, ore gabbros 25-69, anorthosites 10, marbles 0,2-11. Trace elements concentrations in Ti-Mt of basic ore types are irregular. Ores with ∑REE content in Ti-Mt can be divided in two groups: ∑REE less than 2 ppm and more than 4 ppm. All samples are characterized by light prevalence of LREE above HREE and small Eu anomalies of different signs. Besides main components (Ti, V, Mg, Al, Mn and Cr), Li, Sc, Co, Cu, Ni, Zn, Co, As, Sr, Ba, Pb, Nb can be regarded as significant trace elements (n-n*10^2 ppm). Ti-Mt of anorthosites is enriched with almost all elements, especially with chalcophylic, up to ten and hundred times as compared to samples from other rocks. In skarn column (gabbro-ore-skarn-marble) to solid ore on the gabbro contact in Ti-Mt concentration of Sc, V, Co, Ni and Ga is increasing, while Li, Be, Na, and Y decreasing, as well as Zn. Concentrations maximum is slightly shifted to Ti-Mt of gabbroids for Ti, Rb, Sr, Zr, Nb, Mn, Ag, Sn, REE, Hf, Ta and W. Gabbroids itself on the anorhtosite contact have higher REE concentrations (23-52 ppm) with increase to 42-78 ppm in anorthosites, and decrease in the central parts of gabbroid layers (0.8-27 ppm). Ti-Mt of their rocks follows this trend. Differences in Ba and Sr behavior can be noted: gabbroids and comprised ore minerals are enriched in Ba (up to 300 ppm) as compared to anorthosites (less than 80 ppm), the opposite situation is for Sr: in anorthosites peak content of Sr is 700 ppm.

Different meanings for cummingtonite-hornblende association in plutonic rocks (Iberian Massif, Portugal)

Solá, A.R.[1,5*], Moita, P.[2], Santos, J.F.[3], Neiva, A.M.R.[4,5] & Ribeiro, M.L.[1,5]
[1]Unidade de Geologia e Cartografia Geológica, LNEG, Lisboa, Portugal (*rita.sola@ineti.pt)
[2]CGE, HERCULES, Dept. Geociências, Universidade de Évora, Portugal
[3]Geobiotec, Dept. Geociências, Universidade de Aveiro, Portugal
[4]Dept. Ciências da Terra, Universidade de Coimbra, Portugal
[5]Centro de Geociências, Universidade de Coimbra, Portugal

Cummingtonite-grunerite series is frequently related to metamorphism or volcanic environments, but rarely described as belonging to a plutonic assemblage [1]. Recently, in the Iberian Massif (Portugal), there have been several references [2-5] of this Fe-Mg amphibole intimately associated with Ca amphiboles (mainly hornblende) in plutonic rocks. Different textural relationships between two amphibole types have been argued for a primary (igneous) or subsolidus metamorphic origin for Fe-Mg amphibole.

Cummingtonite-grunerite (Cum, hereafter all abbreviation from [6]) from gabbros and diorites of the Carrascal Massif (Central Iberian Zone) occurs as tiny exsolution lamellae within a dominant hornblende (Hbl) crystal [3]. This textural occurrence agrees with the subsolidus growth of the Fe-Mg amphibole, reflecting the equation Hbl+Qtz=Cum+An+H_2O [7].

Nevertheless, in the Hospitais tonalite (Ossa-Morena Zone) Cum occurs as euhedral to subhedral cores usually mantled by Hbl [4]. Although Cum is seldom described in literature as a magmatic mineral in plutonic assemblages, its occurrence in the Hospitais tonalite was interpreted as resulting from an early stage of igneous crystallization [4]. As a consequence of the high water content of calc-alkaline magmas, the Fe-Mg amphibole should reflect the equation Opx+H_2O= Cum+Mag+SiO_2+H_2 [8]. The similarity between Mg # on Cum and Hbl from tonalitic rocks suggests an equilibrium crystallizing assemblage, as pointed out by Wones and Gilbert [9] for a hypabyssal igneous suite.

Mineral chemistry data on Cum from the Carrascal gabbro-dorites (Mg#: 0.49-0.64; Al_2O_3: 0.7-2.37%; TiO_2: 0.01-0.37%) and Hospitais tonalite (Mg#: 0.43-0.53; Al_2O_3: 1.22-2.44 %; TiO_2; 0.05-0.27%) exhibit a significant overlap. Therefore, textural relationships should be the main (only?) tool to distinguish between igneous *versus* metamorphic growth. More detailed petrographic studies on plutonic rocks from the Iberian Massif are needed to ascertain the petrogenetic significance of the association Cum-Hbl.

Crustal sources for the Variscan Danubian granites (South Carpathians, Romania), inferred from oxygen stable isotope and trace elemental data

Stremtan, C.C.[1,2*], Balintoni, I.[2] & Balica, C.[2]
[1]Dept. of Geology, University of South Florida, Tampa, USA ([*]cstremta@mail.usf.edu)
[2]Dept. of Geology, "Babes-Bolyai" University, Cluj-Napoca, Romania

Dynamic processes such as sea-floor spreading, mantle convection, subduction, and continental accretion may be viewed as complex mechanisms of redistribution or recycling of the chemical and isotopic constituents of both crust and mantle. By studying these chemical redistribution processes a more comprehensive understanding of mantle and crustal evolution through geologic time can be achieved. The analysis of oxygen isotopes and trace elemental composition of granitoid rocks has proved to be a powerful tool for tracing the geochemical cycle because of the large difference in oxygen isotopic composition of crustal rocks as compared to rocks derived from mantle material.

The basement of the Danubian domain from South Carpathians of Romania has been intruded by numerous granitoid plutons, majority of them dated as late Variscan (Late Carboniferous to Early Permian in age).

Previous studies have shown that in terms of major elements, the vast majority of the Variscan Danubian granites are calc-alkaline to high-K calc-alkaline, peraluminous to strongly peraluminous but no inference has been made about their possible melt sources. Our preliminary oxygen stable isotope and trace elemental data offer additional information concerning the sources of the melts that eventually generated the Variscan granites. Ten of the Variscan plutons [1] have been sampled and measured for stable isotope and trace elemental composition. Oxygen isotope analyses of the granites reported here were carried out on quartz separates as they are less vulnerable to the effects of post-crystallization re-equilibration. The high $\delta^{18}O$ values measured for the majority of the plutons (highest value of 13.82 and an average of 10.81‰) and the lack of evident subsolidus hydrothermal alteration of the mineral separated support a strong crustal component involved in the production of the melts or their intense contamination with crustal material. The plutons are characteristically Nb depleted, have relatively elevated Rb/Sr, Th/U and low Sm/Nd ratios, consistent with the assertion that the melts had a crustal precursor

However, the presence of magmatic garnet and the REE contents for some of the samples does not preclude the possibility that, at least in some stages, a mantle component was involved as well in the granite generation.

P–T–t evolution of granulite from the Namche-Barwa, Eastern Himalayan: new constraints on reaction textures, fluid characteristics and SIMS U-Pb zircon ages

Su, W.[1*], Ye, K.[1], Chen, Y.[1], Zhang, M.[2], Liu, X.[3] & Liu, J.[1]
[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China ([*]suwen@mail.iggcas.ac.cn)
[2]Dept. of Earth Sciences, University of Cambridge, UK
[3]Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

The fluid evolution of continental crust involved in Cenozoic subduction and continent-continent collision processes was investigated by analysis of fluid inclusions, microstructural properties and mineral characteristics, and U-Pb dating (Cameca 1280 SIMS) on granulites from the eastern Himalaya. Four distinct events of fluid influx have been identified and characterised on the basis of petrographic observations and microthermometric measurements. They involve: I. pure CO_2 fluid, present during granulitic metamorphism (S2). II. A low-salinity and low-density aqueous fluid formed at the early retrograde metamorphic stage (S3). The preserved density (0.91 to 0.94 g/cm^3) of trapping in the fluid inclusions gives a tight constraint on the pressure conditions of this stage (0.82 to 0.87 GPa for temperature of 750 °C). III. A low-density and aqueo-carbonic fluid is responsible of the late stage of retrogression (S4), and density of trapping in the fluid inclusions of 0.62 to 0.54 g/cm^3 constrains the pressure of stage S4 at about 0.44-0.35 GPa for a temperature of 700 °C. IV. A late influx of very-low salinity aqueous fluid and the preserved density of trapping is 0.78 to 0.58 g/cm^3, gives a tight constraint on the pressure conditions 0.43 to 0.2 GPa for temperature of 600 °C, which is in equilibrium with greenschist facies-bearing mineral assemblage. Previous U-Pb dating of zircon suggested that peak granulitic metamorphism occurred between *ca*. 50 and 43 Ma [1], in conflict with SHRIMP U-Pb zircon ages, which are younger than 10 Ma for a granulite from the same area [2].

SIMS U-Pb zircon data record three distinct age populations: 1805 Ma (for inherited core), 482–557 Ma (oscillatory inner zone), 22.4–24.9 Ma and 18.2±0.3 Ma (for metamorphic rim). These new high-precision ages in combination with geological field, petrology and microstructure evidence suggest that continental arc rocks including Precambrian basement materials were involved in the granulite-facies metamorphism of the eastern Himalaya. Furthermore the ages of 22.4–24.9 Ma and 18.2 Ma are interpreted as the time of the south Tibetan crust was thickened and then uplifted, respectively.

CO_2 sequestration into hydrothermal system at Ogachi HDR site, Japan

Ueda, A.[1*], Kuroda, Y.[1], Sugiyama, K.[2], Ozawa, A.[2], Kaieda, H.[3], Kaji, Y.[4], Mito, S.[5] & Wakahama, H.[5]
[1]Dept. of Civil Engineering, Kyoto University, Kyoto, Japan
([*]a-ueda@earth.kumst.kyoto-u.ac.jp)
[2]Mitsubishi Materials Techno Corp., Tokyo, Japan
[3]Central Research Institute of the Electric Power Industry, Chiba, Japan
[4]Chuo Kaihatsu Corp., Saitama, Japan
[5]Research Institute of Innovative Technology for the Earth, Kyoto, Japan

In countries with many active volcanic areas such as Japan, one possibility is to sequester CO_2 in hydrothermal regions. The chemical reaction rates between CO_2-saturated water and hot rocks are usually faster than those at room temperature. For example, Reaction 1 can proceed to the right at high temperatures: $CaAl_2Si_2O_8$ (plagioclase) + H^+ + HCO_3^- + H_2O =$CaCO_3$ (calcite) +$Al_2Si_2O_5(OH)_4$ (kaolinite) (1)

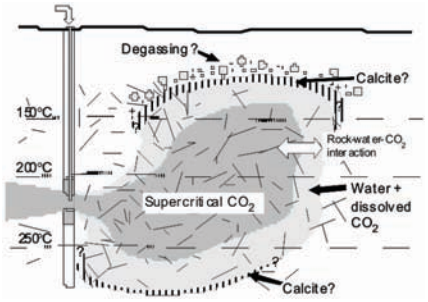

Fig. 1: Outline of CO_2 sequestration into geothermal fields.

Field experiments of CO_2 sequestration into the Ogachi hot dry rock (HDR; the temperature is 200 °C) site were performed to investigate mineralization of a part of CO_2 as carbonates through interaction with rocks (Georeactor; Ca extraction from rocks and carbonate fixation). In 2007, carbonated water (1wt%CO_2; river water with dry ice) with several tracers was directly injected into well OGC-2, Test #1 (from September 2nd to 9th) and Test #2 (from September 11th to 16th). During the Test #2 experiment, additional river water was injected into well OGC-1, 100m apart from well OGC-2, at 2 days after the injection of CO_2 water into well OGC-2 so as to push back carbonated water around this well. Water samples were collected at the depth of ca. 850m by a sampler (500ml in volume) and monitored for their chemical and isotopic compositions. The CO_2 concentrations in fluids collected decreased with duration time and were almost 2/3 of the expected concentration from tracer concentrations. This means that CO_2 injected into well OGC-2 can be removed from fluid by carbonate fixation.

During the field experiments, dissolution or precipitation rates of calcite were determined by using a technique of "in situ observation of crystallization". Calcite crystals covered with Au film were hold in a crystal cell and set in a crystal sonde. The crystal sonde was filled with He gas under a certain pressure and then put into well OGC-2. The fluid at depth of -850m is introduced into the sonde and calcite can start to react with them. After 1 hour, the sonde was recovered to the surface, where the fluid in the sonde is pushed to outside by He gas. The recovered calcite crystal is analyzed for the dissolution or precipitation rates by a newly developed phase shift interferometer. The "in situ analyses" show that calcite precipitation was observed within 2 day after the injection. This probably indicates that the most of CO_2 injected has been fixed as carbonate, supporting our idea that HDR system can be useful for CO_2 sequestration from inland emission sources.

Contribution to the Tertiary Magmatism in Panonian basin (Serbia): REE and HFSE constraints from the volcanics of the Fruška Gora Mt.

Vasković, N.[*], Matović, V., Erić, S. & Arifović, A.
Faculty of Mining and Geology, University of Belgrade, Serbia
([*]nadavask@eunet.rs)

The Eocene/Oligocene-Miocene magmatic rocks in the Pannonian Basin and Tiszia Zone [1] occur in a relatively narrow zone along major faults i.e., Balaton fault - BF, Mid-Hungarian fault – MHF and Sava fault – SF (Fig. 1).

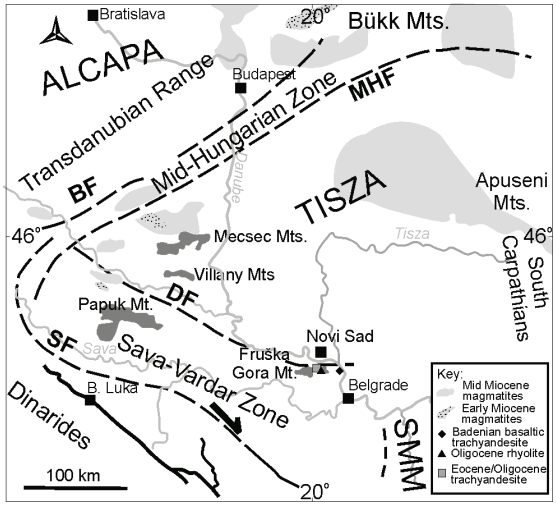

Fig. 1: Major tectonic units and spatial distribution of Paleogene to Mid Miocene magmatic rocks of the Pannonian Basin - [1].

The Eocene/Oligocene (36-31.7 Ma) [2] and Miocene-Badenian shoshonitic to high-K calc-alkaline volcanics from the Mount Fruška Gora are generated in postcollisional settings in the Serbian part of the Pannonian Basin. These rocks exhibit trachyandesitic to rhyolitic (Oligocene) and basaltic trachyandesitic (Badenian) composition (Fig. 2a) as well as the typical geochemical characteristics of subduction-related magmas - elevated LILE, and Pb concentrations, relative depletion in Nb (Fig. 2).

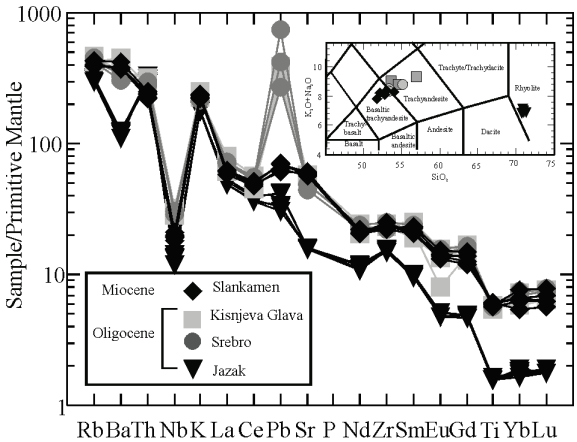

Fig. 2: Primitive mantle–normalized trace-element patterns [3] of Paleogene Eocene/Oligocene and early Miocene volcanic rocks from the Mount Fruška Gora.

Petrographic study of the mylonites in the Druksiai-Polotsk deformation zone in the Lithuania

Vejelyte, I.
Dept. of Hydrogeology and Engineering Geology, Vilnius University, Vilnius, Lithuania (Irma.Vejelyte@gf.vu.lt)

Some E-W crustal-scale deformation zones have been detected in the Proterozoic basement of Lithuania. One of them is Druksiai-Polotsk deformation zone (DPDZ), which is 35-40 km wide, well marked by gravity and magnetic linear anomalies in the North-eastern Lithuania. Microstructural and petrological analyses of granitoids and migmatites, which compose of granitic neosoma and amphibolitic paleosoma show that the DPDZ has a heterogeneous strain profile and both ductile and brittle deformation processes have contributed to the total displacement. Recrystallization microstructures in slightly- to intensely deformed rocks vary in accordance with the degree of strain. The strong shearing localized within the mylonite resulted in the round shape or asymmetrical elongated plagioclase porphyroclasts, amphibole, mica fish, titanite and the generation of fine grained plagioclase, biotite, quartz, amphibole and epidote. Quartz grains are irregular in shape with undulatory extinction, indicating dynamic recrystallization mainly by subgrain rotation. K-feldspar characteristically shows core-mantle structure. Amphibole is long-form, often boudinated. The titanite occurs as subhedral crystals grains and as mantle around opaque minerals, which follows the folation in the host rock. The U–Pb dating of titanite from an augen granitoid mylonite has yielded a concordant age of 1534±9 Ma [1]. The penetrive foliation was obviously formed during retrogression from amphibolite- to epidote-amphibolite facies.

Granulite boulders from Pleistocene terrace of Danube, Hungary

Vígh, Cs.[1*], Horváth, P.[2,3], Józsa, S.[1] & Nagy, G.[3]
[1]Dept. of Petrology and Geochemistry, Eötvös Loránd University, Budapest, Hungary ([*]geocsaba@gmail.com)
[2]School of Geological Sciences, University of KwaZulu-Natal, Durban, Republic of South Africa
[3]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary

The Pleistocene gravel terrace of the Danube has been mined by several gravel pits SE from Budapest and on the Little Hungarian Plain. Although study of the bench gravel dates back about hundred years, the comprehensive investigation-including petrography of rocks types- have started in recent years. The boulder-bearing gravel is very polymict, contains several rock types with unclear origin (e.g. granulites, high-grade gneisses, migmatites, amphibolites, eclogites, granites, syenites). Our aim was threefold: 1. describe the petrography of the granulites, 2. calculate the pressure-temperature conditions, and 3. identify the possible source area of the pebbles. All studied granulites are felsic, two types were identified:

(1.) Garnet-kyanite granulite contains garnet and/or kyanite porphyroblasts within a quartz+K-feldspar+plagioclase matrix. Relicts of perthitic feldspars can be found as porphyroblast and inclusion in garnets. These garnets contain rutile inclusions as well. A second garnet variety contains Zn-bearing spinel and/or ilmenite inclusions and rimmed by plagioclase corona.

(2.) Garnet-sillimanite granulite: Garnet+sillimanite+K-feldspar+plagioclase+quartz+biotite+ilmenite mineral assemblage is stable, but relics of kyanite grains indicating higher pressure are still present.

The garnets have Ca-poor, Prp-Alm-rich compositions (Alm57-72 Prp25-39 Grs2-12 Sps1-4 And0-1), their Ca content decreases from core to rim while their XFe is influenced by formation of retrograde biotite.

Both granulite types have peraluminious composition, the SiO_2 content varies between 71-75% and the Al_2O_3 is 13-16%. Samples are depleted in Sr and HFSE.

EMPA based Th-U-Pb age dating of monazite revealed Variscan ages (330 Ma) for the peak metamorphism of the studied granulite pebbles.

Ternary feldspar thermometry and phase diagram calculations reflects HT-HP peak metamorphism in the Gt-Ky-Mp-Rt-Qtz-liq field at 900-1000°C and about 18 kbar, and it was followed by a decompressional P-T path.

The nearest occurrences of similar felsic granulites are on the Moldanubian part of the Bohemian massif, so they can be regarded as a potential source region of the investigated granulite boulders.

High geothermal gradient and low uplift rate of Paleoproterozoic granulites from North China craton: implications for Early Precambrian tectonics

Zhai Mingguo
Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China (mgzhai@mail.igcas.ac.cn)

Paleoproterozoic high pressure granulites in the North China craton (NCC) were reported by Zhai et al. [1]. Their high pressure of 10-14 kb attracted attention from researchers, and several continental collisional models have been proposed for early Precambrian tectonic evolution of the NCC. Recent studies show that Paleoproterozoic high-grade metamorphic rocks are extensively distributed in the NCC, and can be subdivided into two groups that are high-temperature and high-pressure granulites (HT-HP) and high-ultrahigh temperature granulites (HT-UHT). The HT-HP granulites are mainly garnet-bearing mafic granulites that are metamorphosed and deformed dykes enclosed in the orthogneisses. The HT-UHT rocks are metamorphosed pelites (khondalites), and sapphirine and spinel in khondalite indicates metamorphic temperatures > 900-1000˚C. This study deals with the occurrences, distribution, metamorphic conditions and history, isotopic ages of the two granulites, and emphasizes the following aspects: 1, the peak metamorphic conditions and *PT* paths with a pressure decrease for the two granulite groups are similar. 2, Their metamorphic ages of the peak and followed decompressional stages are also similar. 3, HT-HP and HT-UHT granulites probably occur in area distribution other than in linear distribution. 4, Some researchers suggested that HP granulites and related rocks represent a typical continent-continent collisional orogen like the Himalayas. However, it is still argued that these rocks have much higher geothermal gradient of ~16ºC/km and much slower uplifting rate of 0.33-0.5 mm/yr than those in Phanerozoic orogenic belts, indicating the rigidities of the old continental crust are significantly different from those of Phanerozoic crust. 5, All these observations suggest that we should rethink geological and tectonic models for the evolution of the North China craton.

Metallic mineral deposits related to the style of volcanism in dynamic subduction zone

Watanabe, Y.
Geological Survey of Japan, AIST, Tsukuba, Japan
(y-watanabe@aist.go.jp)

Style and type of hydrothermal metallic deposits are intimately related to the chemistry of source magma and the style of volcanism, which are related to tectonic regime in subduction zones.

In an extreme extensional tectonic regime, rift-related tholeiitic basalt dominates in submarine environment, and massive sulphide base-metal deposits may be associated with the volcanism. In a moderate extensional regime, monogenetic bimodal volcanism of basalt and rhyolite becomes dominant. Large scale calderas are commonly formed in this setting due to the formation of large basaltic magma chambers in the crust. In this regime, kuroko-type massive sulfide deposits form in submarine environment and low-sulfidation epithermal Au deposits form in terrestrial environment. Hydrothermal alteration with low water/rock ratio (sericitic alt.) dominates and normal faults may become the site of mineralization in this regime. A neutral tectonic regime yields a number of polygenetic and composite andesitic volcanoes, which may be associated with precious and base metal epithermal and xenothermal deposits. Hydrothermal alteration with both high and low water/rock ratios is associated with the mineralization. Strike-slip faults may become the site of mineralization. In a slight contraction regime, intrusive activity beneath the polygenetic volcanoes become dominant, and these volcanoes are commonly associated with diatremes and sector collapses. High-sulfidation epithermal Au-Cu and porphyry Cu deposits may form at the apex of the intrusive bodies. Hydrothermal alteration with high water/rock ratio (potassic and advanced argillic alt.) becomes dominant in this regime. In a moderate contraction regime, magmas do not ascend to a shallow crustal level, resulting in lack of volcanic activity and mineralization. These tectonic regimes may change in a couple of million years in the same site, and different volcanic styles and mineral deposits are frequently mixed together in subduction zones.

Main metal species in these mineral deposits reflect the magma chemistry and salinity of hydrothermal fluids. Mantle material rich magmas form the deposits rich in Au, Hg and Cu and crust material rich magmas form the deposits rich in Sn, W, Pb and Zn. Mineral deposits formed in submarine environment are enriched in base metals due to high salinity of the fluids.

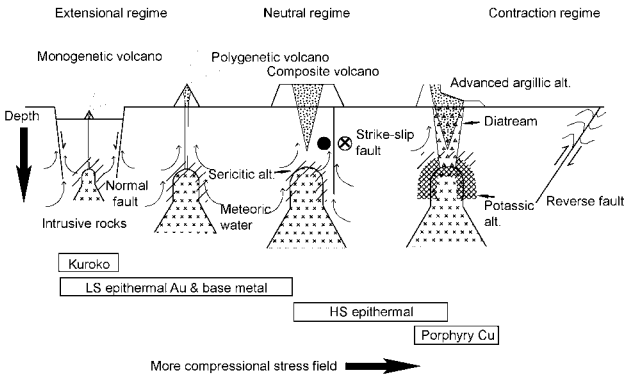

Fig. 1: Schematic figure showing the relationship among the tectonic regime, style of volcanism and associated mineralization.

Magma-sediment-water interaction: a precursor to base metal mineralisation?

Breheny, C.*, Moore, K.R., Costanzo, A. & Feely, M.
Dept. of Earth and Ocean Sciences, National University of Ireland, Galway, Ireland (*c.breheny1@nuigalway.ie)

The Ordovician NE-SW trending volcanic belt, located along the southeast coast of Ireland, is composed of subduction related volcanics and intercalated sediment as a result of Iapetus Ocean closure. Within this belt, the dominantly intermediate composition Bunmahon Formation exhibits a strong island arc tholeiite signature and comprises hyaloclastite, pillow lavas and peperite intercalated with tuff deposits and volcanogenic mudstones. Electron microprobe analysis across sharp to gradational contacts in peperite revealed that magmatic peperite clasts were subject to more extensive alteration than related coherent intrusions, indicating that circulating pore waters within the unconsolidated sediment facilitated the transition to a hydrous chlorite-dominated assemblage. Electron microprobe analysis of mineral compositions showed that chlorite (Fe# = 0.35-0.63) in association with pumpellyite, epidote, pyrite and Fe-oxides formed as a consequence of an iron-rich hydrothermal fluid that interacted with magnesium-rich seawater.

Two distinct types of mineralisation are recognised based on field evidence: (1) stockwork type vein networks composed of quartz and mixed quartz and calcite veins containing sulphides and (2) barren linear veins of quartz or calcite occurring parallel to bedding or fault planes and infilling tension gashes. The role of shallow level intrusions in generating hot mineralising fluids that resulted in vein formation has been investigated using fluid inclusion studies. Fluid inclusions (FIs) hosted in mixed quartz and calcite veins are two phase liquid-rich (liquid + vapour) FIs that homogenise to the liquid phase. Homogenisation temperatures (T_H) range from 100° to 250ºC for both barren and sulphide rich veins. The majority of T_H values observed for both veins occur between 150ºC and 200ºC indicating one fluid population. Isochore modelling based on temperature, composition and salinity show a wide range of temperatures up to a maximum of 375°C true trapping temperature for sulphide-bearing veins. Temperature variations across vein stockworks are consistent with cooling against wall rocks, in which alteration is observed at stockwork zones. Modelled fluid salinities range from 6 to 20 eq. wt% NaCl with a mean of 12.9 eq. wt% NaCl. Two salt systems have been recognised based on phase changes i.e. H_2O-NaCl-KCl and H_2O-NaCl-MgCl. The microthermometry results do not reveal great differences between the stockwork-related and fracture-filling fluids, but coupled with field observations, it is possible that early hydrothermal fluid circulation may have been generated as a result of igneous activity, and these hydrothermal fluids were responsible for the alteration of the host volcanic rocks and concomitant deposition of vein-hosted base metals.

Indium mineralization in magmatic-hydrothermal system

Shimizu, M.[1*], Cook, N.J.[2] & Sundblad, K.L.[3]
[1]Dept. of Earth Sciences, Faculty of Science, University of Toyama, Japan ([*]mshimizu@sci.u-toyama.ac.jp)
[2]Natural History Museum, University of Oslo, Norway
[3]Department of Geology, University of Turku, Finland

Two main primary resources of industrial In are currently from vein and skarn deposits related to felsic magmatism [1] and from massive sulfides [2]. The main In-enriched deposits are subvolcanic and Sn-polymatallic vein types [3]. Tin-bearing, Zn-rich and/or Cu-rich polymetallic vein-type deposits are the primary focus for exploitation of recoverable In as an economically-viable by-product.

The most important mineral is In-bearing sphalerite in Zn-rich polymetallic vein-type deposits. Indium-bearing stannite and cassiterite are generally of lesser importance, whereas minerals with major In content (roquesite, sakuraiite, "zinc-sakuraiite" (Zn analogue of sakuraiite), dzhalindite, etc.) are only minor contributors to the mineralogical balance for In [4],. In Cu-rich deposits, however, roquesite may be the most important, with only minor In contained in stannite, cassiterite, bornite and tennnantite-tetrahedrite, and less in sakuraiite, dzhalindite and so on [5,6].

In situ LA-ICP-MS analysis of In-bearing sphalerite from Toyoha in Japan, Hanes and other deposits in Romania, and deposits in the Svecofennian Domain of the Gennoscandian Shield (some also containing roquesite allows the mechanisms of In mineralization and enrichment of In in sphalerite to be understood. Three In-bearing ore types have so far been recognized in the Fennoscandian Shield: 1) polymetallic (Fe-Zn-Pb-Cu-Sn) skarn at Pitkäranta, 2) polymetallic veins at Korsvik (Cu-As-Sn) and Jungfrubergen (Zn-Pb-Ag), and 3) compact magnetite-sphalerite bodies at Getmossmalmen (Fe-Zn), all related to rapakivi granites.

The physico-chemical environment of In-rich sphalerite can also be compared with that of stannite, stannoidite and roquesite [5]. Sakuraiite and "zinc-sakuraiite" both have high-temperature (cubic, probably isostructural with sphalerite) and low-temperature (tetrahedral) types. Under formation at higher temperatures, partial sphalerite-roquesite solid-solution may be expected, but sphalerite-"zinc-sakuraiite" solid-solution is more preferable. At lower temperatures sphalerite-tetragonal "zinc-sakuraiite" solid-solution is broken down with decreasing of temperature to form roquesite and sphalerite with only residual amounts of In.

Indium-Sn-bearing Zn-rich and/or Cu-rich polymetallic vein-type deposits are generally located in convergent plate margins and orogenic belts with steep geothermal gradients generated by magmatic activity [1]. The Japanese Islands are essentially accretional terrains intruded by various magmas. Back-arc rifts are reasonable tectonic settings for generation of In-rich deposits. In contrast, the highly In-potential rapakivi granites in the Fennoscandian Shield represent an extensional environment within a stable craton.

Submarine volcanism-related hydrothermal alteration in the Darnó- and Szarvaskő Units (NE-Hungary), and in the Dinarides and Hellenides

Kiss, G.[1*], Molnár, F.[1], Bartha, A.[2] & Palinkaš, L.A.[3]
[1]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]gabriella-kiss@chello.hu)
[2]Laboratory Dept., Geological Institute of Hungary, Budapest, Hungary
[3]Inst. of Mineralogy and Petrology, University of Zagreb, Croatia

Comparative studies on hydrothermal alteration were carried out on submarine basaltic volcanites with different origin. Peperitic basalt occurrences related to the Triassic early rifting of the Neo-Tethys were studied in displaced parts of the Dinarides (Darnó Unit, NE-Hungary) as well as in the Dinarides (Kalnik Mts, Croatia, Vares-Šmreka, Bosnia-Herzegovina) and in the Hellenides (Stragopetra Mts.), while Jurassic basalts formed in an intra-oceanic back-arc-basin of the Neo-Tethys were also studied (Szarvaskő Unit, NE-Hungary).

Within the submarine basaltic lava units 7 volcanological facies were distinguished and these bear different types of hydrothermal alteration. Alteration 1 is characterized by albitization of the rock-forming plagioclase at ~300°C and occurs both in the Triassic and Jurassic rocks. Superimposing alterations (alteration 2) were developed during cooling from 280°C to ~140°C (Jurassic rocks) and ~70°C (Triassic rocks) temperature. During the higher temperature part of these processes chlorite formed in the ground mass, however chlorite and rarely quartz formed in the micro fractures and small amygdales of the Triassic basalts, while chlorite, quartz and prehnite precipitated in the micro fractures of the Jurassic rocks. At lower temperatures calcite formed commonly in the larger amygdales, jig-shaw type veins and as other infillings. Some epidote, pumpellyite, prehnite and laumontite also occur in the Triassic basalts, while datolite is a rare mineral in the Jurassic ones. During this process the system was mainly seawater-dominated because fluid inclusions are characterised by 3.2-7.8 NaCl equ. wt% salinities. Late stage alteration 3 is characterised by argillitization occurring at every studied locality; presence of disordered layer silicate (smectite group) is proven by XRD. Though similar processes happened at the Triassic and Jurassic localities, relatively limited fluid-rock interaction was characteristic to the Jurassic basalts, which resulted in minerals formed at higher temperatures and limited amount of hydrothermal infillings (no amygdales or other infillings occur, only short veins).

On the ground of extended petrochemical study, mobilization of the different elements was followed even in single pillow lava-scale, inside a volcanic facies from fresher to more altered parts and between different facies as well. Mass transfer calculation was made to determine the gains and losses which refer to the (1) and (3) alterations, while results of (2) were mainly eliminated (except ground mass chloritization). Increase of Na_2O (i.e. albitization) is characteristic in a pillow from core to rim, though results of low temperature alteration (decrease in SiO_2, MgO) can also be seen. Examining the processes from fresher to more altered part of a facies the (3) alteration mainly overprint the (1). At distal volcanic facies (such as peperitic basalt and pillow fragmented hyaloclastite breccia) the low temperature alteration and the formation of clay minerals are more dominant, though at the hyaloclastite breccia high grade chloritization is also dominant (increase in MgO). The effect of the basalt on the peperitic limestone is characterized with elevated Cr, Ni, Co, Cu in the sediment, while presence of the limey mud during the cooling of the lava resulted in stronger alteration processes in the contact basalt.

Mineral-forming volcanic gases: the Tolbachik factory (Kamchatka, Russia)

Filatov, S.K.[1*] & Vergasova, L.P.[2]
[1]Dept. of Crystallography, St. Petersburg State University, St. Petersburg, Russia ([*]filatov.stanislav@gmail.com)
[2]Institute of Volcanology and Seismology RAS, Petropavlovsk-Kamchatskiy, Russia

The scoria cones of the Tolbachik Eruption of 1975-76 (Kamchatka, Russia) are still hot and discharge gases with temperatures up to 450°C. The gases are highly oxidized due to a large fraction of the admixed air. The monitoring of these gases during the last three decades reveals a permanent precipitation of minerals directly from the gas phase. A complicated system of fractures and cavities developed at the summits of two Tolbachik cones is desirable for the circulation of gases, precipitation of minerals and alteration of surrounding rocks.

The most spectacular and abundant mineralization was observed on the 2nd Cone where the majority of the discovered 30 new minerals was found. This cone is characterized by a large volume of lava and scoria, and a broad development of concentric and radial fracture zones formed due to the post-eruptive contraction and deformation. The gas vent named "Poisonous" was especially active and productive during two first decades of the monitoring period; it represents shallow chamber of ~ 2 m^3 open to the surface. Such conditions made possible stable mineral-forming processes; hundreds kilograms of mineral aggregates (mainly cupper minerals) were formed inside the chamber demonstrating process of the modern ore-formation.

Mineralogy of the Tolbachik incrustations is very diverse, though their specific is mainly controlled by the high oxidation state of the hot gas + air mixture: sulfates, oxosulfates, chlorides, oxides, selenites, carbonates, fluorides, arsenates, silicates, hydroxides and hydrous chlorides, sulfates, carbonates etc. Seldom grains of native elements (gold) and sulphides (pyrite, realgar, orpiment) were also found.

Fine dispersion and heterophase nature of exhalative products make difficult to separate pure material for investigation by different methods. For this reason natural transport of metals by volcanic gases, mineral formation and precipitation were firstly modeled using method of gas chemical transport reactions in evacuated glass or quartz ampoules. Chlorides, oxochlorides, selenites, oxoselenites and other exhalative minerals from Tolbachik volcano were synthesized and investigated by this way.

The brightest feature of low-temperature period activity of the Tolbachik 1975-76 volcano is the formation of bauxites on the 1st Cone. Broad deposits of new mineral lesukite $Al_2(OH)_5Cl{\cdot}2H_2O$ and gibbsite were found in zones of metasomatic transformations of the erupted material that leads to formation of Al mineralization and probably involves microbiological factors.

Amphibole as a petrological sensor: different points of view

Simakin, A.G., Zakrevskaya, O.Ju.[*] & Salova, T.P.
Institute of Experimental Mineralogy, RAS, Chernogolovka, Russia ([*]zakrev@iem.ac.ru)

Magmatic amphibole composition reflects parameters of the parental melt. Diversity of the crystallo-chemical positions and variable composition make amphibole a potentially powerful PT and fO_2 sensor. This potential is still not fully realized. Measuring and (or) interpretation of the iron oxidation state in amphibole is the critical parameter in developing of the predictive models. Easiness of subsolidus oxidation of amphibole with formation of oxy-amphibole by the scheme $Fe^{2+}(OH^-)> Fe^{3+}(O^{2-})+1/2H_2$ devaluates direct methods of the iron oxidation state analysis. Therefore stoichiometric reconstruction of the Fe^{3+}/Fe^{2+} ratio is the only realistic estimate related to the crystallization conditions. Possibility of such reconstruction is based on the assumption that in a crystallizing magmatic mineral both Fe^{2+} and Fe^{3+} bearing minals of amphibole are composed of hydroxyl (partially substituted by Cl, F) varieties and only Ti^{4+} enters in the oxy-component (accepted at IMA-97). We present experimental data on the amphibole crystallization from the high magnesium andesite (Shiveluch, Kamchatka) at P_{H2O}=2 and 5 kbar and high T=950°C. Analysis of our and published data demonstrates that there is a strong negative correlation between the calculated (model IMA-97) content of octahedral Al and the sum Fe^{3+} and Ti^{4+} in M position. Al^{VI} content (Al^6*) at the extrapolated to zero sum Fe^{3+} + Ti (to eliminate fO_2 influence) reflects its activity in the parental melt. It is well established that the proportion of the octahedral Al in the magmatic melt rises with increase of pressure and water content. At pressure increase aluminium mainly transfers from tetrahedral (network-forming) to 5 and 6 oxygen coordinated state in the melt. Our data combined with the published ones, set up a dependence: Al^{VI}* /approx 0.586+0.583 P(kbar). This dependence is valid for subliquidus high temperature (T=950-1100°C) amphiboles crystallized from andesitic to basaltic-andesitic melts. Parameter Al6*decreases if amphibole crystallizes after other phases even at high T. Our correlations allow to estimate the P and fO_2 in different Shiveluch adakitic rocks (extrusions, lavas, pyroclastics) using amphibole composition. Based on our calibration we interpret maximum pressure of amphibole crystallization in metasomatized spinel peridotite xenoliths from Dish Hill, California [1] to be about 5-6 kbar. This pressure is fairly below the value of 20 kbar estimated by Lamb [2] and close to P=5 kbar predicted with the recent empirical calibration proposed in [3]. This comparison makes questionable the applicability of Popp´s model [4] based on the experimental data on the metastable (single phase of constant composition) oxidation and reducing of amphibole.

Formation of chlorine- and sulfur-bearing feldspathoids (sodalite, scapolite, and cancrinite) from silicate-melt and aqueous fluid in alkali-syenite cumulate nodules from the Breccia Museo Formation, Campi Flegrei, southern Italy

Belkin, H.E.[1*], Tarzia, M.[2] & De Vivo, B.[3]
[1]U.S. Geological Survey, Reston, VA, USA
([*]hbelkin@usgs.gov)
[2]Dept. of Materials, Imperial College London, UK
[3]Dip. di Scienze della Terra, Università di Napoli Federico II, Napoli, Italy

Alkali-syenite cumulate nodules from the Breccia Museo Formation, interpreted as fragments of a magma-chamber wall, are especially enriched in Cl and incompatible elements (e.g., U, Zr, Th, and rare-earth elements). Detailed optical petrography, scanning electron microscope imaging, and electron probe microanalysis reveal relatively late-stage precipitation of Cl- and S-bearing feldspathoids among the predominant alkali-feldspar and plagioclase nodule framework. Sodalite, scapolite and cancrinite (the davyne-group) form single crystals and/or complex intergrowths. Sodalite is nearly end-member composition (Cl = 7.1 wt.%) with low concentrations of CaO (0.03 - 0.6 wt.%) and K_2O (~0.11 wt.%). Scapolite is calcian marialite with a limited compositional range; Me ranges from 19 to 21. The scapolite is Cl-rich (~ 4 wt.%) with low SO_3 (< 0.05 wt.%) and a high K_2O content (~ 2 wt.%). The cancrinite chemistry is the most complex. Chlorine varies inversely with SO_3 (r = 0.94); Cl ranges from 5.9 to 10.9 wt.% and SO_3 ranges from 0.1 to 6.7 wt.%. CaO, K_2O, and Na_2O vary from 8.8 to 13.2 wt.%, 2.7 to 11.5 wt.%, and 8.1 to 14.4 wt.%, respectively. Two different groups can be distinguished on the basis of Na_2O and K_2O content; high Na_2O and low K_2O and high K_2O and low Na_2O. The group with K_2O > 8 wt.% are high Cl and low SO_3. These two groups are observed intergrown with anorthite (~An92) and a more Na-rich plagioclase (~An30). No crystallographic determinations were made on any cancrinite phase although the complex textures suggest that such work might yield a mixed analysis. In only one sample was vesiculated glass observed and it coats both sodalite and cancrinite. The glass composition is phonolitic (SiO_2 = 55.5, total alkalis = 15.9 wt.%) with Cl, F, and SO_3 equal to 1.0, 0.8, and 0.04 wt.% respectively; H_2O by difference equals ~ 4 wt.%.

Formation of feldspathoids in the other nodules was from exsolved aqueous brine as suggested by fluid inclusion evidence. The precipitation of the feldspathoids bridges the transition between magmatic and hydrothermal, although a hybrid mixture also could be involved.

Andesites at Mt. Taranaki, New Zealand: assembly of melts and crystals in an arc volcano

Stewart, R.B.[*] & Gruender, K.
INR-CS, Volcanic Risk Solutions, Massey University, Palmerston North, New Zealand ([*]r.b.stewart@massey.ac.nz)

The origin of andesite magmas is a topic that is widely debated. One of the major issues is the widespread disequilibrium between crystals and whole rock compositions in these rocks which makes interpretation of magma processes from whole rock geochemistry difficult. Previous studies of Mt Egmont/Taranaki geochemistry showed that the "phenocrysts" present in the lavas exhibited this typical lack of equilibrium with the whole rock composition of their host. This means they did not crystallise from a melt with the composition of the whole rock, and mineral chemistry showed that the liquid they did crystallise from was more mafic than the host lavas. Further, the matrix glasses present in the lavas and tephras is mostly dacitic to rhyolitic in composition and, in younger lavas, has a high K_2O content. None of the feldspars show an appreciable K_2O component except in some thin rims on larger crystals, consistent with a lack of equilibrium with the glass phase through much of the growth of the feldspar crystals.

Xenoliths of rock types interpreted as lower to mid-crustal in origin are mostly ultramafic pyroxenites to hornblende gabbros, hornblendites and amphibole-bearing gneisses. These xenoliths contain partial melts that are also dacitic to rhyolitic and the xenolith glass major element compositions overlap with those of the matrix glasses in the younger Egmont/Taranaki lavas. One possibility is that the host matrix glass infiltrated along cracks in the xenoliths during entrainment and transport. However, glass is predominantly present in the xenoliths as melt patches enclosed within the xenoliths rather than as crack infill, suggesting a source within the xenolith in most cases. Glass is often found adjacent to amphibole, but also occurs in xenolith lithologies that contain little or no amphibole. Breakdown of aluminospinel to anorthite is also observed. Rare high (80% + SiO_2) glasses were observed as partial melts within quartzofeldspathic sandstones. These exhibit vesicular textures and clearly show melting of the sandstone under hydrous conditions. These glasses have no correlatives within the matrix glass suite.

An alternative view of the Mt Egmont/Taranaki lavas is that they are a mix of crystals from prior fractionation in the subduction "hot zone" that have been remobilised by silicic partial melts of gabbros and ultramafic rocks of the lower crust, possibly significantly driven by amphibole decomposition, and additional inputs from partial melts of other crustal rocks. Although the glass chemistry will be modified by crystallisation and reaction processes in the source rocks, and crystallisation fractionation prior to cooling in the lavas, the lava matrix glass compositions are remarkably similar to the glasses in the xenoliths. The disequilibrium observed between whole rock and mineral chemistry, and between the glass chemistry and minerals, together with the similarities of glass chemistry between xenoliths and lava matrix glasses, is consistent with the mixing hypothesis.

The Goldfield-Superstition Miocene large silicic volcanic province, central Arizona (USA): petrology based on major- and trace-element and mineral compositions

Dombroski, B.A. & Fodor, R.V.*
North Carolina State University, Raleigh, NC, USA
(*rfodor@ncsu.edu)

The Goldfield-Superstition Mountains in central Arizona form a Miocene large silicic volcanic province (LSVP) ~8000 km^2 of peraluminous rhyolite and rhyodacite lavas and pyroclastic flows. Mineral assemblages include plagioclase (An_{50-12}), anorthoclase, sanidine (BaO ≤5 wt%), quartz (mainly resorbed) biotite, amphibole (edenite; Mg#s 66-71), rare clinopyroxene and orthopyroxene (Mg#s 66-70), and accessories that include titanite, zircon, and perrierite (La-Ce-Ti silicate). Important compositional characteristics include negative Nb-Ta and Eu anomalies (wide Eu/Eu* range ~0.95-0.3) in nearly all samples, and moderate LREE-enrichment throughout (La_n ~35-260). Established $^{40}Ar/^{39}Ar$ ages [1] identify initial volcanism as small-scale rhyolite domes, ~20.5 Ma, followed by ~1.5 m.y. of mafic-intermediate magmatism -- and then large-volume eruptions that created the Goldfield-Superstition LSVP ~19-18 Ma.

Petrologic interpretations: Although these silicic rocks are unlikely to be direct partial melts and instead represent at least some fractionation from primary partial melts, we nonetheless propose the following: (i) volcanism began as two types of rhyolite domes. One is undated (Nb-Ta anomaly; no Eu anomaly; mode An_{28-38} only) and has $La/Yb_{(n)}$ ~50, and represents a small percent melt (<5%) of lower crust garnet-bearing amphibolite/pyroxenite. Another dome type, 20.5 Ma (no Nb-Ta anomaly; san_{Or70}+olig+qtz mode; Eu anomaly), has $La/Yb_{(n)}$ ~12, and represents greater melting ~10-30% of the same or similar source (garnet-free, either case). (ii) Melting to produce the domes was provided by heat from the onset of mafic magmatism (SiO_2 ~47 wt%; MgO ~11 wt%). Protracted heat (~1.5 m.y.) from the basaltic magmatism led to (iii) development of the Goldfield-Superstition LSVP. The resulting lavas and pyroclastic flows can largely be modeled as products of various percent melts (10-30%) from lower-crust amphibolite-pyroxenite slightly more incompatible-element enriched than the domes' source(s), and having varying degrees of subduction characteristics (Nb-Ta). These melts experienced differing amounts of crystal fractionation, some magma mixing, and little upper crust contribution (e.g., Eu anomalies; resorbed qtz; spongy-rim plag; Th/Nb <0.5). (iv) The REE accessory perrierite (La_2O_3 11 wt%; Ce_2O_3 20 wt%) had no effect on magma LREE abundances and probably represents REE melt saturation. (v) Application of Al-in-amphibole geobarometry provides ~4 kbar as the highest observed crystallization pressure. (vi) When compared to compositions of other Cenozoic western North American LSVPs, the Goldfield-Superstition province shares most all of their trace element characteristics (e.g., Nb-Ta; varying but some overlapping Th/Nb, Ba/Nb, La/Nb) but remains distinct in details per its source compositions. The Goldfield-Superstition province exemplifies the onset of large-volume silicic volcanism by mantle magmas ponding at or in lower crust for at least 1 m.y.

The origin of sanidine megacrysts in silicic rocks by coarsening: petrological evidence from the dacites of Taapaca volcano, Chile

Higgins, M.D.
Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, Québec, Canada (mhiggins@uqac.ca)

K-feldspar megacrysts are common in granitoids, but rare in chemically equivalent volcanic rocks, of which the Taapaca dacites are the best known. Sanidine megacrysts up to 10 cm long occur in some of the lavas, and contain abundant chadocrysts of plagioclase, sanidine, amphibole and oxides, as well as glassy magmatic inclusion and voids. Chadocrysts are generally isolated from the host by a thin film of glass. The matrix contains abundant plagioclase crystals, as well as amphiboles and oxides. Both megacrysts and host lavas were imaged using cold-cathode cathodoluminescence. Growth of the megacrysts engulfed plagioclase, sanidine and amphibole crystals. Crystal size distributions (CSD) of sanidine megacrysts are hump-shaped. Large crystals are euhedral and small crystals are rounded. These data show that megacrysts developed from the host magma by coarsening: this was enabled by cycling of the temperature of the magma around the sanidine liquidus temperature in response to injections of more mafic magmas and subsequent magmatic overturns. Chemical zonation of the megacrysts reflects heterogeneity of the host magma and not transfer of crystals from other magmas. Plagioclase crystals enclosed in the megacrysts are small and have straight CSDs, which contrasts with the hump-shaped CSDs of plagioclase in the matrix. This shows that plagioclase was also coarsened, starting at the same time as the growth of the sanidine crystals and continuing afterwards.

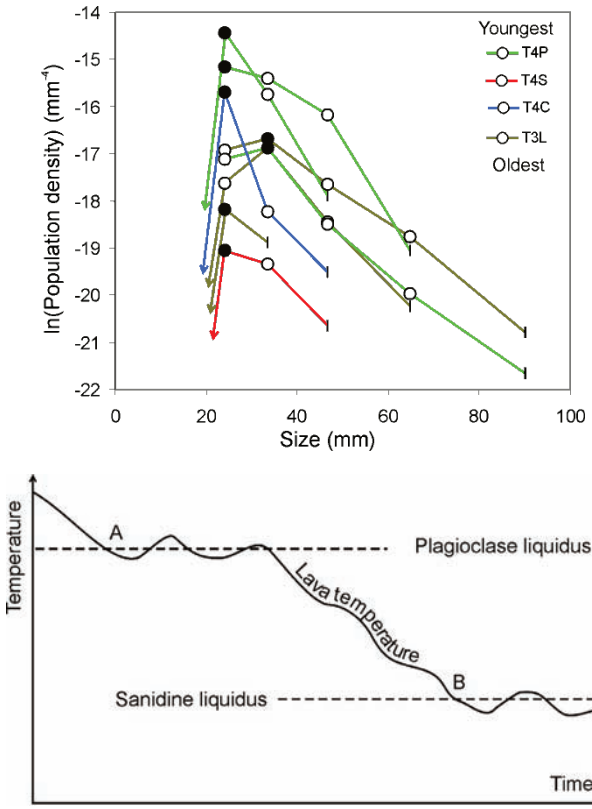

Fig. 1: Eruption of lava between A and B produced plagioclase-phyric rocks. Sanidine megacrysts were only produced if the magma evolved past B.

Combined textural and mineral chemical studies in the reconstruction of magma chamber processes: case studies from the Carpathian-Pannonian region, eastern-central Europe

Harangi, Sz.
Volcanology Group, Dept. of Petrology and Geochemistry, Eötvös University, Budapest, Hungary (szabolcs.harangi@geology.elte.hu)

Reconstruction of magma chamber processes is crucial to evaluate the possible style and as a consequence the potential hazard of volcanic eruptions. Presently there is a change in the paradigm concerning the view of magma chambers or magma reservoirs beneath active volcanoes. There are growing evidences that extended crystal mush zones and multiple open system processes play a major role instead of closed system evolution of magma chambers filled dominantly by silicate liquid. Whole rock composition often reflects the superimposition of several differentiation processes, including crystallization, dissolution, re-equilibration, magma-mixing etc. and thus, the bulk rock geochemical data should be interpreted with caution. Minerals, however, can be strongly sensitive to modifications in the circumstances (e.g., temperature, pressure, volatile content, redox condition) of the magmatic system. Textural and chemical variations of mineral phases could preserve even the complex magmatic processes and therefore, the combined in situ textural and compositional studies have been found to be a powerful tool for understanding the evolution of magmatic systems.

In the Carpathian-Pannonian region, a wide range of volcanic activities, fed by various magmas have occurred for the last 20 Ma. Recently, the members of the Volcanology Group of the Eötvös University have performed integrated textural and compositional investigations in different magmatic systems (basaltic, dacitic and rhyolitic) and could reveal the magma differentiation processes in detail. Here, a couple of key examples are presented to highlight the effectiveness of such research.

During the Miocene (20-12 Ma), repeated eruption of silicic magmas took place resulting in large volume ignimbrites and related fall deposits. Textural and in-situ major and trace element geochemical investigations of the still fresh juvenile glasses and the mineral phases of the ignimbrites and lithic clasts combined with quantitative model calculations revealed open-system magmatic processes, such as remobilization and mixing of crystal mush phases, mixing with variously differentiated melts and particularly the importance of ascent and intrusions of mantle-derived mafic magmas in the silicic magma reservoir.

The in-situ investigation of mineral phases in basaltic rocks formed from 11 to 0.13 Ma provided a new perspective to understand the genesis of mafic magmas. Results of a comprehensive survey on the variation of spinel compositions have shown heterogeneities in the mantle source region in various scales. Furthermore, a major difference could be inferred between the source regions of the mafic magmas in the western and eastern parts of the Pannonian basin.

The last volcanic eruption in this region occurred in the Ciomadul volcano only 30 ka. Complex magma chamber processes have been recognized even in single samples. Remobilization of an almost solidified, possibly granodioritic body by mantle derived mafic magmas, mixing of crystals with various origins and a vertically extended magma chamber has been reconstructed in the genesis of the lava dome rocks.

Compositional sequences in the "Dej Tuff" (Transylvanian Basin, Romania) as recorded by mineral chemistry

Szakács, Al.
Dept. of Environmental Science, Sapientia University, Cluj-Napoca, Romania (szakacs@sapientia.ro)

The rhyolitic Lower Badenian "Dej tuff" is the major (up to 116 m thick) volcaniclastic lithology of the Neogene Transylvanian Basin fill. It basically consists of a complex sequence of diverse lithological entities (coarse volcaniclastics, thick fine to medium-grained tuff beds and alternations of thin tuff and marl layers) mostly resulting from reworking of primarily land-deposited pyroclastic material generated by plinian-type explosive eruptions. Microprobe mineral chemistry of the main rock-forming minerals demonstrates the existence of compositional sequences within the "Dej Tuff" which do not fit the depositional sequences. An% of plagioclase feldspar (Fig. 1), composition and formation temperature of Fe-Ti oxides, along with variation trends in biotite and allanite composition, as well as overall primary mineralogical composition of the rocks themselves, show that the tuff complex records three succeeding and recurrent compositional sequences. Within each of them there is a consistent upward variation trend toward lower An% contents of feldspar and lower formation T of Fe-Ti oxides consistent with the presence of pyroxene and/or amphibole only at the base of the chemical sequences. Slight inter-sequence variation can also be pointed out by shift of the three succeeding sequences towards higher Fe-Ti oxide formation temperatures upward in the lithological sequence. These variation trends in mineral composition likely record varying magma chamber conditions prior to major eruption episodes. Three succeeding explosive eruptions tapped the compositionally and thermally zoned top of the feeding magma chambers hosting differentiated felsic magma derived from a deeper-lying magma of more basic (i.e. calc-alkaline andesitic) composition. It is surprising that the compositional sequences in the tuff complex mimics the right order of magma composition sequences in the magma chamber instead of the expected reverse order. The primarily land-deposited tephra has been reworked in the Transylvanian Basin sea preserving its original compositional zonation pattern, but in the order reproducing the true magma-chamber zonation.

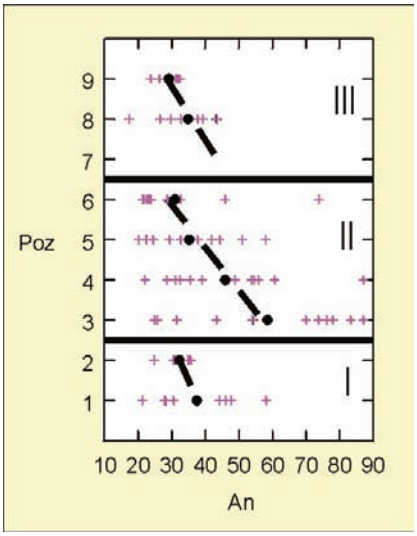

Fig. 1: An% (An) variation in plagioclase with position (Poz, 1 to 9) in the lithological sequence of the "Dej Tuff" at Cepari. Purple crosses are individual microprobe analyses. Black points show average An% for each position, and dashed lines connecting the points show variation trends of An% across tuff levels. I, II and III mark the three compositional sequences pointed out.

The Pleistocene alkali basaltic volcanism at the Perşani Mountains, SE Carpathians, Romania – inferences from olivine phenocrysts and their spinel inclusions

Sági, T.[1*], Harangi, Sz.[1] & Ntaflos, T.[2]
[1]Dept. of Petrology and Geochemistry, Eötvös L. University, Budapest, Hungary ([*]cseregle@gmail.com)
[2]Dept. of Lithospheric Research, University of Vienna, Austria

The Perşani Mountains are situated at the south-eastern part of the Carpathian-Pannonian Region (CPR). At the eastern margin, alkaline basaltic volcanism occurred in the Olt valley. Two active phases were distinguished here, at 1.2-1.4 Ma and 0.5-0.6 Ma, respectively [1]. We collected samples from the effusive products of both phases including also ultramafic xenoliths. Trace element composition of the basalts is fairly similar, although the Racoş basalt from the older phase shows a slight negative Nb-anomaly, whereas in the younger Barc basalt this cannot be observed. The primary magmas could have generated by very low degree of partial melting (about 1-2 %) of spinel-peridotite mantle source. Both basalts are olivine-phyric and the olivines contain commonly Cr-spinel inclusions. In this study we focused on the composition of these minerals to have an inference about the nature of the source regions. For this study the most primitive (Fo>84 mol%) olivine phenochrysts were chosen, in which spinel inclusions appear in the crystal cores. The compositional variation of olivines in the mantle xenoliths was used to estimate the magma ascent rate.

The Cr-spinels have high Al_2O_3- (25-40 wt%), low TiO_2- (<1.5 wt%) and medium Cr_2O_3-content (20-40 wt%). Their cr-number is relatively low (0.2-0.5). Most of the spinels seem to be liquidus phases; therefore their composition could reflect the nature of the residual source region. Their composition resembles the MORB spinels and reflects a MORB-type mantle source. This sharply contrasts what can be observed in the alkali basalts at the western part of the Pannonian basin. Furthermore, a slight change in the source region is inferred between the two eruption phases.

The most primitive olivine phenocrysts have Fo-content close to 90 wt% and they could be in equilibrium with the primitive basaltic melt. Following the calculation scheme proposed by [2], a mantle potential temperature of about 1350°C was calculated, i.e. no thermal anomaly exists beneath this volcanic field. Based on the temperature-dependent diffusion of Ca applied for olivine xenocrysts and olivines in the ultramafic xenoliths, we could estimate the ascending rate of magmas that could be just 1-2 days!

A mineral-scale investigation on the origin of the 2.6 Ma Füzes-tó basalt, Bakony-Balaton Highland Volcanic Field (Pannonian Basin, Hungary)

Jankovics, É.[1*], Harangi, Sz.[1] & Ntaflos, T.[2]
[1]Dept. of Petrology and Geochemistry, Eötvös Loránd University, Budapest, Hungary ([*]jeva182@gmail.com)
[2]Department of Lithospheric Research, University of Vienna, Austria

The Füzes-tó alkaline basalt is the youngest volcanic product of the Bakony-Balaton Highland Volcanic Field (BBHVF; western Pannonian Basin). It was formed by Hawaiian to Strombolian lava fountaining, which built up a scoria cone at 2.6 Ma [1].

The basaltic bombs and massive lava fragments have a unique mineral assemblage, suggesting a complex magma evolution. Approximately the half of the crystals is mantle-derived xenocryst, such as olivine, clinopyroxene, orthopyroxene and spinel. In addition, clinopyroxene and spinel megacrysts can be also found. Peridotite xenoliths are common; they are usually variously altered. The phenocryst assemblage involves olivine and clinopyroxene sitting in a groundmass consisting of clinopyroxene, olivine, plagioclase, Fe-Ti oxides and glass. Clinopyroxene phenocrysts often contain green xenocrystic cores. Thus, the Füzes-tó basalt does not represent a basaltic magma formed in the upper mantle, but a mixture of basaltic melt and mineral phases having various origins.

In spite of the abundance of the mantle-derived xenocrysts, ratios of incompatible trace elements (e.g., Zr/Nb and Nb/Y) could be effectively used to have an inference on the origin of the magma. These suggest that the primary magma was formed in the transitional spinel-garnet stability field, at the uppermost part of the asthenosphere. Spinel inclusions in the olivine phenocrysts provide further information about the nature of the mantle source. Two spinel populations can be distinguished: a dominant Al-rich spinel group (100*Cr/(Cr+Al)<42), which are rare in the alkaline basalts of the Pannonian Basin, and scarce Cr-rich spinels (100*Cr/(Cr+Al)>45). They have Al_2O_3 and TiO_2 content similar to the MORB-spinels (based on the diagram from [2]).

The olivine, orthopyroxene, colourless clinopyroxene and spinel xenocrysts derive from different depths of the subcontinental lithospheric mantle as inferred from their wide range of compositions. The green clinopyroxene cores in the clinopyroxene phenocrysts could represent either high pressure products of crystallization from a more evolved melt than the host magma or they could be derived from mafic lower crustal rocks. The compositions of the olivine and clinopyroxene phenocrysts reflect polybaric crystallization with a final, strongly oxidized stage.

Inferences for the role of primitive mafic magmas in the genesis of the dacitic magmas of Ciomadul (SE Carpathians, Romania): a mineral-scale study

Kiss, B.[1*], Harangi, Sz.[1], Vinkler, A.P.[1,2] & Ntaflos, T.[3]
[1]Dept. of Petrology and Geochemistry, Eötvös Loránd University, Budapest, Hungary ([*]geobalazs@gmail.com)
[2]University of Milano, Italy
[3]Dept. of Lithospheric Research, University of Vienna, Austria

In the Carpathian-Pannonian region, the last volcanic eruption occurred in the Ciomadul volcano at 30 ka. Considering the long repose time of the volcanic eruptions, the continuation of the volcanic activity cannot be unambiguously excluded in the future [1]. Thus, it is crucial to obtain detailed information about the behaviour of this volcano. The pre-eruptive magma chamber processes and the triggering mechanism could be effectively revealed by combined textural and mineral chemical investigation. Here, we report a unique example, where the role of primitive mafic magmas can be revealed in detail in the genesis of a dacitic volcano.

Two types of mafic mineral aggregates were recognized in one of the lava dome rocks: clinopyroxene (CPX) with FeS inclusions ± olivine (OL1) (hereafter T-1 assemblage) and olivine (OL2) with Cr-spinel (Cr-SP) inclusions (hereafter T-2 assemblage). Olivines have high Fo-content (85-90 mol%) and a CaO content >0.1 wt%. The OL2 contains tiny (10-20μm) euhedral Cr-SPs (Cr-number: 61-68). The clinopyroxenes are also magnesian (mg-number>0.85) and show a complex texture (patchy and/or oscillatory zoning) reflecting both crystallization and resorption. The core to rim analysis of CPX shows significant fluctuation in Cr_2O_3 together with mg-number. Remarkably, the crystal zones with high Cr_2O_3 and mg-number are found in the core and in the outermost rim. The texture, inclusions and composition of the mafic minerals in the dacite demonstrate their magmatic origin, i.e. from a fairly primitive basaltic magma replenished periodically by fresh magma batches. The OL2-type olivines show strong resorbtion in contrast to the OL1 and are surrounded by a breakdown assemblage of orthopyroxene + magnetite and mantled by oscillatory zoned amphibole. The CPX±OL1 assemblages, however, are rarely overgrown by amphiboles as OL2 and never mantled totally. These textural features suggest that the T-1 mafic mineral assemblage could have been incorporated into the silicic magma later than the T-2 mafic mineral assemblage, probably just before the eruption. Intrusion of the T-1-hosted basaltic magma into the dacitic magma chamber could provide the triggering mechanism of the eruption. Composition of spinels in the OL2-type olivines suggests a mantle source region with volcanic arc character.

Mineralogy and geochemistry of calcic and/or sodic skarn in the Ulsan Fe-W deposit, Korea

Choi, Seon-Gyu*, Kim, Ji Won & Seo, Jieun
Dept. of Earth and Environmental Sciences, Korea University, Seoul, Republic of Korea (*seongyu@korea.ac.kr)

The Ulsan Fe-W deposit is located within the Cretaceous Gyeongsang volcano-sedimentary basin, Korea. Development of skarn and ore mineralization occurs as a small roof pendant within the Upper Cretaceous sequence along the contact of a Tertiary epizonal granite stock and recrystallized limestone units with serpentinized ultramafic rocks. The deposit represents a unique opportunity to document geochemically the complex evolution of a calcic and/or sodic skarn system which is genetically related to a low sulfidation system. The Fe–W skarn deposit occurs as a nearly vertical ore pipe within recrystallized limestone at the direct contact with the Upper Cretaceous volcanic rocks containing thin layers of pelitic sedimentary rocks.

Calcic skarn is paragenetically characterized by early high-temperature anhydrous mineral assemblages that are dominated by magnetite and late low-temperature hydrous mineral assemblages with scheelite mineralization [1]. Calcic skarn is composed mainly of hedenbergitic clinopyroxene, calcite and andraditic garnet with minor vesuvianite, wollastonite, quartz, Ca amphibole, epidote, chlorite, siderite and ilvite. Albitite has been locally noticed in contact between serpentinite and albitized granite. Based on field relations and geochemical characteristics, the albitite appears to be derived from the Tertiary granite. Sodium enrichment zone in serpentinized ultramafic rocks is characterized by metasomatic textures. The calcic-sodic skarn contains unusual Na-rich clinopyroxene, Na-rich amphiboles (richterite), albite and Sr-bearing plagioclase as accessory phases. Maximum Na_2O concentrations of 6.44 wt.% and 6.53 wt.% are observed in clinopyroxene and amphibole, respectively. Pyroxenes in the sodic skarn show a wide range of variation in composition: diopside-hedenbergite and kosmochlor-acmite solid solutions. Textural evidence indicates that the first stage of skarn was formed as a result of chemical interactions between albitized granites and adjacent ultramafic rocks. The formation of Cr-bearing clinopyroxene and amphibole appears to be related to the release of Cr into the fluid phase by the breakdown of chromite during the prograde skarn stage.

Common origin of the latites erupted on Lipari and Vulcano islands (Aeolian Arc, Italy) in historical time

Davì, M.*, De Rosa, R. & Donato, R.
Dipto. Scienze della Terra, Università della Calabria, Arcavacata di Rende, Italy (*davi@unical.it)

Southern Lipari and Northern Vulcano (Aeolian Arc, Italy) are considered a single Volcanic Complex over the last 50 ka on the basis of petrography, geochemistry and structural studies [1 and references therein].

This study is focused on the historical activity of Lipari and Vulcano during the which intermediate products (i.e. latites) where erupted together with mafic (Vulcanello- Vulcano, 1100-1600 AD) or rhyolitic (Rocche Rosse - Lipari, 1230±40 AD; Commenda and Palizzi -Vulcano, 1200 AD) rocks. Latites were erupted both effusively, as enclaves in the rhyolitic lavas of Rocche Rosse [2] and Commenda or as unmingled lava flows (Palizzi and Punta del Roveto, Vulcano), and explosively, within Vulcanello III cone [3].

These latites are similar in geochemistry and petrography. The latite bulk rocks show the same major, minor and trace elements signature. Clinopyroxene ($Wo_{43-46}En_{39-44}Fs_{13-15}$, Mg#=0.72-0.76) is the dominant mineral phase followed by amounts of feldspar ($An_{25-60}Or_{12-9}$ and $An_{0-4}Or_{50-70}$) and olivine (Fo_{50-75}). The groundmass is microcrystalline with the same minerals occurring as phenocrysts.

Clinopyroxene ($En_{40}Fs_{13}$) of all latites has a homogeneous trace element composition with superimposed REE patterns (Eu/Eu* ~ 0.65 negatively correlated with Mg#). Plagioclase ($An_{50}Or_{10}$) of Commenda, Palizzi and Vulcanello products shows very similar trace element concentrations with a strong positive anomaly of Sr and very low HFSE contents. LREE patterns are also nearly coincident (Eu/Eu* in the range 6-10). K-feldspar (An_2Or_{65}) of Rocche Rosse and Palizzi products displays strongly similar incompatible trace element contents and coincident LREE patterns while HREE are below the detection limit (Eu/Eu* up to 41). Also olivine (Fo_{70}), investigated only within Rocche Rosse and Vulcanello latites, exhibits similar FME contents.

The microanalytical (LA-ICPMS) study led on the latite mineral phases of historical Lipari and Vulcano allows further investigating similarities between the lithotypes and constraining the historical magmatic systems in the southern sector of the Aeolian Islands. In fact, the trace element content of minerals is strongly related to several pre-euptive parameters (e.g. T, P, water content, magma composition), then the strong similarities among the crystals of different latites suggest a similar, if not the same, primitive magma, which underwent similar magma chamber processes. Geochemical models of major and trace elements suggest that the parental magma could have been the shoshonitic basalt younger than 15 ka found in the olivine melt inclusions within La Fossa cone 1888-1890 products [4].

W-molybdenite in Silurian meta-volcanic rocks of Northern Portugal

Dias, P.A.[1], Leal Gomes, C.[1] & Guimarães, F.[2]
[1]CIG-R – DCT, Universidade do Minho, Braga, Portugal
([*]patriciasdias@gmail.com)
[2]LNEG – S. Mamede de Infesta, Porto, Portugal

In Silurian metavolcanic formations of Serro (Serra de Arga, Minho, Portugal) proto-tuffitic felsic rocks, have disseminated sulphides (with pyrite-pyrrotite predominant), and some rare phases such as W-molybdenite, which occur in small sized crystals (±50 μm), idiomorphic (fig.1), oscillatory zoned (when viewed in EPMA – BSDE) and show a consistent compositional trend from core to rim – border enriched in Mo. W occurs in significant amount.

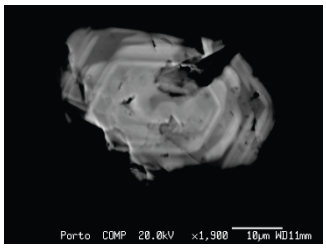

Fig. 1: EPMA - BSDE image of W-molybdenite.

Table 1: Representative core EPMA analysis of molybdenite (Fig. 1)

Fe =	0.17
S =	35.89
W =	14.79
Mo=	46.11
Total=	96.98

The W-molybdenite is considered an exceptionally rare phase formed in association to metasomatic processes: [1] showed experimentally the variability between Mo (molybdenite) and W (tungstenite) end members in the solid solution (Mo W) S_2; [2] observed W-Mo phases as scheelite hosted inclusions in replacement products in Ferbetal paradigmatic deposit; W rich-molybdenite was described by [3] in fenites of the Kola alkaline Complex.

In Serro, the presence of W-molybdenite in felsic meta-volcanics suggests peculiar conditions to the evolution in a primordial hydrothermal stage. According to the experimental data of [2] and [4], W enrichment in molybdenite is correlated with high sulfur activity during early crystallization.

The textural and compositional relationships of the observed crystals - oscillatory zoning, Mo-rich overgrowths and aspects of corrosion - suggest rebalancing with several and repeated fluctuations of oxidation degree (fO2) in the growth medium. According to [4], Mo enrichment to the rim is accompanied by increasing fO2.

The introduction of W in the system possibly accompanied water-interaction, concomitant with the deposition of sulphide mineralization, in a VHMS type model. The evolution to an oxygenated environment would reflect the observed deposition of vein tourmalinites (Cr-rich dravite) in tuffitic protoliths including W-molybdenite, possibly due to exhalitic remobilization. Also, it would facilitate the occurrence of molybdenite, without W content, which is observed in metafelsites, and scheelite, occurring in calcsilicate rocks and amphibolites of the same suites.

Petrography of lava flows in the northern area of Nevado del Ruiz Volcano, Colombia

Forero, J.A.[*] & Zuluaga, C.A.
Dept. of Geosciences, Universidad Nacional, Bogotá, Colombia
([*]jhaforerohe@unal.edu.co)

The Nevado del Ruiz Volcano (NRV), located in the Colombian Central Cordillera, has a high geothermal potential with an important energetic interest. We present a petrographic study of lava flows outcropping in the Northern area of the volcano, between La Plazuela creek and El Gualí river, as part of a geothermal exploration research project in the Nevado del Ruiz Volcano. The study includes petrographic characterization of fresh and altered rock samples of lava flows and their hydrothermal alteration products (about 30 samples).

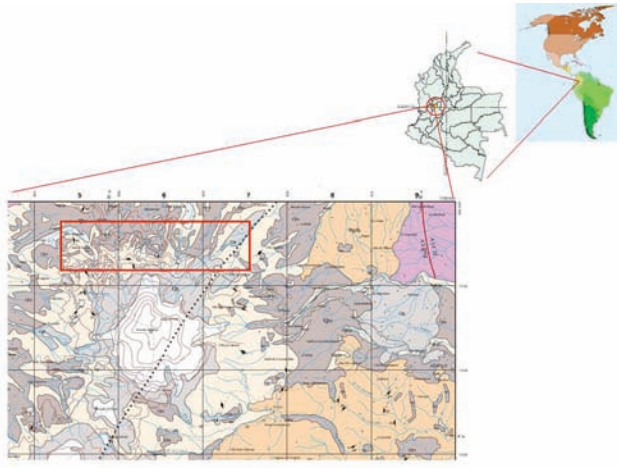

Fig. 1: Sketch geologic map of the study zone, the red rectangle highlight the sampled area.

Several authors [1-4] proposed two different lava suites based in their K content. The lavas with high K content represent almost the 98% of lavas in surface and have been classified as calc-alkaline andesite and dacite. We focus this study in identifying specific petrographic characteristics that allow us to infer the magmatic evolution of the system as well as identify alteration products that have been generated by the active and inactive hydrothermal systems in the study area.

With this study we hope to contribute to the understanding of the evolving volcano and its associated hydrothermal system studies knowing the potential of the system for the exploitation of geothermal energy.

Crystal chemistry of volcanic allanites indicative of naturally induced oxidation-dehydrogenation

Hoshino, M.[1], Kimata, M.[2], Chesner, C.A.[3], Nishida, N.[4], Shimizu, M.[2] & Akasaka, T.[5]
[1]Mineral Resource Research Group, Institute for Geo-Resources and Environment, Geological Survey of Japan - AIST, Tsukuba, Japan ([*]hoshino-m@aist.go.jp)
[2]Earth Evolution Sciences, University of Tsukuba, Japan
[3]Dept. of Geology and Geography, Eastern Illinois University, Charleston, IL, USA
[4]Chemical Analysis Division, University of Tsukuba, Japan
[5]Center for Tsukuba Advanced Research Alliance, University of Tsukuba, Japan

The crystal chemistry of volcanic allanites from the Youngest Toba Tuff (YTT), Sumatra, Indonesia and SK100 volcanic ash beds (SK100-VAB), Niigata, Japan has been investigated by electron microprobe analysis (EMPA), Fourier-transform infrared spectroscopic analysis (FTIR), and single-crystal structure analysis. In the FTIR study, based on the Diamond ATR accessory, YTT and SK100- VAB allanites were observed to have different OH contents, respectively (Fig. 1): the former has 0.64 wt% H_2O (OH: 0.40 apfu.), while the latter has 1.65 wt% H_2O (OH: 1.00 apfu.).

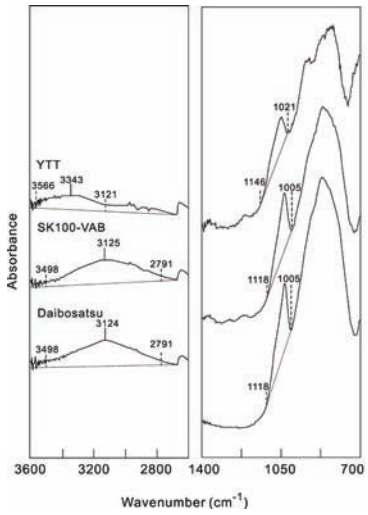

Fig. 1: FTIR-ATR spectra of the powdered allanites from YTT, SK100-VAB and Daibosatsu granitic pegmatite.

The crystal structures of these two allanites were refined to R= 3.64 and 4.25 %, respectively. The OH-poor YTT allanite has the shorter b axis, longer c axis, and larger β value than the relatively OH-rich SK100-VAB one. The bond valence sums of O4 (accepter oxygen for H atom) and O10 (donor oxygen for H atom) are 1.962 and 1.709 v.u. for YTT allanite (valence sum: 3.671 v.u.) and 1.754 and 1.271 v.u. for SK100-VAB one (valence sum: 3.025 v.u.). The difference from the ideal total bond valence value (4.00 v.u.) of O4 and O10 in YTT allanite (0.33 v.u.) is smaller than that in SK100-VAB (0.98 v.u.). These difference values are also broadly consistent with the corresponding differences in OH content between the YTT (OH: 0.40 apfu.) and SK100-VAB allanites (OH: 1.00 apfu.) determined by FTIR- ATR. Therefore, it is concluded that welding of the YTT caused the following post crystallization changes to occur in YTT allanite: oxidation of Fe^{2+} to Fe^{3+}, release of H_2, and the concomitant replacement of OH^- by O^{2-}. These oxidation and dehydrogenation processes advanced during the welding to thereby produce oxyallanite. Oxyallanite had been reported only in laboratory studies where it was produced by heating natural allanite. Our report on natural oxyallanite suggests that it may be present in other welded silicic volcanic rocks as well.

Textural and compositional features of zircons from the Ciomadul dacites (Romania)

Németh, G.[1*], Harangi, Sz.[1], Kiss B.[1] & Ntaflos, T.[2]
[1]Dept. of Petrology and Geochemistry, Eötvös University, Budapest, Hungary ([*]cordelia1987@gmail.com)
[2]Inst. of Lithosphere Studies, University of Vienna, Austria

The last volcanic eruption in the Carpathian-Pannonian region occurred at the Csomád (Ciomadul) volcano in the Eastern Carpathians (Romania), very close to the Vrancea seismic zone. Recent radiocarbon dating suggests that the youngest volcanic rocks were formed 30 ka. In order to evaluate the nature of this volcano, it is essential to understand the pre-eruptive magma chamber processes.

Zircon is a highly resistant mineral phase, durable to chemical and physical influences and particularly useful for geochronological investigations as well as to constrain the physico-chemical condition of the magma evolution. Combined textural and geochemical investigation of individual zircon grains along with the study of the enclosed melt inclusions could help to reconstruct stages of the magma chamber processes.

In this study we examined two samples from the Csomád volcano, one from a dacite lava dome and another one from a younger pyroclastic deposit. The zircon grains display different zoning patterns, such as patchy zoning, oscillatory zoning and unzoned to weakly zoned texture. This difference in texture is associated with a large range of trace and minor element (Hf, Th, U) composition. Variation in the Hf content implies crystallization at different temperature. The fairly high Hf concentration (>10000 ppm) is consistent with a near-solidus condition. In the patchy zoned zircons, we observed Th-U-rich and Hf-poor cores with abundant tiny pores and thorite inclusions. These could have been formed from a crustal magma at relatively high temperature. The oscillatory zoning with the fluctuation of Hf content suggests occasional perturbation of the crystallization temperature possibly due to replenishment of the silicic magma. The low-temperature outer zones and the high silicic rhyolitic melt inclusions indicate that the zircon grains could have been formed in an evolved crystal mush and were subsequently incorporated into the erupted hybrid dacitic magma.

A study on volcanic tuff deposits of the Outer-Carpathian region, Buzău county, Romania

Popa, R.G.*, Tita, P., Baratu, D.A. & Stochici, R.
Dept. of Mineralogy, University of Bucharest, Bucharest, Romania (*razvangabriel.popa@yahoo.com)

Proofs for volcanism outside the Carpathian Mountains have been looked for since the 1940's [1] but neither of them could confirm the suggested hypothesis. However, traces of activity are visible in the Outer-Carpathian space (east and south-east of the Eastern Carpathians), represented by mineral springs with permanent flow, hydrothermal mineralizations; and by Miocene volcanic tuff deposits which coincide with the volcanic activity of the inner-Carpathian volcanoes.

Our study signals the presence of volcanic tuff deposits within Oligocene formations, documenting them for the first time, and provides their first mineralogical analysis. The studied tuffs are located south of the Carpathians Bend Area, east of Sibiciu Valley, in the close proximity of Colți village, Romania. The area belongs to the External Marginal Carpathian Flysch Formation, more precisely to the Văleni protuberance [2], its main sedimentary characteristic being the Kliwa facies.

The field observations have emphasized extended stratified volcanic tuff outcrops (Fig. 1) in alternation with Kliwa sandstones (Oligocene) and centimetre-thick shale interlayers.

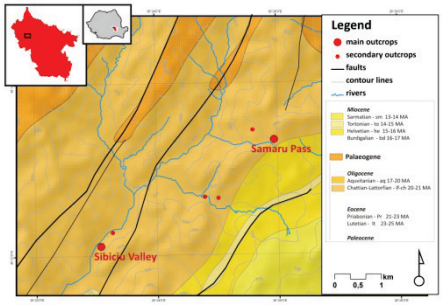

Fig. 1: Geological map of the studied area and location of tuff outcrops, reproduced after 29 L-35-XXI Covasna sheet, scale 1:200.000 (Geological Institute of Romania)

Optical microscopy revealed that these tuffs are dominated by vitroclasts (between 40-70 %) and crystaloclasts (up to 15 %) of which 10% quartz, 4% plagioclase feldspar and 1% biotite, potasic feldspar optically similar to microcline and chlorite pseudomorphosed most probably after pyroxene. Ghoetite is also identified under the same circumstances as chlorite. The remaining mass cannot be identified neither by optical nor by diffractometric means, being most probably composed of fine fragments of shards and crystals. Under diagenetic conditions, pseudomorphs of phyllosilicates have resulted, covering between 5- 50 % of the hyaline mass. Vulcanoclasts measure up to 0.12 mm and show angular, irregular shapes. Taking into consideration the quantitative representation of each mineral phase in contrast with the amount of volcanic glass, it can be stated that these tuffs were most likely related to an acidic, viscous magma that caused an explosive eruption.

In the hyaline mass siliceous diatomic frustules belonging most probably to the Coscinodiscus genre could be identified. In some tuffs frustules are perfectly conserved, while in others they were extensively transformed, crystallizing into quartz. Because of the frustules abundance, the chemical analysis of tuffs is not edifying when defining the original amount of silicon.

Native gold, vanadium and tellurium minerals in sublimates from high-temperature gases of Colima volcano, Mexico

Taran, Y.A.[1*] & Ostroumov M.[2]
[1]Institute of Geophysics, Universidad Nacional Autónoma de México, Mexico City, Mexico (*taran@geofisica.unam.mx)
[2]Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

Gases, condensates and silica tube precipitates (sublimates) were collected from a 800°C fumarole and hot (~600ºC) steaming ground at Colima volcano, Mexico. We used the silica tube experiments under temperature-controlled conditions for the study of mineral precipitates from volcanic gases. Some results of this study have been already published [1,2].

Here we report new findings and review all the data obtained. The main difference of Colima gas vents from other well studied high-temperature fumarolic fields (Kudryavy, Momotombo, Merapi, Satsuma-Iwojima, Showa-Shinzan) was a very diffuse emission of a hot air-magmatic gas mixture from the whole surface of the former summit dome. Therefore, the mineral set deposited on the inner wall of the silica tube was quite different from minerals of "common", reduced gases. We found in all three silica tube experiments native gold [2], V-sulfates and sulfides [1,3] and Te-sulfates which have never been found inside silica tubes and in natural incrustations before. Native gold was observed in natural incrustations at other volcanoes, but never in silica tubes. The deposited "pneumatolitic" material in silica tubes is close in chemical composition to a rich "high-sulfidation" ore body of precise metals. The observed distribution of metals along temperature gradient is in a good agreement with the modeled distribution using the SOLVGAS computer code with a modified thermodynamic data base. The redox-state and variability of mineral phases is discussed in details, in particular, the cause of the V- and Te- enrichment and the absence of "common" Mo and Cd phases in Colima sublimates. The REE abundances and distribution is also discussed.

Mineralogy, petrography, and geochemistry of the Permian syn-eruptive deposits in the Mecsek Hills, Hungary

Varga, A.[1,2*] & Raucsik, B.[3]
[1]Dept. of Petrology and Geochemistry, Eötvös L. University, Budapest, Hungary
[2]Hortseed Ltd., Mezőkovácsháza, Hungary
([*]andrea.varga.geol@gmail.com)
[3]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary

The upper Paleozoic succession of the Circum Pannonian Region records the change from the Pangean configuration and compressive regime inherited from the Variscan orogeny to the development of a broad zone of strike-slip and extensional basins [1]. For both tectonic settings intensive synsedimentary volcanism is characteristic and reworked volcanic materials became an integral part of the sedimentary filling sources [1,2].

In southern Transdanubia, SW Hungary, Permian sequences are represented mostly by continental siliciclastic rocks; however, volcaniclastic deposits are also documented [2]. Based on the previous state of knowledge, the upper Permian Cserdi Formation transgressively overlies the eroded surface of the lower Permian Gyűrűfű Rhyolite [1,2]. With respect to the lower part of the Cserdi Formation, however, petrography and geochemistry of the samples previously interpreted as alluvial fan deposits suggest a syn-eruptive volcaniclastic origin (moderately welded ignimbrite). The major goal of this study is to characterize the mineralogical, petrographic, and geochemical features of the Cserdi rocks from different wells (cores D 9015, XIII, and XV) in the western Mecsek Hills.

Based on our petrographic observations, the lower part of the Cserdi Formation consists of welded, poorly sorted fine to coarse tuffs, instead of lithic-feldspathic wacke to litharenite. These rocks are characterized by pumice and/or fiamme fragments with lithic and crystal fragments floating in a fine grained matrix. In the volcaniclastic Cserdi samples, volcanic ash and glass dominantly altered to clay minerals, although chlorite, feldspar and silica minerals are also formed. Other post-depositional processes such as devitrification, albitization, and anhydrite replacement are also common.

X-ray diffraction studies indicate that the mineral assemblage is dominated by quartz and albite. Hematite, illite±muscovite, K-feldspar, dolomite, smectite (S), and chlorite (C) is a minor to trace component. Clay fraction consists of illite (I; 80-90%), kaolinite (0-20%), and mixed-layer I/S or C/S (<10 %). Illite crystallinity (IC) values fall partly in the diagenetic zone (core D 9015, average: IC=0.66), partly in the anchizone to epizone (core XV, IC=0.19-0.39).

Compared with the non-volcaniclastic Cserdi rocks, the volcaniclastic Cserdi samples are enriched in high field strength (Th, Zr, Hf, Nb, Ta) elements, and are significantly depleted in first-row transition elements (V, Cr, Co, Ni, Zn). Therefore, discrimination between these rocks is possible using immobile elements such as Al, Ti, and Zr and first-row transition elements (e.g., $[V+Ni+Cr]/Al_2O_3$ *vs* Zr/TiO_2 diagram).

The mineralogical, petrographic, and chemical composition observed in the volcaniclastic Cserdi samples reveals primary characters and diagenetic modifications, as well as a local metamorphic overprint. These data suggest that combined petrologic and geochemical techniques are required to reconstruct the primary features of rocks and the nature of deposits in the Permian syn-eruptive and subsequent siliciclastic rocks from southern Transdanubia, Hungary.

Manitoba: a "hotspot" of carbonatitic magmatism in the Precambrian

Chakhmouradian, A.R.[1*], Böhm, C.O.[2], Mumin, A.H.[3], Coëslan, C.G.[2], Demény, A.[4], Reguir, E.P.[1], Simonetti, A.[5], Creaser, R.A.[6], Kamenov, G.D.[7], Kressall, R.D.[1] & Lepekhina, E.N.[8]

[4]Institute for Geochemical Research, Budapest, Hungary
[5]University of Notre Dame, Notre Dame, Indiana, USA
[6]University of Alberta, Edmonton, Alberta, Canada
[7]University of Florida, Gainesville, Florida, USA
[8]Center for Isotopic Research, VSEGEI, St. Petersburg, Russia

Identification of a carbonate rock as carbonatite is not always trivial, particularly in Precambrian settings affected by deformation. In such settings, carbonatite bodies can easily pass unrecognized during routine regional-scale mapping due to their small size, metamorphic fabric and obscured exposure. Carbonatites were not known in Manitoba prior to the discovery of soviet dikes at Eden Lake in the Paleoproterozoic Trans-Hudson orogen in 2002 [1]. The sövite intruded silica-saturated syenitic rocks of shoshonitic affinity, which were transformed into fenites at the contact. These rocks were emplaced after the assembly of the northern part of the orogen ca. 1815 Ma. The most remarkable textural characteristics of the Eden Lake sövite are the presence of microcline and aegirine-augite megacrysts and evidence of post-emplacement ductile flow and remobilization of rare-earth elements (REE). In the southern section of the orogen, beforsite was intersected by drilling in the SW part of Wekusko Lake. Beforsite dikes cross-cut Paleoproterozoic metasedimentary rocks and are not associated with any alkaline rocks. The carbonatite contains abundant phlogopite phenocrysts and diamond-indicator minerals, which explains the initial identification of this rock as kimberlite. This occurrence is much younger (560 Ma) and petrogenetically distinct from the Eden Lake complex. Immediately SE of the Trans-Hudson orogen, deformed Archean gneisses of the Superior craton host modally and texturally diverse calcite and calcite-dolomite carbonatites initially recognized during detailed mapping of the Paint Lake area [2]. These rocks occur as dikes exposed over 21 km of the Superior Boundary Zone. The carbonatites exhibit evidence of modal and cryptic metasomatism along the contact, and contain a variety of REE accessory phases (allanite, titanite, monazite and bastnäsite). Their textural diversity results from post-emplacement tectonic remobilization in the Paleoproterozoic. Further towards the interior of the craton, carbonatites were recognized in association with feldspathoid-syenitic and alkali-granitic rocks at Cinder Lake. The syenites host carbonate ocelli and veinlets, interstitial calcite, and are locally carbonatized and sericitized. The carbonate paragenesis consists of Sr-REE-rich calcite, phlogopite, magnetite, albite, apatite, monazite and britholite. The Cinder Lake complex formed ca. 2700 Ma during the consolidation of the Superior craton.

Our collective work shows that carbonatitic magmatism affected vast areas of the Canadian Shield outside the well-known extensional structures in northwestern Ontario, and spanned at least two billion years. These discoveries have far-reaching implications for the correct interpretation of the tectonic history of the Trans-Hudson orogen and Superior craton, and for mineral exploration in central Canada.

Petrology and petrogenesis of carbonatitic rocks in syenites from Central Anatolia, Turkey

Cooper, A.F.[1*], Durmus, B.[2] & Palin, J.M.[1]

[1]Dept. of Geology, University of Otago, Dunedin, New Zealand ([*]alan.cooper@stonebow.otago.ac.nz)
[2]Tunceli University, Tunceli, Turkey

The A-type Karaçayır pluton in Central Anatolia, Turkey, intrudes and entrains xenoliths of Paleozoic limestone. Carbonatitic magmatic rocks within the syenite have been previously interpreted [1] to result from metasomatic alteration and syntectic melting of marble.

Carbonatites and associated calcite-syenites exhibit mineralogical characteristics (Ab-rich plagioclases, Ba-rich K feldspars, low Mg# biotites) that are petrogenetically more evolved than the host syenitic suite. Carbonate-rich magmatic rocks are greatly enriched in Sr, Ba, Th, and REE, and have higher LREE/HREE ratios than either syenites or marbles. Carbonatites have $d^{13}C_{VPDB}$ and $d^{18}O_{VSMOW}$ of -2.1 to -3.5 ‰ and +10.4 to +11.5 ‰ respectively, compared to marble values of +1.5 to +2.7 and +18.9 to +26.3 ‰. Syenites have intermediate values between these two extremes. $^{87}Sr/^{86}Sr$ ratios of calcite-syenite and carbonatite average 0.70749, they are similar to foid syenite (0.70751) and significantly lower than marbles (average 0.70806). Overall, the mineralogical and geochemical characteristics of the carbonatites are incompatible with binary mixing of syenite and marble, but their origin is consistent with derivation of carbonatite from petrogenetically evolved foid syenite. Carbonate-silicate rock types have modal variations compatible with an origin by fractional crystallisation, rather than liquid immiscibility.

Carbonatites and associated nephelinites from São Vicente, Cape Verde Islands

De Ignacio, C.[1*], Muñoz, M.[1] & Sagredo, J.[2]
[1]Dept. Petrología y Geoquímica, Fac. Ciencias Geológicas, Universidad Complutense, Madrid, Spain ([*]cris@geo.ucm.es)
[2]Instituto de Geología Económica, CSIC, Universidad Complutense, Madrid, Spain

The island of São Vicente, in the northern part of the Cape Verde archipelago, has been credited for having the most abundant outcrops of carbonatite in those islands [1]. Field survey of its main outcrops has shown that they comprise: extrusive carbonatites forming part of eroded, poorly-exposed but still recognizable volcanic centres; carbonatite dykes; scattered blocks, sometimes resembling bombs, and small apophysis of intrusive carbonatite. These outcrops are occasionally crowned by nephelinite plugs and locally, nephelinite lavas are interspersed with carbonatite lenses, indicating that the same conduits might have been used by both kinds of magmas.

The volcanic carbonatites and dykes show flow texture and modal banding, where carbonate layers alternate with oxide-rich bands. In contrast, the intrusive carbonatite blocks show roughly equigranular, coarse-grained textures, and a wider range of rock-forming minerals including: clinopyroxene (aegirine-augite), iron oxides (magnetite-hematite), fluorapatite, K-feldspar (orthoclase), zircon and mica (phlogopite-biotite).

The three kinds of carbonatites, together with plug nephelinites have been sampled and analysed, for whole-rock geochemistry and mineral composition. Carbonatites define two distinctive geochemical groups. The volcanic ones and dykes are richer in MgO (7-10 wt%), Ba (7000 ppm) and REE (total rare earths = 2000-4000 ppm), also displaying high Sr contents (3000-5000 ppm). They plot close to and within the magnesiocarbonatite field in the classification scheme [2] and could represent more primary compositions. Intrusive carbonatites, however, range from Mg-bearing (5-6 wt% MgO) to Mg-poor (0.5-1 wt% MgO) calciocarbonatites, showing similar Sr contents to those of volcanic carbonatites and dykes, but remarkably lower Ba (300-400 ppm) and total REE (500-900 ppm). The latter seem to be mainly controlled by apatite.

Associated nephelinites contain Ti-rich diopside phenocrysts and small, aegirine-augite crystals in the matrix, together with nepheline, mica, apatite, Fe-oxides, pseudomorphosed olivine and, rhönite. Rhönite is, to our knowledge, described for the first time in the Cape Verde nephelinites. Its occurrence as euhedral, slender prisms with well-defined boundaries indicates that it is a primary phase, which attests for high Ti contents in the nephelinite magma. The rare-earth spectrum of the nephelinite displays the same pattern as the less-enriched, intrusive carbonatites, indicating a possible link between carbonatite and alkaline silicate magmas.

[1] Hoernle, K. et al.(2002) *Contrib. Mineral. Petrol.*, **142**, 520-542. [2] Woolley, A.R. & Kempe, D.R.C. (1989) in Bell, K. (ed.) *Carbonatites: genesis and evolution*. Unwin-Hyman, 1-14.

Graphite-bearing carbonatite of Dolbykha massif, Polar Siberia, Russia

Zaitsev, V.A.[*], Sorokhtina, N.V. & Kogarko, L.N.
GEOKHI RAS, Moscow, Russia ([*]va_zaitsev@inbox.ru)

Dolbykha is a small (~3 km^2) concentrically-zoned alkaline-ultramafic massif, located 75 km south of the Guli massif.

Dolbykha intruded Cambrian dolomitie, which was transformed to dolomitic marbles near the contact. The central part of massif consists of melteigites. These are surrounded by ijolites, and the outer part of massif consists of biotite and biotite-pyroxene carbonatites. Carbonatites of other types form concentric dikes.

This carbonatite is anchimonomineral calcitic rock (sovite) with minor amounts of dolomite, phlogopite, amphibole and K-feldspar. Accessory minerals are apatite, pyrite, graphite, and Nb-bearing rutile.

Graphite forms crusts on the carbonate crystals and intergrowths with phlogopite. G band FWHMs (24-34 cm^{-1}) in Raman spectra of the graphite correspond to temperature 320-500°C [1].

The formation conditions of the mineral association in the Dolbykha carbonatite can be estimated from the reactions:

3 Do +1 H_2O +1Kfs =3 CO_2+3 Cc +1Phl (1)

3 Do +1 H_2O +1 Kfs = 3 Cc +3 Grph +3 O_2 +1 Phl (2)

The reaction (1) allows estimation of the temperature of equilibrium as 400-500°C.

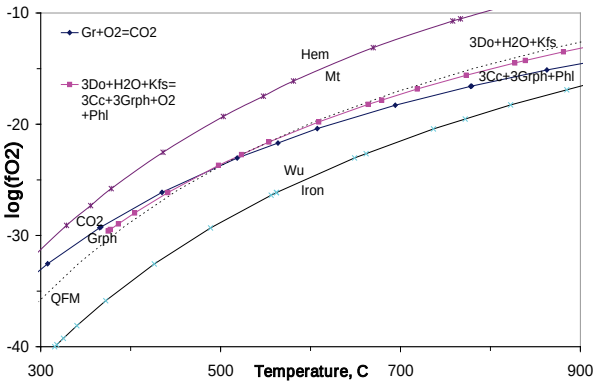

Fig. 1: f(O2)-T conditions for dolomite + K-feldspar + calcite + phlogopite + graphite association estimated by thermochemical calculations with program complex BAYES.

The equilibrium (2) allows estimation of the oxygen fugacity (Fig. 1). The topology of the T-f(O2) diagram (Fig. 1) shows that cooling along the QFM-buffered line results in formation of graphite, calcite and phlogopite after K-feldspar and dolomite at temperatures lower than 500-550°. This means that graphite can be formed as a result of the influence of the fluid, equilibrated with QFM-buffered rock in carbonatite at temperatures lower than 500°C.

Fingerprinting of kimberlite sources by isotope studies of accessory minerals: a mantle tracer

Sarkar, C.[1*], Storey, C.[2], Hawkesworth, C.J.[3], Sparks, S.[1] & Field, M.[4]
[1]Dept of Earth Sciences, University of Bristol, UK ([*]c.sarkar@bristol.ac.uk)
[2]Dept. of Earth and Environmental Sciences, University of Portsmouth, UK
[3]Deputy Principal and Vice-Principal for Research, University of St Andrews, Scotland, UK
[4]DiaKim Consulting Limited, Wookey Hole Wells, UK

Interest in determining the radiogenic isotope and trace element geochemical characteristics of uncontaminated kimberlitic magma has been rekindled by recent studies of accessory groundmass minerals e.g., perovskites, which are strongly resistant to isotope modification [1]. In-situ Sr, Nd, and Hf isotope data along with U-Pb geochronology on perovskites have been preferred over bulk rock studies and they have been interpreted as the primary geochemical signature of kimberlite magma [2,3].

In this study we have analysed several individual groundmass perovskites from different litho-facies of Group I kimberlites of Orapa, Botswana to investigate the trace element and isotope characteristics of the source material and how they vary among different lithofacies. Both in-situ (LA-MC-ICPMS) and solution (MC-ICPMS) analyses have uniform Nd isotopic composition with an average $^{143}Nd/^{144}Nd$ ratio of 0.512742 ± 34. But the initial results show that the $^{87}Sr/^{86}Sr$ ratios of individual grains are heterogeneous and vary from 0.703590 - 0.705407 ± 22. Samples with more radiogenic Sr also correlate with HREE enrichment. In a εNd vs $^{87}Sr/^{86}Sr$ diagram all samples plot within the Group I kimberlite field, defined by whole rock analyses, and they are interpreted to be derived from a primitive mantle source.

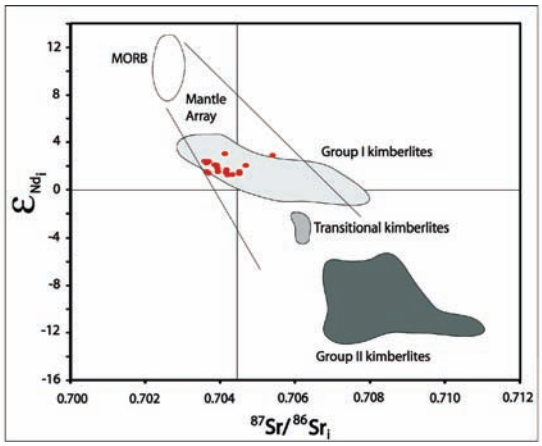

Fig. 1: εNd_i vs $^{87}Sr/^{86}Sr_i$ of perovskites from Orapa along with fields showing group I, group II and transitional kimberlites.

Though the uniformity of the data from perovskites compared to the bulk rock analysis emphasises their reliability over bulk rock geochemistry, some of the variation in Sr isotopes might be a result of post emplacement hydrothermal alteration, which is not always visually recognised. It may be that the perovskites are not as resistant to isotope modification as previously thought and, therefore, more care should be taken while interpreting the geochemical data from perovskites.

[5]Geological Survey of Canada, Ottawa, Canada

The diamondiferous Catoca and Cucumbi-79 kimberlite pipes are located on the Kasai Craton, Angola. Different suites of mantle xenoliths have been characterized by optical petrographic and SEM-BSE studies.

Three types of xenoliths are found in Catoca: eclogites, garnet clinopyroxenites (with G9 [1] garnets and chromian dipside), and garnet lherzolite (with G9 garnets and chromian diopside). Phlogopite is found as a rare accessory in Catoca peridotites. In contrast, the Cucumbi-79 kimberlite contains at least the following types of xenoliths: garnet clinopyroxenites (with G5 garnet, diopside and phlogopite), garnet lherzolites (showing different proportions of G5 or G9 garnets, chromian diopside, enstatite and phlogopite), PIC suite xenoliths (phlogopite, ilmenite, diopside) and glimmerites.

Two main different trends for garnet can be identified in Catoca depending on the REE patterns. Eclogitic garnet has "normal" [2] REE_N patterns, while garnet from lherzolite xenoliths usually has "sinusoidal" [2] REE_N patterns and rarely "normal" REE_N patterns. Eclogitic clinopyroxene is LREE-enriched. Garnet from the lherzolite xenoliths is characterized by a LREE-enrichment, a maximum around the LREE-HREE limit and flat HREE. Unlike in Cucumbi-79, garnet from lherzolite xenoliths presents "normal" patterns with lower REE values. Garnet from phlogopite-rich xenoliths presents "normal" patterns, but their values are significantly (about 10x chondritic value) lower. Only clinopyroxene from phlogopite-rich xenoliths exhibits higher values in LREE than the same xenoliths in Catoca.

Data indicate that the mantle sampled by these two kimberlites might have been under different equilibration conditions and different degrees of metasomatism. Hence, the "normal" pattern exhibited by the Cucumbi-79 garnets might be explained as the result of refertilization of previously depleted peridotite by infiltration of melt [3]. In contrast with garnet patterns in Cucumbi-79, the "sinusoidal" REE_N patterns of garnet from lherzolite xenoliths in Catoca may be the result of different degrees of re-enrichment in incompatible elements.

Trace element distribution in carbonatites from Vuorijarvi (Kola Peninsula, Russia)

Smith, B.* & Downes, H.
Dept of Earth and Planetary Sciences, Birkbeck University of London, UK (*barbara.smith28@btopenworld.com)

The Vuorijarvi ultramafic carbonatite complex belongs to the Palaeozoic Kola Alkaline Province. The poorly exposed dyke system at Vuoriyarvi is representative of silica-rich sövites. Geochemical studies were performed on major and trace element distribution in some of the less common minerals in the carbonatites such as monticellite, pyroxene, kimzeyite and phlogopite, as well as the common ones like calcite, apatite and perovskite. Calcite in all the samples exhibits a polygonal recrystallised texture. There are morphological indications of immiscibility between silicate liquid and carbonate or phosphate liquids illustrated by features such as globules and dumbells of calcitic and apatitic composition present in monticellite. Perovskite is very rare, but typically contains numerous apatite and calcite inclusions, giving it an unusual spongy appearance. The rare kimzeyite garnet forms relatively large grains (up to 1mm). The unusual character of kimzeyite lies in its high ZrO_2 content which can be >12 wt%. The striking similarity of perovskite and kimzeyite (Fig. 1) regarding the shape, size, sporadic occurrence and association with apatite suggests that both minerals crystallised in similar condition but probably not in the system which is hosting these phases now.

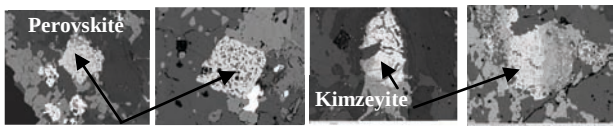

Fig. 1: Perovskite in Vuorijarvi sövite (BR18 left and B218 to the right). Photomicrographs of rare Zr-rich garnet in BA18A and B218A respectively, both intimately associated with apatite.

EPMA analyses show moderately high concentration of Sr in calcite (1-1.5 wt% SrO), typical for a primary carbonate phase. Apatite contains 0.9-1.2 wt% F, classifying this phase as a fluorapatite. The mg# in phlogopite varies from 0.88 to 0.91 but is lower in xenocrystic phlogopite (0.87), suggesting crystallisation from a host liquid slightly depleted in MgO. Rare olivine has high mg# = 0.90, whereas that of monticellite is much lower (0.77-0.79).

Constituent minerals in sövite were analysed for trace elements using LA-ICP-MS (Fig. 2). Perovskite and apatite are strongly enriched in LREEs whereas calcite and phlogopite are 3-4 orders of magnitude lower, with phlogopite displaying anomalously higher MREE concentrations. Monticellite is slightly enriched in HREEs. Most of the analysed minerals are characterised by very high La/Lu ratios (900 for perovskite and 100 for apatite) although La/Lu=40 in calcite and 0.5 in monticellite, suggesting that some phases in carbonatites have taken an important part in the fractionation of the REE.

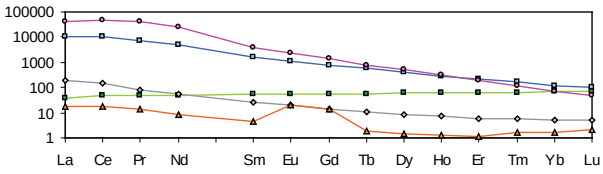

Fig. 2: Average REE distributions pattern in sövite (chondrite-normalised) of the fallowing phases: perovskite (pink), apatite (blue), calcite (grey), monticellite (green), and phlogopite (orange).

Trace element partition coefficients for apatite, calcite and carbonatite melt at crustal pressures and temperatures

Wall, F.[1*], Rosatelli, G.[2] & Jeffries, T.[3]
[1]Camborne School of Mines, University of Exeter, Penryn, UK (*f.wall@exeter.ac.uk)
[2]Dipto. di Scienze della Terra, Universita` G. d'Annunzio, Chieti, Italy
[3]Dept. of Mineralogy, Natural History Museum, London, UK

Partition coefficients are essential for modelling petrogenetic processes. Understanding the fractionation of REE in carbonatitic systems has applications to problems ranging from formation of REE ore deposits to mantle metasomatism. Apatite and calcite are key and almost ubiquitous minerals in carbonatites and thus important controls on REE distribution.

There have been few studies of partition coefficients in carbonate magmas. Apatite-carbonatite melt partition coefficients determined by experiment at 1 GPa, 1250°C, showed that REE are incompatible in apatite [1] and contrasted with coefficients calculated during a trace element study of apatites in various intrusive carbonatites [2].

In this study, we have isolated carbonatite lapilli from calcite carbonatite lapilli tuff at Kaiserstuhl, Germany [3], assumed that these represent a melt composition and analysed them by whole rock ICP-AES and ICP-MS to determine major, minor and trace elements. We have then determined the trace element contents of apatite and calcite (and pyrochlore) by LA-ICP-MS analysis and calculated the partition coefficients.

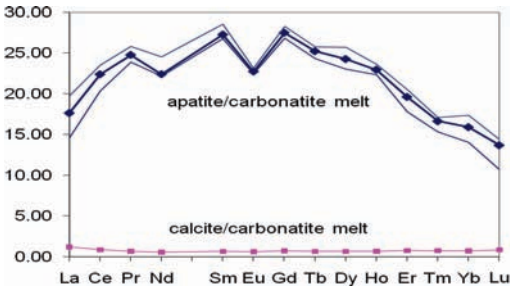

Fig. 1: Partition coefficients for REE in apatite and calcite in calcite carbonatite.

The apatite-carbonatite melt partition coefficients of 14 - 27 calculated here for the REE (Fig. 1) are two orders of magnitude higher than the values calculated from experiment [2]. Results from silicate magmas found that apatite REE partition coefficients are higher in melts with high SiO_2 content and also higher at lower temperature but vary little with pressure [3]. Our K_d values are of similar order to the values calculated using trace element compositions of apatite in intrusive carbonatites [2]. These would have crystallised at lower P and T than used in the experiments [1] and by analogy with silicate melts, the temperature difference in particular could have a large effect on the values. We conclude that the partition coefficients presented here are useful for calculations involving emplacement and crystallisation of carbonatites. The lower apatite coefficients at high P and T, coupled with the low partition coefficients for calcite, even at crustal P and T, could help to explain why deep-seated volcanic carbonatites have low REE.

Hudsonite, an alkali-amphibole-dominant ultramafic rock associated with magnetite deposits in the Hudson Highlands of New York

Martin, R.F.[1*] & Lupulescu, M.V.[2]
[1]Earth & Planetary Sciences, McGill University, Montreal, Canada ([*]robert.martin@mcgill.ca)
[2]New State Museum, Research and Collections, Albany, New York, USA

The Hudson Highlands, in southeastern New York, are the site of a swarm of unusual alkali-rich amphibole-dominant peridotites emplaced in upper-amphibolite- to granulite-facies rocks of Grenvillian (Proterozoic) age. The intrusive rocks are coarse-grained, undeformed, and cut their host rocks with a sharp contact. They are spatially associated with small deposits of magnetite that were exploited 150 years ago. The peridotites do contain magnetite, and may also contain net-textured disseminations of pyrrhotite with pentlandite domains and chalcopyrite. They invariably also contain coarse crystals of phlogopite and, locally, almandine interpreted to be xenocrystic, and also subject to gravitational accumulation. Because of the local presence of interstitial calcite, and of the inferred dominance of CO_2 in the early postmagmatic fluid phase, the olivine is still fresh. The primary rock-forming amphibole is hastingsitic, and rather unusual in being enriched in K and the halogens. Some localities contain a chlorine-dominant K-rich calcic amphibole, whereas elsewhere in the vicinity, fluorine is the dominant halogen. The Greenwood iron mine, in Orange County, is the type locality of fluoro-potassichastingsite, a newly defined end-member [1], ideally $KCa_2(Fe^{2+}{}_4Fe^{3+})Si_6Al_2O_{22}F_2$ (Mg# 0.33, 1.24% Na_2O, 2.93% K_2O, 2.23% F, 0.61% Cl). The amphibole is LREE-enriched. Along with accessory phlogopite, it is the last phase to crystallize, and constitutes the intercumulus phase amidst Cpx + Ol cumulates. It is a property of such amphiboles to approach the bulk composition of a magma of OIB type; for this reason, an unusually coarse grain-size is typical. In view of the variable enrichment in F or Cl, the presence of xenocrystic almandine, the presence of Cpx + Ol cumulates, and saturation in a sulfide melt, the alkaline magmas are considered ultimately of asthenospheric derivation, emplaced at a stage of tectonic relaxation after the culminating Grenville collision in this area, but highly modified by assimilation of granulitic lower crust in which the plagioclase-bearing assemblages had largely been destroyed by alkali metasomatism. How does one classify such ultramafic rocks? The term “cortlandtite” refers to a subalkaline hornblende-dominant peridotite, and thus does not seem relevant; we prefer to revert to the name originally applied to these alkaline peridotites, *hudsonite*.

Mineralogy of carbonatized mantle beneath Antarctica (Oasis Jetty)

Kogarko, L.N.
Vernadsky Institute of Geochemistry and Analytical Chemistry, Moscow, Russia (kogarko@geokhi.ru)

Some mantle-derived East Antarctic rocks have bulk-rock and mineral trace element and isotopic compositions that provide evidence of strong carbonate metasomatism. 46 spinel and garnet peridotite xenoliths from lithospheric mantle beneath Lambert-Amery Rif were studied. Investigated spinel and garnet peridotite xenoliths represent about 80 km thick cross of subcontinental litospheric mantle.

Distinct correlations is observed between contents of MgO and other petrogenetic elements CaO, Al_2O_3, FeO, Na_2O, Co, Ni, V. Comparison of these correlations with estimated trends of batch and fractional melting of initially fertile mantle peridotite [1] demonstrate that Jetty peridotites plot at lower values for SiO_2 and other components.

Garnets are characterized by positive europium anomaly, unusual high LIL element concentrations (Ba/La=4000) and clinopyroxenes from the spinel peridotite suite are highly enriched in LREE [$(La/Yb)_N$ =14] and in HFSE.

The decoupling of major and REE elements and observed mineral assemblages (which include dolomite, calcite, Sr- and LREE-rich apatite,Ti- Ba-rich phlogopite, titanite, perovskite, henrymeierite) indicate that the upper mantle of East Antarctic has been affected by very strong metasomatism.

Henrymeierite was found in mantle material for the first time [2].

Our isotopic data showed complete absence of isotope equilibrium among the rock forming minerals in the xenoliths – Opx, Cpx and Grt. Garnets are characterised by the most radiogenic Sr isotope composition (0.709024-0.714127), whereas Cpx exhibits the lowest $^{87}Sr/^{86}Sr$ ratios (0.702861-0.703711). On the one hand garnets are depleted in terms of Sm-Nd system and on the other hand they are significantly enriched in radiogenic Sr. Such anomalous signature in Antarctic mantle rocks confirm the influx of carbonate metasomatising fluid (or melt) from the source with a time integrated LIL-elements enrichment and more rapid Sr but not Nd diffusion to garnets compare to Cpx.

It is probable that the interaction of primary dolomitic melts-fluids with mantle material according to reactions:
$2Mg_2Si_2O_6+CaMg(CO_3)_2 = 2Mg_2SiO_4+CaMgSi_2O_6+2CO_2$ (1)
$3CaMg(CO_3)_2+CaMgSi_2O_6 = 4CaCO_3+2Mg_2SiO_4+CO_2$ (2)
resulted in wehrlitization and carbonatization. The fluids responsible for this metasomatism were probably derived from the plume that arrived beneath the region at this time.

High-pressure experiments on anhydrous carbonated eclogite at 9-20 GPa – implications for the recycling of carbonate into the mantle

Kiseeva, E.S.[1*], Litasov, K.D.[2], Yaxley, G.M.[1], Ohtani, E.[2] & Kamenetsky, V.S.[3]
[1]Research School of Earth Sciences, Australian National University, Canberra, Australia ([*]kate.kiseeva@anu.edu.au)
[2]Tohoku Univesity, Aramaki Aoba-ku, Sendai, Japan
[3]CODES and School of Earth Sciences, University of Tasmania, Hobart, TAS, Australia

Significant amounts of carbonates may be subducted with the high pressure form of oceanic mafic crust (eclogite) deep into the mantle. However, little experimental work has investigated the fate of subducted carbonated eclogites deeper than about 300 km (>10 GPa). We present the phase relations and solidus temperatures of carbonated eclogite compositions at 9-20 GPa.

Multianvil experiments were conducted using the 3000-ton press at Tohoku University, Sendai at 9, 13, 17, and 20 GPa, and from 1200 to 1800°C. The experimental compositions were GA1 (average MORB) and Volga (GA1-6.5% SiO_2) [1] with the addition of 10% of calcite (10%cc).

The subsolidus mineral assemblages varied with pressure, although garnet (Grt) was the most abundant phase in all runs. At 9 and 13 GPa, clinopyroxene (Cpx), carbonate (Carb) (both calcitic and magnesitic), a high-pressure modified form of rutile (Ru) (only at 9 GPa) and minor stishovite (St) were also observed. No K-rich phase was detected and we infer that K partitions entirely into Cpx (0.3-0.6 wt% K_2O). At 17 GPa Cpx was no longer present; the assemblage consisted of Na-rich majoritic Grt, Carb (both calcitic and magnesitic) and K-hollandite (K-Holl), which contained most of the K. St was observed in most of the runs at 17-20 GPa. At 20 GPa, CAS (in GA1+10%cc) and Ca-perovskite (Ca-Per) (in Volga+10%cc) appeared in addition to Grt and calcitic Carb. K-Holl was also detected at low temperatures. In most GA1+10%cc and few of Volga+10%cc diamonds crystallised, coexisting with crystalline Carb.

Above-solidus runs contained carbonatitic melts in which the amount of alkali elements (Na, K) increased with pressure. None of the runs reached more than about 25% melting and the main melt-contributing phases were Carb, Ru, Cpx in lower pressure runs and K-Holl, CAS, Ca-Per, Carb in high-pressure runs, leaving St and Grt residual phases.

A striking feature of the new data is the relatively flat solidus located between 1200 and 1300°C at all investigated pressures. This may be the result of the relative incompatibility of Na_2O and K_2O with increasing pressure. In the lower pressure runs, Na behaves compatibly due to the high stability of the jadeite component in Cpx. With increasing pressure progressive dissolution of Cpx into majoritic Grt may lead to Na becoming incompatible and it may flux melting at a sodic carbonate solidus. Although being located at lower temperatures relative to other (K-free) carbonated eclogite studies [2] it remains at higher temperatures than the hottest estimated subduction geotherm (e.g. [3]), in good agreement with previous, lower pressure studies [4-6]. Thus, subducting carbonates in eclogite may reach the deep convecting mantle, where they may partially melt to produce carbonate-rich liquids which could have a role in fertilizing the surrounding peridotite mantle and producing enriched magma sources.

Alkaline magmas and carbonatites, the ultimate source of granulite fluids

Touret, J.L.R.
Musée de Minéralogie, Mines-Paristech, Paris, France (jacques.touret@ensmp.fr)

Lower crustal granulites, at world scale, have been invaded at peak metamorphic conditions by large volumes of low H_2O-activity (dry) fluids, either high-density, pure CO_2 and/or highly saline aqueous solutions (brines) [1]. Even if it cannot be excluded that some fluids, notably brines, are locally derived, a number of concordant evidences suggest that most of these fluids originate in the mantle, transported into the lower crust by mantle-derived, synmetamorphic intrusives. Fluid inclusions identical to those found in granulites occur also in a number of mantle minerals, including diamond [2]. Regarding CO_2, the case of lake Nyos (Cameroon) illustrates a possible way by which this fluid has been generated at depth [3]. In mantle lherzolitic xenoliths, inclusions occur predominantly, if not exclusively, in clinopyroxenes, whereas neighbouring olivine and, to a lesser extent, orthopyroxene, are virtually inclusion-free. Maximum CO_2-density preserved in inclusions is well above 1.1 g/cc, corresponding to an internal pressure at magmatic temperature of at least 1 GPa (30 km depth). These values are minimal, corresponding to the maximal overpressure that the inclusion host mineral can stand, not too far away of pressure at which carbonatite melts would destabilize during mantle melting (about 2 GPa). The geochemical signature of these xenoliths shows precisely metasomatic contamination by carbonate-rich melts [4]. I consider these melts as the primary source for CO_2, according to a tentative reaction: olivine (or orthopyroxene) + carbonate → clinopyroxene + CO_2.

Brine inclusions are much rarer than CO_2-ones in mantle-derivates, but not absent. Besides diamonds, they have recently been found in amphibolite-bearing peridotite from Ethiopia [5]. The fluid source is assumed to be recycled oceanic lithosphere. Brines as well as CO_2 can thus be generated in the mantle, prior of being transported into the lower crust by synmetamorphic, dominantly alkaline intrusions.

The crucial role of lithosphere structure in the generation and release of carbonatites: geological evidence

Woolley, A.R.[1*] & Bailey, D.K.[2]
[1]Dept. of Mineralogy, Natural History Museum, London, UK
([*]a.woolley@nhm.ac.uk)
[2]Dept. of Earth Sciences, University of Bristol, Bristol, UK

In recent years there has been a significant increase in the numbers of known carbonatite localities. The new occurrences have been incorporated into a comprehensive database and world distribution map [1]. They support previous observations of spatial and temporal aspects of these rocks, but also provide new observations that are important for understanding their petrogenesis. The data reveal that there is an overwhelming concentration of carbonatites in Precambrian cratonic areas, most of which are generally elevated topographically. Thus, although approximately two thirds of carbonatites are Phanerozoic in age, at least 86% of all carbonatites are located in the cratons, demonstrating a remarkable tendency for a Precambrian host. This observation is noteworthy as suggesting a link with kimberlites, which are similarly concentrated in cratonic areas, with diamondiferous kimberlites being confined to the Archaean [2]. The collected age data confirm that in many carbonatite-bearing provinces there has been repetition of carbonatite emplacement, with up to five such episodes being separated by hundreds of millions of years. In at least three provinces such activity extends from the late Archaean to relatively recent times and, because of the drift of the plates, this precludes any role for mantle plumes in carbonatite genesis. Instead it underlines the importance of structural control within the continental lithosphere. A model involving lithosphere metasomatism and lithosphere focussing in structurally controlled areas is therefore invoked.

Deep mantle melting and carbonatitic activity in the mantle beneath central Spain

Humphreys, E.R.[1,2*], Bailey, K.[1], Hawkesworth, C.J.[1,3], Wall, F.[2,4] & Jeffries, T.[2]
[1]Dept. of Earth Sciences, University of Bristol, UK
([*]emma.humphreys@bristol.ac.uk)
[2]Dept. of Mineralogy, Natural History Museum, London, UK
[3]University of St Andrews, UK
[4]Camborne School of Mines, University of Exeter, Penryn, UK

A single crystal of aragonite demonstrates the high-pressure origin of volcanism from Calatrava, Spain. High-pressure and high temperature experimental determinations on the stability of aragonite constrain it to greater than 100km depth, assuming a H_2O+CO_2 bearing mantle lithology. In Calatrava, the lithosphere is estimated to be ~80km thick. Therefore this volcanism may have sampled the sublithospheric mantle and melting is predicted to originate below 100km. Rapid ascension and quenching is required to maintain the aragonite crystal structure. The fine-grained leucitite groundmass and glassy carbonate-silicate melt inclusions also indicate rapid quenching.

The aragonite occurs as an inclusion within olivine (Fo_{87}) from a leucitite lava flow. Olivine is xenocrystic and inclusions of carbonate are common. Carbonate inclusions typically occur as calcite, dolomite or aragonite. Only one example of aragonite has been identified, but many other examples of poly-crystalline calcite with radiating fractures in olivine suggest calcite after aragonite. We observe two distinct groups of inclusions; those with euhedral to subhedral outlines, usually composed of carbonate. The second group have rounded outlines and contain carbonate and coexisting silicate glass or silicate minerals.

LA-ICPMS of individual carbonate inclusions reveal their absolute trace element concentrations and the variation that exists between inclusions. Figure 1 details our results for twenty-three inclusions. Primitive mantle normalised rare earth element concentrations vary over two orders of magnitude, but have similar profiles and are low (<1*Primitive mantle, PM). There is some evidence of light rare earth enrichment, but otherwise the profiles are flat. A negative Ce anomaly is observed in all inclusions, including aragonite (thick blue line, fig. 1).

Petrographically, most inclusions studied show no evidence of interaction with the host magma. Therefore, the trace element profiles of many inclusions may be derived from a carbonated mantle melt. The melt was either trapped by growing olivine phenocrysts, or crystallised, in the case of aragonite, with olivine at high pressures (~3GPa). Our observations suggest that REE contents of high-pressure carbonates are low. Our observations of the REE content of carbonate from the leucitite groundmass show enrichments of LREE up to 100*PM suggesting that REE become more compatible in carbonates at lower pressures.

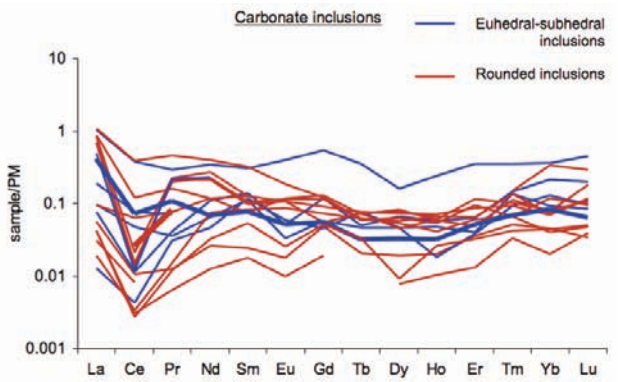

Fig. 1: Rare earth element analyses of carbonate inclusions.

The kinship between lamprophyres and carbonatites: evidence from the south coast of Ireland

Brady, A.* & Moore, K.R.
National University of Ireland Galway, Ireland
(*a.brady9@nuigalway.ie)

Explosive pipes, dykes and sills of phlogopite-bearing lamprophyric and carbonatitic compositions occur in three groups along the coast in County Cork, Ireland (Moore et al, this volume). The lithologies present are summarised in the following groups: xenocryst and xenolith-bearing alkaline ultramafic lamprophyres (Al-UML) of aillikite affinity, xenocryst and xenolith-free alkaline lamprophyres (AL), dolomite-silicocarbonatite, calcite-silicocarbonatite, and subordinate carbohydrothermal calcite-carbonatite. All silicocarbonatite lithologies also contain accidental material. Xenoliths include pargasite-clinopyroxenite.

The Al-UML has high but variable Mg number (59 – 70), and Cr, Ni and V concentrations (up to 419 ppm, 445 ppm and 236 ppm respectively), characteristic of primitive mantle-derived magmas. The alkaline lamprophyres contain higher SiO_2, Al_2O_3 and Na_2O, and lower Mg (27 – 65), Cr and Ni than the Al-UML. However, overlapping major element concentrations and similar concentrations of trace elements suggest that the alkaline lamprophyres are not related to the Al-UML solely by fractionation from a single parent magma, but by progressive overstepping of the solidus in shallower mantle with some subsequent fractionation.

Dolomite-silicocarbonatite contains magnesite and Cr-spinel macrocrysts≤ (40.14 wt.% Cr $_2O_3$), low REE concentrations and exceptionally high Ni and Cr concentrations (up to 971 ppm and 868 ppm respectively). The major element composition and the presence of elevated Ni and Cr content is consistent with both experimental data and the composition of established primary mantle-derived dolomite carbonatites worldwide. Calcite-silicocarbonatite composition contrasts with that of the dolomite-silicocarbonatite in that it contains a lower Mg-number, higher REEs in addition to a pronounced negative Ta anomaly. Phlogopite in calcite-silicocarbonatite contains less titanium than phlogopite that crystallised from the primary magmas, while bulk titanium concentration remains relatively constant. Variations in phlogopite compositions occur due to increasing oxidation of evolving magmas, which promotes the crystallization of Ti-magnetite. Thus, the evolved phlogopite compositions in calcite-silicocarbonatite do not reflect a primary magma from the mantle and the bulk rock geochemistry suggests that the calcite-silicocarbonatite has not fractionated from the dolomite-silicocarbonatite.

The possibility that a continuum between carbonatite and ultramafic lamprophyre exists as a consequence of melting of a carbonated mantle has been experimentally proven [1]. However, observed rock major and incompatible trace element patterns, and xenolith compositions, for the Al-UML, alkaline lamprophyre and dolomite-silicocarbonatite suggest primary derivation by similar fractions of partial melting from a heterogeneous mantle source, accompanied by reaction between magma and wall-rock. Between the Al-UML and calcite-silicocarbonatites, a strong compositional continuum in Si, Ti, Al, Ca, Mn, P, Cr, Ni, Nb and LREE concentrations supports a different genetic relationship. Moderate fractionation of dominantly high Mg-number silicate minerals in the crust accounts for the presence of calcite as the dominant carbonate phase in most carbonatitic intrusions. Supporting evidence for further extensive fractionation is present as the essentially silica-free calcite carbonatite that is considered to be carbohydrothermal residua.

New forms of carbonate volcanism: what to look for and where

Bailey, D.K.
Dept. of Earth Sciences, University of Bristol, U.K.
(ken.bailey@bris.ac.uk)

Volcanoes in the melilitite-nephelinite-leucitite province of Calatrava, central Spain, have erupted carbonate in a variety of forms, notably dominated by maars and cinder cones. Both forms carry mantle debris and megacrysts. Lava flows are rare. Similar volcanism occurs in Limagne province, central France, and in other intra-continental provinces in Europe and Africa, and may be expected in other continents. In Spain there are ~250 vents, with a similar number in France: all examined to date have erupted carbonate, with potentially hundreds of cases.

As the igneous nature of the carbonate had previously passed unrecognised in these areas, it is vital to look more closely at all alkaline mafic-ultramafic provinces, where field geology and petrography will provide the first pointers to carbonate eruptions. Maar rim-breccias and scoria cone deposits have carbonate matrices. Immense quantities of mantle debris have been erupted from maars. Fresh silicate glass is present, with no signs of water driven eruption: maar and scoria deposits pass into carbonate-supported tuff and agglomerate, with carbonate contents > 50%. Sheets of carbonate rich tuffs are spread widely away from the emission centres, and constitute the most abundant effusive carbonate. Carbonate-supported scoria tuffs have the distinctive fabric of black silicate melt clasts in a pale matrix. These pristine silicate glasses, quenched at temperatures >1100°C, contain globules of immiscible carbonate and carbonate phenocrysts, which must be cognate, and intrinsic to the high T melts. Other characteristics are the platy habit of carbonate crystals, and euhedral Ti magnetite spinels with Cr-rich cores.

Pyroclastic eruptions are characteristic of alkaline mafic-ultramafic volcanism but traditionally research has centred on lava flows: there is now a clear need for close examination of fragmental eruptions, especially tuffs with black clasts in a pale matrix. Eruptions composed largely of carbonate are typically lapilli tuffs, and in places show spectacular depositional structures not previously described for igneous carbonates. For any successful search, evidence from the pyroclastic rocks will be vital. As eruptions of carbonate with these compositions have not been witnessed, these eruptive modes may not be in the classic canon of volcanology.

Carbonatite melt inclusions in coexisting magnetite, apatite and monticellite in Kerimasi carbonatite, Tanzania: implications for melt evolution

Guzmics, T.[1*], Mitchell, R.H.[2], Szabó, Cs.[1] & Berkesi, M.[1]
[1]Lithosphere Fluid Research Laboratory, Eötvös University Budapest, Hungary ([*]tibor.guzmics@gmail.com)
[2]Lakehead University, Thunder Bay, Ontario, Canada

Kerimasi calciocarbonatite consists of calcite, apatite, magnetite and monticellite. Carbonatite melt and fluid inclusions can be found in apatite and magnetite, and silicate melt inclusions in magnetite. Calcite contains fluid and S-bearing Na-K-Ca-carbonate inclusions. Our study shows compositional data for quenched S- and P-bearing, Ca-alkali-rich carbonatite melt inclusions in magnetite (Fig. 1) and apatite. Magnetite-hosted silicate melt inclusions have peralkaline composition with normative sodium-metasilicate. Based on our homogenization experiments, apatite-hosted melt inclusions and forsterite-monticellite phase relationships, temperatures of the early stage of magma evolution are estimated to be 900-1000°C. At this time three immiscible liquid phases coexisted: (1) a Ca-rich, P-, S- and alkali-bearing carbonatite melt, (2) a Mg- and Fe-rich, peralkaline silicate melt, and (3) a C-O-H-S-alkali fluid. During the evolution of coexisting carbonatite and silicate melts, the Si/Al and Mg/Fe ratio of the silicate melt decreased with contemporaneous increase in alkalis due to olivine fractionation. In contrast, the alkali content of the carbonatite melt increased with concomitant decrease in CaO resulting from calcite fractionation. Overall peralkalinity of the bulk composition in the immiscible melts increased, causing a decrease in the size of the miscibility gap in the pseudoquaternary system. The studied melt inclusion data indicate the formation of a carbonatite magma that is extremely enriched in alkalis with a composition similar to that of Oldoinyo Lengai natrocarbonatite.

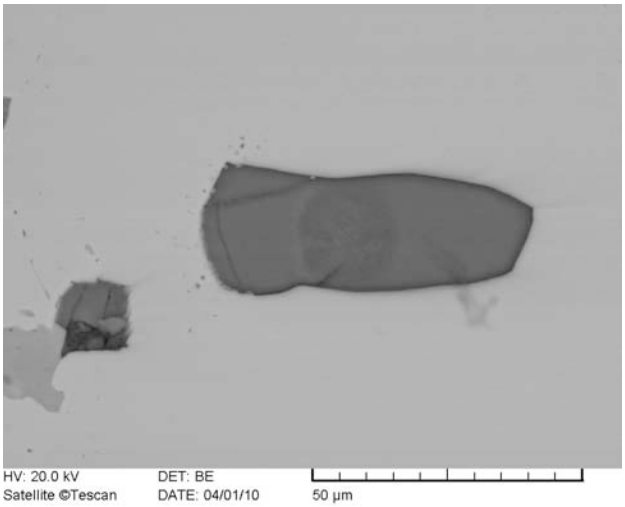

Fig. 1: Magnetite-hosted, quenched carbonatite melt inclusion after heating to 880°C (BSE image).

The compositions of carbonatite melt inclusions are considered as representatives of parental magma composition contrarily to any whole rock that contains negligible amount of alkalis. Consequently, implications for magma composition and evolution using bulk rock carbonatite composition should be reconsidered.

Sadiman volcano, Crater Highlands, Tanzania: does it really contain melilitites and carbonatites or it is just a phonolite-nephelinite volcano?

Zaitsev, A.N.[1*], Wenzel, T.[2], Markl, G.[2], Spratt, J.[3], Petrov, S.V.[1] & Williams, C.T.[3]
[1]Faculty of Geology, St. Petersburg State University, St. Petersburg, Russia ([*]burbankite@gmail.com)
[2]Institut für Geowissenschaften, Universität Tübingen, Germany
[3]Dept. of Mineralogy, Natural History Museum, London, UK

Sadiman is 4.8-4.0 Ma old volcano located in the Crater Highlands area in northern Tanzania [1,2]. Limited published data [2-4] and field observations show that it consists of interlayered phonolitic tuffs and nephelinitic lavas. Rare xenoliths of phonolite and ijolite were observed in the nephelinites. It was suggested that Sadiman volcano contains melilititic and carbonatitic rocks [5]. These also occur as tuffs in the Laetoli area where fossilised footprints from human ancestors are known [6,7] which is why Sadiman is of special interest as a possible source of them.

We found that nephelinites range from phenocryst-poor to phenocryst-rich rocks; the latter seem to be cumulates. Nepheline and diopside are the principal phenocryst minerals; rarely observed are shorlomite, perovskite or wollastonite. Microphenocrysts and groundmass consist of diopside, nepheline, sanidine, titanite, sodalite and apatite in various proportions. Perovskite also occurs as corroded relicts in titanite crystals. Aenigmatite (in grownd mass and as a reaction rim on titanite), magnetite, and pyrrhotite are accessory minerals. Nephelinites are low-magnesium rocks (Mg# = 0.17-0.26) with a peralkaline index ranging between 0.88 and 1.21. On a volatile-free basis these rocks contain 46.3-52.6 wt% SiO_2 and 10.5-15.9 wt% Na_2O+K_2O. Mineralogical and geochemical data suggest that they are highly evolved phonolitic nephelinites.

Phonolites are phenocryst-rich rocks with anorthoclase and nepheline being the principal minerals. Diopside and titanite are minor phases.

Tuffs contain sanidine as a major mineral, as well as highly altered nepheline and diopside. Heavy mineral concentrates from tuffs are enriched in euhedral perovskite crystals.

No evidence was found for the presence of melilite or primary calcite in any of the samples studied. Also, minerals which can be considered as indicators of carbonatitic activity, and known e.g. from the close Kerimasi carbonatitic volcano (nyerereite, pyrochlore or baddeleyite [8]), have not been found at Sadiman. Only secondary calcite, formed during low-temperature (?) alteration of tuffs, occurs as isolated anhedral crystals and forms veinlets.

All available data do not currently support the occurrence of melilitites and carbonatites at Sadiman volcano.

Oxygen isotopic composition of garnet, clinopyroxene and zircon megacrysts from kimberlites in Democratic Republic of Congo: insights into their petrogenesis

Pivin, M.[1*], Valley, J.W.[2], Spicuzza, M.J.[2] & Demaiffe, D.[1]
[1]Dept. des Sciences de la Terre et de l'Environnement, Université Libre de Bruxelles, Belgium ([*]mpivin@ulb.ac.be)
[2]Dept. of Geoscience, University of Wisconsin, Madison, WI, USA

Garnet, clinopyroxene (cpx) and zircon megacrysts from the central DRC Mbuji-Mayi diamondiferous kimberlite province (Cretaceous) and garnet megacrysts from the south-eastern DRC diamond-poor Kundelungu kimberlite field (Lower Oligocene) have been analyzed by laser fluorination and mass spectrometry for oxygen isotope compositions at the University of Wisconsin-Madison.

Garnet megacrysts from both localities display similar $\delta^{18}O$ values that match the range of mantle values from garnet peridotites but average ~ 0.2‰ higher than those of garnet megacrysts from other localities worldwide (Fig. 1a,b). The addition of DRC garnet megacrysts (n=51) to the worldwide megacryst population (S. Africa, N. America and Australia, n=121) slightly increases the mean $\delta^{18}O$ value [1] to 5.30±0.42‰ (2SD). The results for cpx are also within the mantle range for peridotites (Fig.1c). Zircon megacrysts show a very narrow $\delta^{18}O$ range, similar to that of other zircon megacrysts worldwide (Fig.1d).

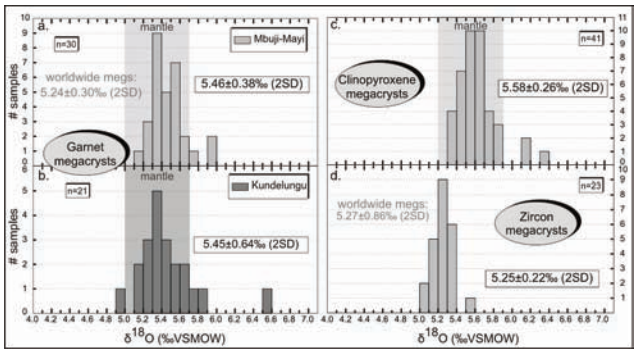

Fig.1: $\delta^{18}O$ distribution histograms for Mbuji-Mayi garnets (a), cpx (c) and zircons (d), and for Kundelungu garnets (b). Also: number of samples analyzed and average of $\delta^{18}O$ compositions. Worldwide megacryst averages: (a) and (b) from [1] and (d) from [2,3]. Mantle $\delta^{18}O$ compositional ranges (a-b-c) from [4].

The homogeneity in zircon megacryst $\delta^{18}O$ values from Mbuji-Mayi confirms the unlikelihood of a metamorphic genesis in a subducted oceanic crust and rather suggests a magmatic/ metasomatic origin [2,3].

DRC garnet and cpx are thought to result from metasomatic transformation of mantle peridotites by a precursor kimberlite fluid which produced a Ti-Fe-K-LREE enrichment [5]. Identical $\delta^{18}O$ averages for Mbuji-Mayi and Kundelungu garnet megacrysts suggest a similar origin. Moreover, the $\delta^{18}O$ ranges of DRC garnet and cpx megacrysts overlap those of mantle peridotites, suggesting a possible genetic relation. DRC garnets display slight but regular $\delta^{18}O$ – major element co-variations that could be explained by the percolation of a metasomatic fluid whose composition gradually changes (open system) through interaction with peridotite wall-rocks.

Magma mingling and mantle xenolith transport in the feeder system of diatreme root zones: evidence from the south coast of Ireland

Moore, K.R.[*], Brady, A. & Dempsey, C.
National University of Ireland Galway, Ireland
([*]kathryn.moore@nuigalway.ie)

A suite of late Carboniferous subvolcanic intrusions has cut through the sedimentary sequence of the South Munster Basin in County Cork (Ireland) utilising Caledonian lineaments that were reactivated during the Variscan. Three loci of thermo-hydraulic explosions have been identified. (1) The White Ball Head pipe is a root zone breccia spatially associated with carbonate-bearing lamprophyres. (2) The Cahermore root zone breccia is cut by a silico-carbonatite sill-like pipe that is partly constrained by bedding and jointing in the host rocks. (3) The deep-seated diatreme at Black Ball Head is filled with massive alkaline ultramafic lamprophyre, the inner zone of which contains an anastomosing fluidised fabric rather than a feeder channel (and which is cut by later calcite carbonatite), and the outer zone of which comprises a substantial root zone breccia. The three localities together describe a classic example of the evolution of a diatreme volcano structure by downward propagation of the root zone [1].

Dykes and sills are associated with the three areas of thermo-hydraulic explosions, but the spatial and geochemical associations do not coincide. The centrally-located White Ball Head area includes a dyke and two sills that are found to resemble the Black Ball Head and Cahermore localities in terms of their transported mantle material, geochemistry and mineral assemblages. All three intrusions contain primary mantle carbonate and two of the intrusions contain juvenile magmatic enclaves and schlieren. It is likely that magma mingling occurred shortly before emplacement and caused the evolution of volatiles that may have acted as a trigger for rapid magmatic ascent and entrainment of mantle material. The distribution and constitution of entrained mantle and crust material was examined in order to place some constraints on magma flow rates, which are consistent with previously calculated velocities for Minette dykes [2]. However, the size, abundance and distribution of mantle peridotite xenoliths indicate that, although flow velocity was maintained during ascent and through dykes, it decreased within sills allowing xenolith settling towards the lower half of the intrusion.

Numerous dykes devoid of transported mantle material and evidence of magma mingling have similar trace element signatures to, but not the characteristic chemical markers of, the compositions of explosive root zone intrusions. It is likely that these dykes were feeder dykes for limited duration scoria cone eruptions. In contrast, the xenolith-bearing White Ball Head intrusions are interpreted as a dyke-sill feeder system where magma periodically drained towards the loci of thermo-hydraulic explosions. The initiation of the explosions may be a shallower crustal response to the rapid ascent rates and volatile exsolution caused by magma mingling.

Cumulates and crystal mushes: insights into alkaline magma chambers from glass-bearing mafic xenoliths

Downes, H.*, Kelly, J.L. & Beard, A.D.
Dept. of Earth and Planetary Sciences, Birkbeck University of London, UK (*h.downes@ucl.ac.uk)

Cumulate xenoliths consisting of pyroxene and amphibole are common in many regions of mafic alkaline magmatism and represent parts of magma chamber walls. Although most xenoliths were solid when entrained, some contain glass, indicating that melt was still in place when they were brought to the surface. Thus they represent unconsolidated parts of magma chambers which could be described as "crystal mushes". We have investigated such xenoliths from Santo Antao in the Cape Verdes islands, which contain variable proportions of clinopyroxene (diopside) and amphibole (kaersutite to Ti-pargasite), together with accessory apatite, titanite, sodalite-group feldspathoid and Fe-Ti oxides. The interstitial glass, which can reach >20% in some samples, has a broadly tephri-phonolitic composition. The glass compositions are identical to the most evolved lava compositions on Santo Antao [1], indicating that the xenoliths represent fragments of a crystallising magma reservoir beneath the island. In some cases the trapped magma contains vesicles, which are the result of exsolution of volatiles from the magma within the xenolith during eruption.

We have analysed the phases for a wide range of trace elements using LA-ICP-MS (Fig. 2). The interstitial glass has a mantle-normalised incompatible trace element pattern similar to that of evolved lavas from the island. Titanite is the most enriched mineral phase, although it has lower abundances of Rb, Ba, Pb and Sr than the glass. Amphibole and clinopyroxene have similar abundances of most trace elements except for Nb-Ta, Ba and Rb. Haüyne is a significant repository of Sr only. Apatite (only one analysis to date) is strongly LREE-enriched but shows troughs for all the HFS elements (Zr, Hf, Nb, Ta, Ti).

Our results can be used to calculate trace element distribution coefficients for common minerals in equilibrium with phonotephritic magma. The results will be compared to those obtained by Downes et al [2] who investigated similar xenoliths from Germany and Israel that contained basaltic glass.

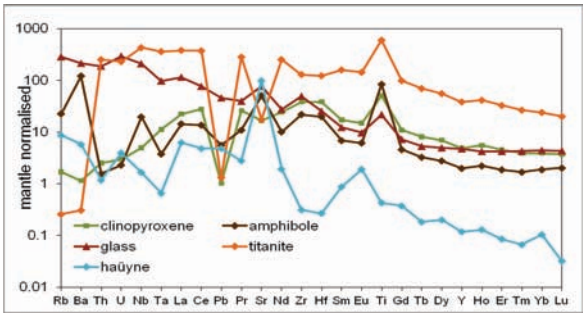

Fig. 1: Average trace element compositions of phases from glassy xenolith CV1.

[1] Holm, P.M. et al. (2006) *J. Petrol.*, **47**, 145-189. [2] Downes, H. et al. (2001) *Lithos*, **75**, 1-17.

Zircons from kimberlites at Lac de Gras, Canada - a section through the continental crust

Nuber, N.[1*], Gerdes, A.[1], Brey, G.[1] & Grütter, H.[2]
[1]Institut für Geowissenschaften, Goethe-Universität Frankfurt, Frankfurt, Germany (*nuber@em.uni-frankfurt.de)
[2]BHP Billiton World Exploration Inc., Vancouver, B.C., Canada

The determination of diamond grain size distribution is an important aspect of the economic assessment of primary deposits. Initial analysis is typically achieved by subjecting 40 to 200 kg samples of kimberlite to caustic fusion in order to quantitatively recover microdiamonds. Only diamonds, zircons, oxide minerals, corundum and occasional rutile survive this intense chemical process. We have analyzed such zircons from six different kimberlites from the Ekati property in the Slave Province, Canada. We consider kimberlite diatremes as drill cores through the continental crust which may provide us with information from the deeper continental crust. The age distribution together with the Hf isotopic composition of the zircons would provide constraints on the time of formation of continental crust. Furthermore, we measured the REE abundances to obtain information about the host rocks.

Three main age groups can be distinguished in 150 LA-ICP-MS analyses we have completed on 100 zircon grains The youngest U-Pb ages are between 54 and 61 Ma (25% of the population) which correspond to the kimberlite emplacement ages at Ekati [1]. However, our zircon REE data is unusual for kimberlite hosts. Typically zircons from kimberlites have low REE abundances and no Eu anomaly [2]. The zircons in this study have high REE contents and a pronounced negative Eu anomaly and thus resemble crustal zircons crystallized from felsic melts. Their εHf scatter from -7.5 to +11.9 indicating that they crystallized from heterogeneous or distinct protoliths.

A second U-Pb age group lies between 93 and 104 Ma (17%), ages so far unknown in this area. Their Hf isotopic composition is highly variable and ranges from juvenile (initial εHf of +11) up to Palaeoproterozoic crustal residence times (T_{DM} ~ 2.0 Ga; initial εHf of -18) of the protoliths.

The third age group forms about 40% of the zircon population and is defined by Archean zircon with U-Pb ages of 2.54 to 2.87 Ga. The majority of them have early Archean depleted mantle model ages (average crustal residence time) of 3.2 to 3.6 Ga, with maxima at 3.3 and 3.5 Ga. Others are more juvenile, pointing to Mesoarchean crust formation of around 2.9 Ga. They arose from several intrusions with variable chemistry from tholeiitic to tonalitic and granodioritic [3].

Paleoarchean crust formation is also support by one grain which yielded an age of 3.3 Ga and a εHf of +1.5.

A minor group of zircons (4%) with ages around 1.8-1.9 Ga suggests Paleoproterozoic recycling of Mesoarchean crust. These could represent recycling in one of several Paleoproterozoic diabase-producing magmatic events. Furthermore, some zircons, with concordant Jurassic to Palaeproterozoic (1.9 Ga) ages and positive εHf, point to very minor addition of juvenile crust during that time.

In summary, the crust of the Ekati-mine district in the Slave province was predominantly formed during Archean times in two phases at Paleoarchean (3.5 – 3.3 Ga) and the Mesoarchean (~ 2.9 Ga) and subsequently recycled during the Neoarchean. In addition, minor amounts of juvenile crust formed through dikes or smaller intrusions sporadically until Eocene.

Tracing chemical evolution of primary pyrochlore from plutonic to volcanic carbonatites: the role of F

Bambi, A.[1], Melgarejo, J.C.[2*], Costanzo, A.[3] & Gonçalves, O.A.[1]
[1]Dept. de Geologia, Universidade Agostinho Neto, Luanda, Angola
[2]Dept. Cristal·lografia, Mineralogia i Dipòsits Minerals, Universidad de Barcelona, Catalunya, Spain (*joan.carles.melgarejo.draper@ub.edu)
[3]School of Natural Sciences, Earth and Ocean Sciences, National University of Ireland, Galway, Ireland

Three carbonatite outcrops from Angola were selected in order to evaluate change in composition of pyrochlore group minerals during the magmatic evolution in different levels of emplacement: a) Tchivira carbonatites occur in a plutonic complex and are associated with alkaline and basic rocks; b) Bonga carbonatites represent an example of hypabyssal carbonatites and c) Catanda carbonatites consist of volcanic carbonatites, either as lavas or as pyroclastic rocks.

In Tchivira plutonic carbonatites pyrochlores are euhedral and zoning is poorly developed. F fullfill the position for the additional anions, and Na is close to 1 apfu. Zoning may account to substitutions of Nb in the B position, although the content of Ti, Ta and Zr does not reach 0.01 apfu. Contents of REE, U, Th, and LILE are also very low.

Pyrochlores from the hypabyssal Bonga carbonatites are abundant, generally euhedral and vary in grain size up to 1 cm. Oscillatory zoning is also commonly observed. F and Na contents are lower than in Tchivira (~0.8 apfu). In the B position the content of Th, Ti and Ta increases slightly. Accordingly, in the A position the substitutions of Na by Th, U and REE increases, as well as the vacant number. Ca remains approximately constant and close to 1 apfu.

Pyrochlore crystals from Catanda are very small (less than 50 μm), euhedral and display complex internal textures. They generally have a rounded core, relatively corroded and mantled by two or three late generations. Composition of the core is close to that of Bonga pyrochlores. The rims of the crystals are strongly enriched in Zr (up to 0.3 apfu), Ta (up to 0.12 apfu), Th (up to 0.15 apfu), Ce (up to 0.12 apfu) and U (up to 0.17 apfu), but impoverished in F and Na.

Results from this study show that F and Na contents decrease from plutonic to volcanic carbonatites; this trend is also associated to other trends of enrichment such as Th, U and REE in the A position and Ta and Zr in the B position. Zoning in the pyrochlore may be explained by changes in the F fugacity, mainly due to crystallization of fluorite or apatite in the deeper carbonatites, or by degasification in the volcanic carbonatites.

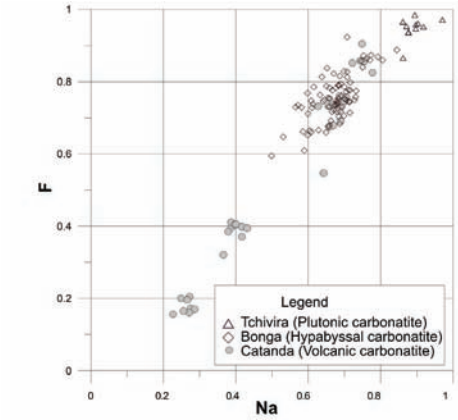

Fig. 1: Plot of Na vs. F contents of pyrochlore in carbonatites from Angola.

A new type of Zr-Nb ore mineralization from the Gremiakha-Vyrmes massif, the Kola Peninsula

Sorokhtina, N.V.[1*], Kogarko, L.N.[1] & Shpachenko, A.K.[2]
[1]Vernadskyernadsky Institute of Geochemistry and Analytical Chemistry RAS, Moscow, Russia (*nat_sor@rambler.ru)
[2]Geological Institute KSC RAS, Apatity, Russia

Gremiakha-Vyrmes is an Early Proterozoic multiphase alkaline-ultrabasic intrusive complex. This massif includes four rock complexes: 1 basic-ultrabasic (gabbro-norites, gabbro-wehrlites, monzodiorite, anorthosites); 2 alkaline-granites, granosyenites and quartz syenites; 3 alkaline rock (melteigites, ijolites, juvites, nepheline syenites, foyaite, foidolites); 4 carbonatites, various albitites, aegirinites which cross-cut ultrabasic and foidolitic rocks [1]. Zr-Nb ore mineralization has been found in albite-microcline and aegirine-albite rocks. Albitites, aegirinites and carbonatites are located in the Aegirine Navolok section in the central zone of the massif and are surrounded by the foidolitic rocks. The rare metal mineralization is represented by zircon and pyrochlore-group minerals. The pyrochlore mineralization is confined to aegirine-biotite albitites, foidolites and syenites.

The following evolutionary sequences of rare metal minerals has been observed: 1 in albitites to gabbro - betafite - uranpyrochlore – thorogummite and coffinite and U-Si-Nb phases – "silicified" pyrochlore; 2 in albitites to foidolites and syenites - pyrochlore – bariopyrochlore or uranpyrochlore or pyrochlore-Sr - "silicified" pyrochlore – deficient hydrated pyrochlore and Fe-Nb, Al-Nb phases.

Extraction and accumulation of rare metals in the rocks of the Gremiakha-Vyrmes massif took place under low temperature hydrothermal conditions at elevated concentrations of Si, Al, Fe sometimes U and Th in solution. Primary pyrochlore is leached, it is hydrated, enriched in Si and deficient hydrated pyrochlore and new phases of Nb, U, Th, Fe-Nb, Al-Nb are formed. This process of transformation of primary Nb minerals is similar to the evolution of rare metal phases in alkaline complexes analogous to Lovozero [2] and in carbonatites.

Isotope data obtained for carbonatites of the Gremiakha-Vyrmes massif, linked to albitites point to a mantle source. Albitites could have formed during the metasomatism triggered by intrusion of carbonatites into the alkakaline complex of the massif.

Recognition of a postcollisional (Oligocene) carbonatitic activity from the Sillai Patti carbonatite complex, Malakand Agency, North West Pakistan: constraints from fission-track dating of apatite

Khattak, N.U[*] & Asif Khan, M.
National Centre of Excellence in Geology, University of Peshawar, Pakistan ([*]nimat_khattak@yahoo.com)

The Sillai Patti carbonatite complex represents the second largest carbonatite complex of the Peshawar Plain Alkaline Igneous Province (PAIP) of northern Pakistan, the first being the Loe-Shilman carbonatite complex. The Sillai Patti is situated about 70 km north of Peshawar and about 20 km west of Malakand, near Sillai Patti village, in Malakand Agency of the North West Frontier Province. This carbonatite body occurs along a thrust fault in the form of a sheet which is striking in the NNE-SSW direction and is roughly dipping to the south. The carbonatite body is about 12 km long and 2-20 m thick. The carbonatite sheet is emplaced either within the metasediments or at the contact of metasediments and granite gneiss.

Emplacement time of the Sillai Patti carbonatite complex has been under considerable dispute since long ago. To resolve the dilemma fission-track dating studies on the crystals of apatite using the external detector method and age standard approach (the ζ method) were carried out. A fission-track age of 29.6 ± 1.5 Ma was obtained for the Sillai Patti carbonatite body. Close resemblance of the fission-track apatite age of this study with the fission-track as well as other high temperature radiometric ages from the same as well as the neighboring carbonatite bodies of the alkaline belt of northern Pakistan strongly suggests that the Sillai Patti carbonatite body was emplaced at high crustal level (shallow burial depths) and cooled there relatively fast to near ambient temperatures (<60°C) required for the complete retention of fission tracks in apatite and that the fission-track age of 29.6 ± 1.5 Ma of this study is the emplacement age of the Sillai Patti carbonatite.

Trace elements and volatile components in silicate and silicate-salt magmas of the Mushugai-Khuduk carbonatite-bearing alkaline complex, southern Mongolia

Andreeva, I.*& Kovalenko, V.
Institute of Geology of Ore Deposits, Petrography, Mineralogy, and Geochemistry, Russian Academy of Sciences, Moscow, Russia (*andreeva@igem.ru)

Inclusions of mineral-forming media were studied using various techniques including X-ray spectral and ion microanalysis. Based on this study, trace elements and volatile components were evaluated in silicate and silicate-salt melts (melt inclusions) from minerals of major rock groups (melanephelinites, shonkinites, phonolites, quartz syenites, and rhyolites) of the Mushugai-Khuduk alkaline carbonatite-bearing complex (Mongolia). The silicate melts form a continuous series from basic to rhyolitic compositions with SiO_2 contents from 47 to 77 wt% [1]. The salt-silicate melts are silicate-phosphate in composition containing up to 10-20 wt% of P_2O_5.

Our data on the trace-element composition of glasses in homogenized silicate melt inclusions in alkaline rocks of the Mushugai-Khuduk complex indicate that all of the melts are characterized by similar trace- element patterns. Glasses in melt inclusions in silicate minerals from the mafic rocks are enriched in REE Th, U, and Li but depleted in Ti and K. Comparing the trace-element and REE patterns of glasses in inclusions in minerals of the mafic rocks (melanephelinites and theralites) and glasses in inclusions in minerals from more evolved derivatives (syenites and rhyolites), one can note that the REE and P_2O_5 patters are similar for all of the inclusions, and the concentrations of these components systematically decrease in inclusions in minerals from more acid rocks, first of all, in apatite, which is the main REE concentrator. The differences in the Ba behavior, which is characterized by positive anomalies in the melanephelinites and theralites and negative ones in the syenites and rhyolites, are likely explained by the fractionation of alkali feldspar, the main Ba concentration of these rocks. Glasses in silicate-salt melt inclusions in apatite from the shonkinites, theralites, and quartz syenites also display similar trace-element patterns. Compared to the silicate melts, they are more strongly enriched in REE, Ba, Th, and U but depleted in Ti, Nb, K, and Zr.

Our data on the trace-element composition of the melts of the alkaline rock series at the Mushugai-Khuduk complex testify that these rocks are genetically interrelated and were likely produced at silicate-salt immiscibility in the magma. The silicate-salt magmas were thereby significantly enriched in certain trace elements and REE compared to the silicate melts. This led us to believe that the genesis of the REE-bearing magnetite-apatite rocks was related to the identified silicate-salt melts. The magma of the mafic rocks of the complex started to crystallize at high temperatures of 1220-1070°C and was poor in water. The water content in the magma of the intermediate and acid alkaline rocks increased in the course of differentiation and reached 4-7.6 wt%.

Pyrochlore from metasomatic rock at Bolshetagninskoe niobium deposit (Eastern Siberia, Russia)

Azarnova, L.A.* & Temnov, A.V.
All-Russian Scientific Research Institute of Mineral Resources Moscow, Russian Federation (*lazarnova@mail.ru)

The Bolshetagninskoe deposit is one of the most important Russia niobium occurrences. It is confined to carbonatite complex of the same name that is situated in the Sayan Mountains, Eastern Siberia. About half of the Bolshetagninskii complex comprises carbonatite the rest consisting of syenite, ijolite and alkaline metasomatic rocks. Pyrochlore is the main economic mineral of niobium at the deposit. It is unique in that the pyrochlore is mostly concentrated in alkaline metasomatic rocks which consist predominantly of microcline and carbonate ("microclinite") or biotite and apatite ("sljudite").

Pyrochlore was analysed in fresh (43 analyses) and weathered (74 analyses) microclinites samples by electron microprobe (fig. 1). Pyrochlore from fresh microclinite has a high A site occupancy of between 1.702-2.009 per 2 B cations. A site is occupied by Na, Ca, Sr (up to 0.080 pfu), U (up to 0.005 pfu). There are sr-bearing pyrochlore nodules in the fresh microclinite pyrochlore. The mineral has low A site occupancy of between 1.399-0.947 and contains Sr 0.116-0.235 pfu.

Secondary pyrochlore occurs throughout weathering metasomatic rocks. The weathering profile of the deposit is represented leaching microclinite in which the major components are microcline, goethite, apatite. The first type of weathered pyrochlore is weakly leaching pyrochlore which has a lower A site occupancy of between 0,849 to 1,771. A site is occupied by major components Na, Ca and minor ones Sr (up to 0,040 pfu) and Ce (up to 0,044 pfu). Another type of weathered pyrochlore is kalipyrochlore. The deposit is the second known locality of kalipyrochlore. The first one is the Lueshe complex, Zaire [1]. Kalipyrochlore has a (Å) 10.54±0.01, very low A site occupancy between of 0.215-0.363 and chemical composition close to kalipyrochlore from Lueshe. The mineral grain is zoning and has A site occupancy 0.267 in central part and 0.281 in outer one (0.201 and 0.190 K, 0.028 and 0.044 Ca, 0.002 and 0.004 Na). Kalipyrochlore grains are zoned with B site cations too: central parts contain (pfu) Nb 1.769, Ti 0.187, Fe 0.044; outer ones contain Nb 1.633, Ti 0.338, Fe 0.030.

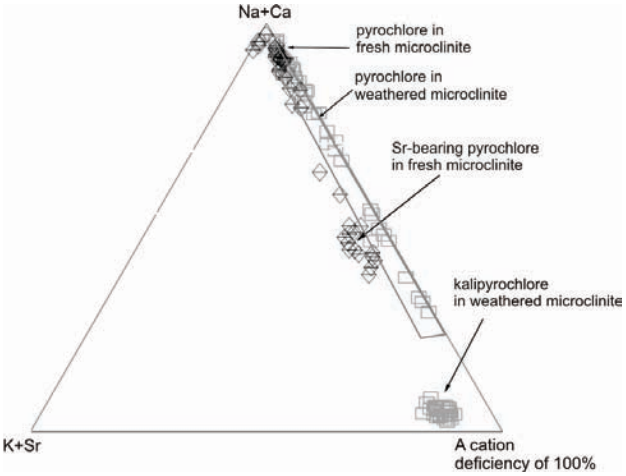

Fig.1: A cation occupancy of pyrochlore of Bolshetagninskoe deposit (calculated per 2 B site cations).

Acknowledgements: The authors thank N.I. Chistjakova and I.S. Naumova (FGUP «VIMS», Moscow) for performing pyrochlore X-Ray and energy-dispersion microprobe analyses.

Mineralogy of felsic globular structures of camptonites, Ditrău Alkaline Massif, Romania

Batki, A.* & Pál-Molnár, E.
Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Hungary (*batki@geo.u-szeged.hu)

The Ditrău Alkaline Massif (DAM) is a Mesozoic alkaline igneous complex situated in the S-SW part of the Giurgeu Alps belonging to the Eastern Carpathians (Romania). It outcrops right east of the Neogene-Quaternary Călimani-Gurghiu-Harghita calc-alkali volcanic belt by breaking through the pre-Alpine metamorphic rocks of the Bukovina Nappe. According to our present knowledge, the DAM is an intrusive rock body with an eastern, north eastern tilt, built up by several tectonic blocks providing the massif a complex form. Great number of different rock types appears on the surface (ultrabasites, gabbros, diorites, monzonites, syenites, nepheline syenites, granites, lamprophyres, etc.). Based on K/Ar data [1] originating from various mineral fractions of different rock types has shown that the DAM is the result of a long lasting (Middle Triassic – Lower Cretaceous) two phase magmatic process, which started during the Triassic by the opening up of the Tethys and the detachment of the Getida-Bukovina Microplate from the Eurasian Plate.

Camptonites are alkaline lamprophyres with more plagioclase than alkali feldspar, can include Na-foids and containing essential amphibole which dominates over biotite. They are a group of alkali-rich igneous rocks and form subvolcanic dykes, sills, plugs, stocks or vents [2]. This paper reports new results on the mineralogy of felsic globular structures (ocelli) of camptonites which were absolutely not discussed in former works of the DAM.

Mineral compositions were determined by Cameca SX-50 electron microprobe under probe current of 15 nA and acceleration voltage of 20 kV operating conditions at the Department of Earth Sciences, University of Uppsala, Sweden. Cathodluminescence studies were carried out by Reliotron cold cathode luminoscope and Eclipse 600 polarizing microscope at the Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest.

Camptonites occurring in the northern part of the DAM are 20 cm-2 m wide dykes. Based on textural features and mineral composition two types of camptonites can be divided: a pyroxenic and a pyroxene free variety. Pyroxenic camptonites consist of diopside phenocryst, groundmass kaersutite and Mg-biotite, interstitial albite-oligoclase and ocelli filled with euhedral calcite in the core and anhedral plagioclase at the rim. Some of these large calcite crystals can be 2.7 mm in size. The cathodluminescence images of the calcites show homogeneous texture and lighter orange in colour at the rims than in the cores which reflect their variable Fe- and REE-content. The ocelli can contain La-Ce-bearing allanite within plagioclase cores as well which is characteristic at kaersutite-plagioclase intergrowth. Pyroxene free camptonites have groundmass hastingsite–magnesiohastingsite, Fe-Mg-biotite and albite-andesine with the same silica-rich mineral assemblages in the felsic globular structures. In these ocelli the euhedral titanite ($CaTi_{0.89-0.95}Fe_{0.03-0.07}Al_{0.04-0.06}SiO_5$) (up to 550 μm) and apatite are always bigger than the anhedral ones in the groundmass.

The texture and mineral composition of felsic globular structures of the pyroxenic camptonites suggest that they formed by the separation of CO_2-rich volatiles at late-stage of the crystallisation process. The silica-rich ocelli of the pyroxene free camptonites were produced by liquid immiscibility at the final stage as well.

Mineralogical control on the behaviour of Nb-Ta and Zr-Hf pairs in Cenozoic nephelinites and peralkaline phonolites from Saghro (Moroccan Anti-Atlas)

Berger, J.[1*], Ennih, N.[2], Mercier, J.C.C.[3] & Liégeois, J-P.[4]
[1]Université Libre de Bruxelles, Brussels, Belgium (*juberger@ulb.ac.be)
[2]Université Chouaïb Doukkali, El Jadida, Morocco
[3]Université de La Rochelle, La Rochelle, France
[4]Royal Museum for Central Africa, Tervuren, Belgium

Nephelinites and phonolites from Saghro are amongst the most Si-undersaturated and alkali-rich lavas of the Circum-Mediterranean Cenozoic igneous provinces [1,2]. Despite the paucity of lavas with intermediate composition between nephelinites and phonolites, the continuum of clinopyroxene compositions, fractional crystallisation modelling [2] and Sr-Nd-Pb isotopic ratios suggest that the two groups of lavas are linked by a fractional crystallisation process.

Nb concentration does not increase from primitive to evolved nephelinites, whereas Zr content linearly increases with decreasing Mg. This can be explained by early fractionation of perovskite (which can trap up to 2 wt% Nb_2O_3). Phonolites are strongly enriched in the most incompatible elements compared to nephelinites, except for Sr, REE (apatite effect) and Ta. They show high Nb, Zr, Th and U contents (up to 2100 ppm Zr and 600 ppm Nb) with fractionated Nb/Ta and Zr/Hf ratios. Both ratios increase during differentiation (Fig. 1): from 19±1 and 40±10, respectively, in the nephelinites, to 30-69 and 61-82, respectively, in the phonolites; this reflects the more compatible behaviour of Ta compared to Nb and of Hf compared to Zr.

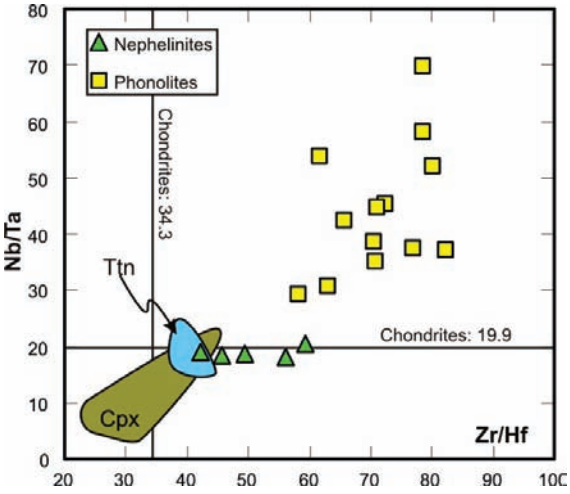

Fig. 1: Nb/Ta and Zr/Hf ratios in Saghro lavas and their minerals.

LA-ICP-MS analyses of the main mineral phases show that both clinopyroxene (cpx) and titanite (ttn) fractionate Nb-Ta and Zr-Hf pairs (Fig.1) with the difference that these elements are incompatible or moderately compatible in the clinopyroxene lattice but strongly compatible in titanite with $D_{Hf}>D_{Zr}$ and $D_{Ta}>D_{Nb}$ (D_{Zr}: 6; D_{Hf}: 9; D_{Nb}: 22, D_{Ta}: 42).

The final steps of crystallisation and differentiation are evidenced by segregations of peralkaline, Zr-, Nb- and volatiles-rich melts that crystallised pure aegirine, apatite, hainite and delhayelite in small microdomains interstitial to the feldspar laths network of phonolites. Brown augite phenocrysts were transformed into green aegirine-augite during reaction with these highly differentiated melts, while titanite reacted into lorenzenite and eudyalite-group minerals.

Geological significance of the Shatingaobao aegirine syenite in Alxa area, Inner Mongolia: constrains from SHRIMP zircon U-Pb geochronology and petrogeochemical characteristics

Cai Jianhui[1*], Yan Guohan[2] & He Guoqi[2]
[1]Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, China ([*]caijh_cags@163.com)
[2]Faculty of Earth and Space Sciences, Peking University, Beijing, China

The Shatingaobao aegirine syenite complex (1.42 km^2) occurs at the Northern margin of Alax League, Inner Mongolia, China, which tectonically belongs to the middle part of the Central Asian Paleozoic orogenic belt. The stock mainly consists of alkali feldspar (65-70%), plagioclase (10-15%) and aegirine. In this paper the SHRIMP U-Pb age (246.4±1.9Ma) of zircons from the Shatingaobao aegirine syenite is reported for the first time, suggesting that its main intrusion is a product of early Triassic alkaline magmatic activity, and there is an early Triassic alkaline intrusion – A-type felsic volcanic rock belt parallel to the suture between the North China – Tarim plate and the Siberian plate, which is composed of the Weiya quartz-syenite (246Ma [1]) in Xinjiang, the Shatingaobao aegirine syenite and the Xilinhaote – Xiwuqi A-type felsic volcanism in Inner Monglia (245Ma, [2]).

According to the contents of major and trace elements (Table 1), the Shatingaobao syenite has low silicon and higher alkalis, with a Rittman index of 5.9-8.3, enriched in Rb, Ba and depleted in Nb, Ta. The contents of REE are high with an average ∑REE of 356×10^{-6}, light REE enriched slightly and a weak negative Eu anomaly. These results have shown that the Shatingaobao syenite is deemed to be both alkaline and an A-type granite, formed in a post-orogenic extensional environment of the Central Asian orogenic belt in the Triassic, the same as the Weiya and the Xilinhaote complexes.

Table 1: The petrogeochemical data of the Shatingaobao aegirine syenites in Alax area, Inner Mongolia

NO.	01ST-1	01ST-2	01ST-3	ST-8	ST-10	NO.	01ST-1	01ST-2	01ST-3	ST-8	ST-10

U	7.64	8.47	7.67	0.00	4.00	Yb	2.22	1.88	2.30	1.71	1.81
Th	35.98	33.09	34.93	7.00	22.00	Lu	0.32	0.27	0.33	0.28	0.31

The data is analyzed by XRF and ICP-MS (wt% and ppm)

The development of the Central Asian orogenic belt involved three stages: orogenic, post-orogenic and non-orogenic. The post-orogenic stage started at about 320Ma according to previous research. The end time is constrained by the formation age of the early Triassic alkali intrusive – A-type acid volcanic rock belt mentioned above. It is suggested that the post-orogenic stage of the middle part of the Central Asian Palaeozoic orogenic belt is between 320-245Ma.

The origin of the tantalum-bearing Upper Fir carbonatite, east-central British Columbia, Canada: preliminary results

Chudy, T.C.[*] & Groat, L.A.
Dept. of Earth and Ocean Sciences, The University of British Columbia, Canada ([*]tchudy@eos.ubc.ca)

The Upper Fir carbonatite is the largest system within a group of carbonatite-alkaline-ultramafic rocks in the Monashee Mountains of British Columbia, Canada. These form sill-like bodies of variable thickness that have been multiply deformed and metamorphosed (upper amphibolite grade) together with the regional miogeoclinal strata. Three compositionally different carbonatite types, an ultramafic rock, a REE-bearing pyroxenite, fenites and various pegmatitic veins have been identified. The most abundant rock type is a magnesio-carbonatite which consists mostly of ferroan-dolomite, fluorapatite, amphibole and minor amounts of zircon, iron oxides and sulfides, and the Nb-Ta minerals pyrochlore and ferrocolumbite. Textures range from fine-grained to porphyritic to coarse-grained carbonatites which also exhibit various degrees of deformation resulting in mylonitized, foliated or cataclastic patterns. Local accumulations of amphiboles or apatites, some of which are also enriched in pyrochlore, underline the compositional heterogeneity. The calcio-carbonatites form inconsistent layers or lenses of variable thickness within the magnesio-carbonatites. Typical flow-like textures result from large, anhedral, ovoid magnetite blobs that mantle apatite and amphibole grains, all suspended or aligned in a very fine-grained calcite matrix. Volumetrically of minor importance are moderately deformed, medium- to coarse-grained mica-magnesio-carbonatites that are composed of biotite, dolomite and apatite. Subordinate rock types are highly altered and heterogranular pyroxenites and undeformed pyroxene-apatite rocks. The latter contain approximately 60 vol.% pyroxene with 30 – 40 vol.% apatite and locally abundant biotite, calcite, monazite, allanite, and pyrochlore. Pegmatitic veins show a wide range of compositions, mostly pyroxene-amphibole-calcite assemblages, and are usually <50 cm thick. Fenites are inconsistently developed at the contact of carbonatites and country rocks.

The Upper Fir carbonatite is a compositionally and texturally heterogeneous system of carbonatites and related rocks, which is also reflected in its Nb-Ta mineralization. Pyrochlore and ferrocolumbite are the major Nb-Ta carriers in this carbonatite and occur as individual grains in the carbonates, as inclusions in other phases, and as composite grains that consist of both phases in variable proportions.

In order to successfully ascertain the petrogenesis of these rare magmatic rocks and the reason for their economically important tantalum enrichment, future work will include (1) detailed petrography of all rock units with emphasis on mineral assemblages, textures, and phase relations; (2) mineral chemistry of rock forming and trace minerals in all identified units; (3) fluid inclusion studies of apatite; and (4) investigations of the isotopic systems of carbon, oxygen, strontium and neodymium (in whole rock and minerals). Results obtained from step (4) will provide important information about any (preserved) magmatic, metasomatic, or metamorphic overprint(s), and contamination, and define the source of the carbonatites. Steps (1) to (3) relate to the magmatic evolution which in general involves the processes of fractional crystallization or liquid immiscibility.

The influence of carbonatite during petrogenesis of nepheline syenites at the Poços de Caldas Complex (Brasil): evidence from geochemistry and fluid inclusions

Costanzo, A.*, Moore, K.R. & Feely, M.
School of Natural Sciences, Earth and Ocean Sciences, National University of Ireland, Galway, Ireland
(*alessandra.costanzo@nuigalway.ie)

The Poços de Caldas caldera complex in São Paulo State, Brazil is almost entirely composed of evolved alkaline rocks. Rock types include phonolites, tinguaites, nepheline-syenites and eudialyte-bearing nepheline-syenites [1]. Intense potassium-rich hydrothermal and metasomatic alteration are responsible for mineralization in the district, which is strongly enhanced by supergene enrichment in some places (e.g., zircon and caldasite occurrences, the U-Zr-Mo ore bodies of the Campo Agostinho and the open pit Osamu Utsumi uranium mine). The Poços de Caldas Alkaline Massif has carbonatite Sr and Ba enrichment, chondrite normalized REE distribution patterns similar to carbonatites, carbonatite-like metasomatism, zirconium mineralization and minor carbonatitic intrusions. These occurrences might imply that carbonatite magma+fluid existed at depths beneath the massif. Geochemistry and fluid inclusion data are used to test the carbonatite influences in the generation of alkaline magmas at Poços de Caldas.

Fluid inclusions (FI) are present throughout the Poços de Caldas rock suite and are hosted most commonly in nepheline. They consist of well-developed, monophase liquid and vapour inclusions, two-phase (liquid-vapour) and three-phase (solid-liquid-vapour) inclusions. Microthermometric data reveal low temperature phase behaviour with temperatures of homogenization below 400°C, but also the occurrence of different populations with higher temperatures (above 400°C). Na^+, K^+ and Cl^- are the dominant phases present in the inclusions. Ca^{2+} and Mg^{2+} are also present in small amounts. Spectra from LRM analyses of solid-rich FIs reveal the presence of burbankite, a rare carbonate mineral previously found as solid inclusions hosted by in carbonatite minerals or silicate minerals in carbonatite complexes. From the fluid inclusion assemblage identified (pyroxene-ilmenite-dolomite), which is similar to the host rock, it is suggested that the solid phases represent trapped solids or trapped melt that crystallized later on. The occurrence of burbankite in the nepheline-hosted inclusions is significant because the mineral assemblage trapped in the inclusions frequently accompanies burbankite in carbonatite. The presence of burbankite crystals in primary FIs in voluminous silicate rocks in addition to carbonatite-like metasomatism, and zirconium mineralization may imply the presence of more extensive carbonatite at depth and earlier in the eruption history of the volcano-plutonic complex. A model for multiple stages of magma generation at the massif will be presented.

Stable carbon and oxygen isotope compositions of carbonatites at Speewah, Kimberley, Australia

Demény, A.[1*] & Gwalani, L.G.[2]
[1]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary (*demeny@geochem.hu)
[2]Speewah Fluorite-Carbonatite Research Project, NiPlats Australia Limited, Perth, Western Australia, Australia

Carbonatites at Speewah in the Kimberley region of Western Australia, about 110 km southwest of Kununurra, form dykes that were emplaced along a north-trending splay from the northeast-trending Greenvale Fault at the western boundary of the Halls Creek Orogen. The carbonatite dykes intrude a thick composite sill of the Palaeoproterozoic Hart Dolerite (~1790 Ma), comprising tholeiitic dolerite and gabbro with its felsic differentiates that form the Yilingbun granophyres and associated granites. The dykes are comprised of massive calcite-carbonatite that hosts very coarse, pegmatitic veins and pods of calcite, and have largely replaced (carbonatitized) and fenitized the country rock Hart Dolerite suite (in a zone up to 150 m wide). Dykes of red-brown siliceous fluidized-breccia and epithermal-textured veins consisting of bladed quartz, adularia and fluorite are closely associated with the carbonatite dykes. Fluorite occurrences (resources currently reported as 6.7 Mt at 24.6% CaF_2) are also thought to be related to carbonatite emplacement. Although the precise age of the carbonatite is not known, it is thought to be post early Cambrian. Carbonatite occurrences from two areas (Yungul and Willmot) have been investigated by means of carbon and oxygen isotope analyses in order to determine the origin of the carbonate. The carbon isotopic compositions have indicated C isotope ranges of about –5.2 to –6.3‰ that support primary, mantle-derived origin for the carbonatites. The C and O isotope compositions show an overall positive correlation that can be attributed to both magmatic and magmatic-hydrothermal processes in their evolution. The Yungul carbonatites show rather wide C and O isotope ranges, whereas the Willmot localities are much more homogeneous, fitting the Yungul compositions. The magmatic C-O isotope trend also indicates crustal contamination and/or low-temperature water/rock exchange.

Microprobe and fluid inclusion evidence for late-stage zirconium, phosphorus, titanium and REE mineralisation in fenite

Dowman, E.[1,2*], Rankin, A.[1], Wall, F.[3], Carter, A.[4] & Jeffries, T.[2]
[1]School of Geography, Geology and the Environment, Kingston University, Kingston upon Thames, Surrey, UK
([*]emma@abdm.co.uk)
[2]Dept. of Mineralogy, Natural History Museum, London, UK
[3]Camborne School of Mines, University of Exeter, Cornwall Campus, Penryn, Cornwall, UK
[4]Dept. of Earth Sciences, UCL, London, UK

Most carbonatite complexes are surrounded by an aureole of metasomatised rocks, known as fenite. These rocks contain high levels of Na and K, with alteration assemblages of aegirine, sodium-rich amphibole and turbid K and Na feldspar. We are studying the mobility of the REE, Nb, P and Zr in well-developed fenite aureoles associated with REE-rich and apatite-magnetite-pyrochlore-bearing carbonatites at Kangankunde and Chilwa Island, Malawi.

Recrystallised quartz in the outer fenite has trapped typical portions of carbonatitic fluids as mostly secondary inclusions (c. 2-20 microns in size). That these traces are closely associated with CO_2-rich and alkali chloride-carbonate-bearing brines is shown by the occurrence of nahcolite ($NaHCO_3$), halite, calcite and the REE-carbonate phase, burbankite, as daughter minerals within fluid inclusions. Trace mineralisation in the form of solid inclusions (30-150 microns) of Nb-bearing rutile, zircon, baryte, strontiantite, fluorite and titanite is present in these outer fenites, together with REE-bearing banded fluorapatite, monazite, bastnäsite, and more rarely, epidote, celestine and plumbopyrochlore. Such assemblages are characteristic of late-stage carbonatitic fluids from mineralised carbonatite complexes. Rutile and fluorapatite are also present as trapped solids within inclusions, and co-eval with the mineralisation.

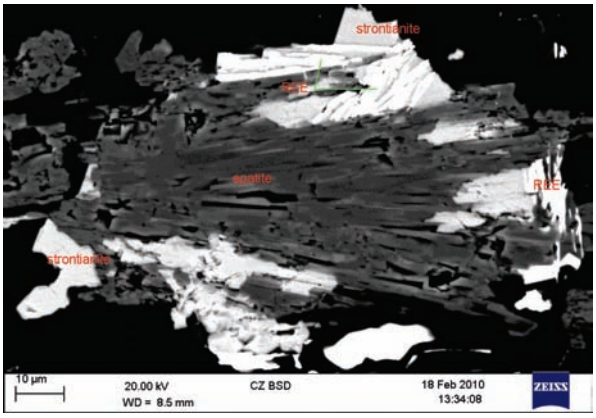

Fig. 1: SEM image of Kangankunde mineral assemblage.

The presence of such late-stage mineralisation derived from carbonatitic fluids in fenitised rock at some distance from carbonatitic intrusive centres supports previous work on the transport capabilities of such fluids [1] and suggests that the fenitising fluid has a direct relationship to the main REE mineralization in the central part of the complex. Fission track dating of apatite confirms a carbonatitic age but zircon from the assemblage dated by LA-ICP-MS gave an older age and may be originally, at least in part, derived from the country rock.

The alkaline ring complexes of Egypt, revisited

El-Kaliouby, B.A.[1], Imbarak, S.H.[2*] & Buda, G.[3]
[1]Geology Dept., Ain Shams University, Cairo, Egypt
[2]Geology Dept., Suez Canal University, Ismailia, Egypt
([*]imbarak25@yahoo.com)
[3]Inst. of Geology, Eötvös Loránd University, Budapest, Hungary

The ring complexes of Egypt represent the northward continuation of the chain of ring complexes that associate the East African Rift System. Some fourteen alkaline ring complexes are encountered in the Eastern Desert of Egypt. They were formed during a long period of time extending from the Cambrian to the Upper Cretaceous and are characterized by special geological environments and form a number of characteristic rock associations. The distribution of the ring complexes in Egypt follows certain trends and is restricted to crests of anticlines due to high degree of fracturing along these crests. The largest ring complexes are those formed where two trends intersect. They are circular to elliptical in plain, and include a wide variety of rock types of alkaline affinities, ranging from mafic to felsic and from undersaturated to quartz-bearing syenitic rocks and their volcanic equivalent, all arranged in a concentric fashion.

The presence of nepheline syenite and related feldspathoidal types was described at the central part of Gabal Abu Khrug, Gabal El Kahfa, Gabal Nigrub El Fogani and Gabal El Naga, The presence of some syenite occurrences in connection with the ring complexes at South Eastern Desert is known at Zargat Naam.

There is a distinct change in the degree of alkalinity and silica saturation with age of the complexes. The older complexes are generally silica oversaturated and relatively low in alkalis, whereas the younger complexes are dominated by silica undersaturated rock types and are rich in alkalis

The origin of these complexes is probably due to alkaline melts that have been formed in the asthenosphere by shear heating, caused by changes in plate motion. These melts were emplaced along reactivated Pan-African fractures or pre-existing zones of weakness. The major structural features of the Nubian shield were formed during the Pan-African compression-accretion process (1,000-550 Ma BP) NE-SW and NW-SE zones of weakness. Most of the alkaline complexes of Egypt are associated with these lineaments.

The Egyptian ring complexes are classified into five types on the basis of their magmatic differentiation reflected in the variety of rocks they include, and on the degree of development of the ring nature and complexity of the structure:

(a) **Gabal Abu Khruq type**: These are fully differentiated complexes of a complicated structure containing nepheline syenites.

(b) **Gabal El Gezira type**: These are also highly differentiated complexes but with no nepheline syenite.

(c) **Gabal Mishbeh type**: This type is characterized by the slight differentiation of its rocks, the hardly recognizable ring nature and the rather complicated internal structure. They are formed of a variety of alkaline quartz syenites and some nepheline syenite.

(d) **Gabal Mansouri type**: These are the same as the Mishbeh type but lack any nepheline syenite.

(e) **Gabal Tarbtie type**: These are ring complexes of a simple structure and composition, formed of alkaline quartz syenite (nordmarkite) with relics of the volcanic cone. The dominant structure is a system of ring dykes.

K/Ar ages on mineral separates (biotite and hornblende) from these complexes yielded ages that range from 554 m.y. for Wadi Dib complex to 89 m.y. for Abu Khruq complex, i.e. from the Cambrian to the Upper Cretaceous [1].

In-situ radiogenic isotope analysis and geochronology of accessory phases in alkaline complexes: Kaiserstuhl-Hegau Complex (Germany) as an example

Ghobadi, M.[1*], Gerdes, A.[1], Brey, G.P.[1], Höfer, H.E.[1] & Keller, J.[2]
[1]Institute of Geosciences, Goethe University, Frankfurt, Germany ([*]M.Ghobadi@em.uni-frankfurt.de)
[2]Institute für Mineralogie-Geochemie, Albert Ludwigs Universität, Freiburg, Germany

The origin and genesis of carbonatites and associated alkaline silicate rocks are since long in the focus of many research studies. Up to now most previous studies on the isotope composition of carbonatites have been based on whole rock analyses. Here we apply in-situ analytical methods to study the elemental and isotopic composition and variability of different accessory phases from the Miocene Kaiserstuhl and Hegau Alkaline Complexes. Our aim is to compare the mineral with whole rock data and to see if we gain additional information about the evolution of alkaline rocks and processes controlling their geochemical variations. Due to high absolute REE and Sr contents in alkaline rocks, the Rb-Sr and Sm-Nd isotope systems are relatively insensitive to crustal contamination and alteration processes.

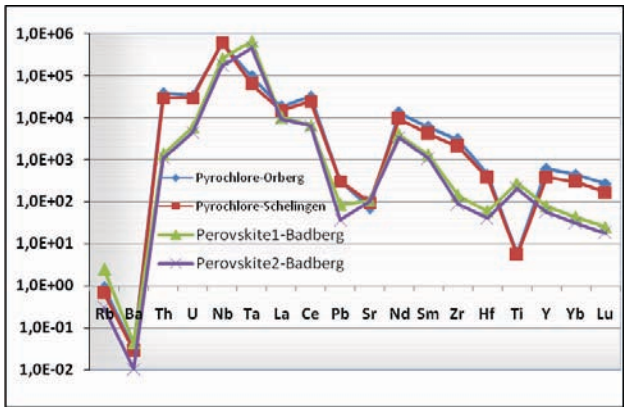

Fig. 1: Primitive Mantle normalized trace element diagram of perovskites and pyrochlores.

Our first results from in-situ LA-SF-ICP-MS Rb-Sr, Sm-Nd, and U-Pb spot analyses of perovskite and pyrochlore agree, in general, well with previous carbonatite whole rock data [1] and K-Ar ages. The εNd for perovskite and pyrochlore show a relatively narrow range from 3.2-4.3 and 3.2-4.4, respectively. This is slightly higher than previous measurements based on whole rock analyses (2.8-4.0) [1]. In the case of Sr isotopes the majority of the pyrochlore analyses ($^{87}Sr/^{86}Sr$: 0.7033-0.7048) overlap with the range known for carbonatites [2]. However, some pyrochlore (0.7052-0.7072) and all perovskite analyses (0.7048-0.7060) yielded considerably higher values. This could suggest either an analytical problem due to incomplete interference correction during isotope analyses or some alteration of the minerals due to interaction with a crustal fluid. The latter process is in line with our $^{206}Pb/^{238}U$ ages of perovskite (14.8 ±0.9 Ma) and pyrochlore (15.5 ± 0.4 Ma), which overlap with the lower range of published K-Ar ages but are significantly younger than the Ar-Ar sandine and phlogopite ages (17.2 and 17.3 Ma, respectively) [3].

REE distribution in clinopyroxenes and amphiboles from Panozero sanukitoid pluton - indication of postcrystallisation autometasomatism

Guseva, N.S.[*] & Skublov, S.G.
Institute of Precambrian Geology and Geochronology RAS, St.-Petersburg, Russia ([*]nadezhda_guseva@mail.ru)

The late Archean Panozero pluton in Central Karelia (Baltic Shield) is a multi-phase high-Mg, high-K intrusion with sanukitoid affinities, emplaced at 2.74 Ga. The magmatic history of the intrusion may be subdivided into three discrete magmatic impulses. The pluton includes rocks ranging from pyroxenites to monzonites. These rocks are products of fractional crystallization of a parental magma in a periodically replenished, periodically erupted magma chamber.

First estimation of the composition of the parental magma shows that it is enriched in LREE, Sr, Ba, Cr, Ni and P [1]. But our study of REE distribution in clinopyroxenes and amphiboles, added to data for the Sm-Nd isotopic system, indicates that there was a stage of LREE enrichments at some stage in the history of the pluton.

Clinopyroxene is the first crystallizing phase of the rocks of first and second impulse, so they in the most part reflected the composition of the parental magma. Clinopyroxenes are unzoned and have Mg# 0.72 –0.75. Amphiboles are calcic and according to the classification [2] are Mg-hornblende, edenite and pargasite (hornblende group) and actinolite-tremolite.

REE in minerals were determined on a CAMECA-IMS-4f ion microprobe. Sm-Nd isotopic system data were adopted from [1].

The results indicate that CPx with nondisturbed Sm-Nd system has moderate LREE enrichment while the CPx with disturbed Sm-Nd system has strong LREE enrichment.

The shape of these REE patterns is unusual for most part of igneous clinopyroxenes, although similar patterns have been noted in clinopyroxenes from some alkaline rocks and metasomatized mantle xenoliths [3].

In the majority amphiboles (in both hornblende and actinolate) the shape of REE distribution is similar to clinopyroxenes that is characteristic for magmatic amphiboles, crystallizing in the conditions close to equilibrium with clinopyroxenes. In some amphiboles the second type of REE distribution, without enrichment by the easy rare earths is observed. Such REE distribution is observed in amphibole from rocks with strong Nd-isotopic system distribution.

REE-distribution patterns in clinopyroxene and amphibole allows us to make the conclusion that the rocks of Panozero pluton have undergone certain process after crystallization which have partially disturbed the Nd-isotopic system in rocks and minerals and led to the REE redistribution between minerals. Such a process may have been capillary metasomatism, caused by the influence of the fluids, which have separated from (parental?) subalkaline magma.

Rare element minerals within Ditrău alkaline intrusive complex, East Carpathians, Romania

Hîrtopanu, P.[1*], Andersen, J.[2], Fairhurst, R.[2] & Jakab, G.[3]
[1]Dept. of Mineralogy, University of Bucharest, Romania
([*]paulinahirtopanu@hotmail.com)
[2]Camborne School of Mine, University of Exeter, UK
[3]IG Mineral, Gheorgheni, Romania

The Ditrău alkaline intrusive complex is situated within the crystalline rocks of the inner part of the East Carpathians. It has a distinct ring structure and a succession of magmatic events from gabbroic and dioritic magma to syenitic and various postmagmatic events as well, developed between a Triassic extensional stage and a Jurassic rifting stage. The succession of magmatic events in Ditrău could be completed with carbonatite intrusion, that followed after the alkaline intrusion and used the same pathways of the previous alkaline silicate melt. Its affiliation to anorogenic alkaline magmas explains their general feature Nb>>Ta and the predominance of LREE. The Ditrău carbonatite alkaline intrusive complex represents the end of long lasting fractionation processes in the crust and deep upper mantle, respectively. This explains the modest dimensions of Ditrău intrusion and its enrichment with incompatible elements. The high petrographic complexity of Ditrău massif is doubled by a great diversity of mineral occurrences. In addition to the 85 minerals previously mentioned, approximate 200 were recently identified, many of them being first occurrences in Romania.

The rare element minerals which were determined in Ditrău complex intrusion, belong to the following classes (in the predominant order): I. LREE(Y) carbonates: bastnaesite-(Ce), bastnaesite-(La), parisite-(Ce), parisite-(La), synchysite-(Ce), kainosite-(Y); II. Oxide minerals of Nb, Ta, REE(Y), Ti, Zr, Th, U: 1. Pyrochlore group with two subgroup: A. Pyrochlore subgroup: pyrochlore, yttropyrochlore, thorpyrochlore, ceriopyrochlore, bariopyrochlore, uranpyrochlore; B.Betafite subgroup: betafite, yttrobetafite-(Y); Microlite subgroup, with Ta>Nb is absent; 2. Fergussonite group: fergussonite-(Y); 3. Columbite-Tantalite group: ferrocolumbite, mangancolumbite; 4. Aeschynite group: Aeschynite-(Nd), Aeschynite-(Ce), Aeschynite-(Y); 5. Niobian rutile group; 6. Ilmenorutile group; 7. Baddeleyite group; 8. Secondary Th, Ce, U oxides: thorianite, cerianite-(Ce), uraninite; III. REE(Y), Phosphates: REE-apatite, REE-carbonatfluorapatite, monazite-(Ce), brabantite-huttonite, huttonite-monazite series, cheralite, karnasurtite-(Ce), karnasurtite-(Y), xenotime-(Y); IV. Silicates of REE-(Y), Th, Zr, Pb: allanite-(Ce), thorite, Fe-thorite, Fe-Zr-thorite, Pb-thorite, cerite-(Ce), lessingite-(Ce), cevkinite, zircon, Th-zircon; V. Halides class: Y-fluorite; VI. Tellurides class: Bi-Te (hedleyite) and unnamed Bi,Pb-Te. All these rare element minerals belong to the two different mineralization types, localized in two different areas of the Ditrău massif: Jolotca area, of vein type with rare element minerals rich in LREE, Nb, sulphides (pyrite, sphalerite, molibdenite, galena) linked to calcite- ankerite-, dolomite carbonatite in NV of massif, and Belcina area with Y and Th mineralization, less LREE, less sulphides and rich in Fe-oxides and hydroxides, situated outside the massif (towards SE), in the surrounding metamorphic rocks of Tulgheş Group. The Ta content of pyrochlore group in this area is high, but it maintains lower than Nb (Ta<Nb). The Belcina occurrence could be the last later stage, lower temperature carbonatites.

One can consider the Ditrău carbonatite alkaline intrusive complex as an example of primary magmatic crystallization in the first alkaline stage, followed by a carbonatite magma and then a hydrothermal or carbothermal depositions of largely rare element minerals. On the other hand, some rare element minerals, like Fe-thorite, Pb-thorite, Zr-thorite, Th-zircon, Bi-Pb telluride, etc could be new mineral species.

Morphological and spectroscopic features of microdiamond from Chagatay carbonatites (Uzbekistan)

Isaenko, S.I.[1*], Shumilova, T.G.[1] & Divaev, F.K.[2]
[1]Institute of Geology, Komi SC, UD, RAS, Syktyvkar, Russia
([*]s.i.isaenko@gmail.com)
[2]Central Geological-Geophysical Expedition of Government Geological Committee of Republic Uzbekistan

The new genetic type of diamond connected with carbonatites of Chagatay trachyte-carbonatite complex at the northern slopes of the Southern Nuratau Mts. [1] was discovered at the end of 20th century. By this moment the data about mineralogical particularities of the carbonatitic diamonds are very limited. Here we report for the first time about spectroscopic features of microdiamond enriched from the host rock with the method of thermochemical dissolution. The unique crystal was investigated using optical transparent microscopy, electron scanning microscopy and Raman spectroscopy.

The microdiamond crystal has skeletal habit and size about 50 μm, it is optically transparent and almost colorless with brilliant glance on facets. The crystal has been described with 13th facet variety of octahedron by Shafranovsky I.I. classification.

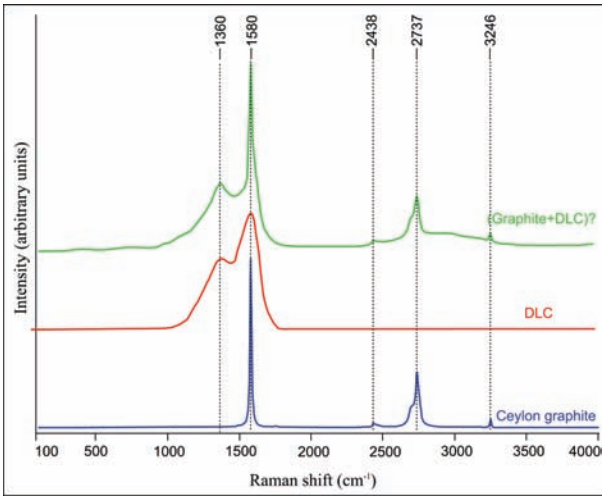

Fig. 1: Raman spectra of the microdiamond and reference standard of DLC and graphite. Raman spectrometer LabRam HR 800 with 488 nm line of external Ar^+ laser was used in this study at room temperature.

Using Raman spectroscopy two main types of spectra were identified. The first type is the spectrum with a peak of 1332 cm^{-1}, which corresponds to the frequency of diamond lattice oscillations at room temperature. The second type of spectrum is additive (Fig. 1, upper) – it consists of overlapping characteristic bands for graphite and DLC (diamond-like carbon). For comparison, reference spectra for the Ceylon graphite and DLC are also shown in the figure.

The received data are very important for understanding of formation mechanism of the new type of origin diamond objects.

Alkaline rocks in the Aris area, central Namibia, Africa

Koller, F.[1*], Palfi, A.G.[2], Szabó, Cs.[3], Niku-Paavola, V.[4] & Popp, F.[1]
[1]University of Vienna, Austria ([*]friedrich.koller@univie.ac.at)
[2]Eximus Technologica Corporation (Pty) Ltd., Windhoeck, Namibia
[3]Lithosphere Fluid Research Lab, Dept. of Petrology and Geochemistry, Inst. of Geography and Earth Sciences, Eötvös University, Budapest, Hungary
[4]Geological Survey, Windhoek, Namibia

In the Aris area, south of Windhoek (Central Namibia) a cluster of Tertiary alkaline volcanic rocks were emplaced on and into the Paleoproterozoic basement gneisses. The alkaline suite consists mainly of highly variable phonolites, formed as subvolcanic or extrusive plugs, nepheline trachytes, extrusive trachytes as pyroclastic rocks and one under-saturated trachybasaltic sill.

The phonolites contain as main minerals nepheline, sodalite, sanidine, albite and aegirine. Blue amphiboles occur extremely rare and were found only at one locality so far. Nepheline and sodalite can be altered to natrolite. Further accessoric minerals are Mn-pectolite and goetzenite and various other unidentified phases. The alkali pyroxene is commonly zoned with a Di+He rich core (acmite >30%) and a Na-rich rim (acmite >90%). The nephelines can be defined by X_{Ks} of 0.15-0.19, sodalite with X_{Cl} values of 0.80-0.85. Both, sanidine and albite are homogenous and rather close to their end members with $Or_{0.90-0.95}Ab_{0.10-0.05}$ and $Ab_{0.97}Or_{0.03}$.

The bulk geochemistry of all phonolites is rather uniform with a Na/K ratio of ~3. In contrast to the homogeneous bulk composition there are strongly varying contents of F (200-12000 ppm) and Cl (50-6200 ppm), further a wide variation in the trace elements. In the phonolites Zr may range in individual complexes from 1300-2600 ppm with a Zr/Y ratio from 50-250. Also Nb show huge differences between the individual phonolite outcrops ranging from 330-1030 ppm. The REE-patterns show highly enriched LREE with La_N/Lu_N ratios are varying in a range of 25-50 and in some cases with a small negative Eu anomaly.

The nepheline bearing trachyte dikes are crosscutting the phonolites and are slightly Mg and Ca richer than the phonolites, but clearly Na poorer with a Na/K ratio around 2. The Zr, Nb, and REE are also slightly lower. The pyroclastic trachytes are K rich and lower in all trace elements.

Peculiarities of garnets from kimberlites of Nakynsky field, Yakutia

Kornilova, V.P., Spetsius, Z.V.[*], Lelukh, M.I. & Gerasimchuk, A.V.
ALROSA Co Ltd, Mirny, Yakutia, Russia,
([*]spetsius@cnigri.alrosa-mir.ru)

The Nakynsky kimberlite field is situated on the east part of Yakutian kimberlite province, about 250 km north–east from the town Mirny. Two diamondiferous kimberlite pipes (Botuobinskaya and Nyurbinskaya) with industrial grade of diamonds have been discovered within the Nakyn field about 10 years ago. Two additional little pipes (Mayskaya and Marxinskaya) were discovered only recently, in 2006. Unlike the other kimberlitic pipes of Yakutian province that belong to group 1, kimberlites of the Nakynsky field are similar to group 2, and are characterized by low K_2O and TiO_2 content, nearly full absence of ilmenite and high diamond grade.

Study of mineral inclusions in diamonds from these kimberlites reveal the presence of unusually large number of orange garnets, indicative of eclogite association. These data are confirmed by a wide distribution of eclogitic garnets in kimberlites of these pipes, which in the whole combine about 50% of garnet population from kimberlitic concentrate (Fig. 1).

Chemistry of garnets from the Nuyrbinskaya and other pipes testify that primary source of kimberlitic magmas of this field was strongly depleted mantle that have been intensively modified by later metasomatose enriched in potassium component.

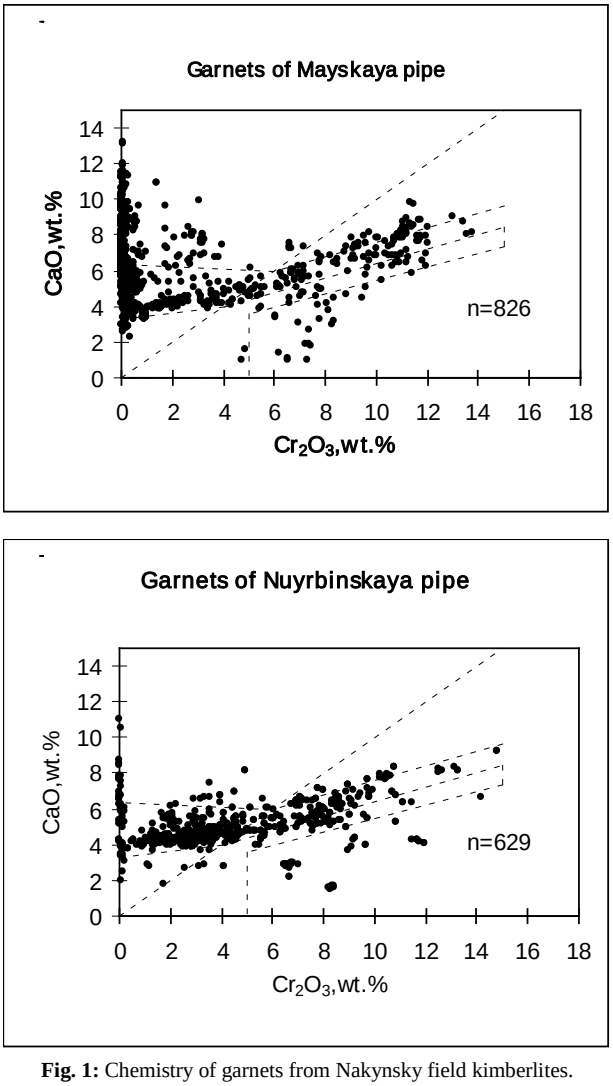

Fig. 1: Chemistry of garnets from Nakynsky field kimberlites.

Rare-earth mineral phases in carbonatites (Timan province, Russia)

Kovalchuk, N.
Institute of Geology, Komi Science Centre of RAS Urals Division, Syktyvkar, Russia (kovalchuk@geo.komisc.ru)

The research object is rare-earth mineral phases in carbonatites from the Kosyu massif (Timan province, Russia). Carbonatite massives are known in various parts of the globe, they are one of the basic sources of rare-earth raw materials. In the world more than 500 carbonatite bodies are known, many of them are commercial deposits. In Russia there are several well studied carbonatite provinces. However the Timan province, despite a number of industrial works in 1970-80s, differs by the least exploration degree. At present problems of phase attributes of rare-earth elements are still badly studied, which is one of the major problems for further estimation of prospects of the given object. The Kosyu carbonatites are characterized by considerable number of rare-earth mineral phases, the most frequent of them were analyzed by V. I. Stepanenko [1]. The modern instruments allows advanced study of substance at microlevel, provides more accurate data on mineral phases.

For the first time for the given object we carried out microprobe investigations of rare-earth mineral phases. In total about 100 analyses of the given type of mineralization have been done, and the phase diagnostics using the database of the museum named after A. E. Fersman and E. I. Semenov's basic monography have been performed. Microprobe studies as well as SEM allowed estimating features of chemical composition of the studied phases and receiving preliminary data on interrelations of rare-earth phases with rock-forming and ore components. In the Kosyu carbonatites the following phases are diagnosed: monazite, bastnaesite, pyrochlore, ancylite, Sr-rare earth carbonate, Nb-containing rutile and also Sr-Ce-La-phase. Rather wide variations of chemical composition of monazite have been determined, its leading geochemical specialization has been defined and its various morphological types of segregations have been determined.

The phase diagnostics has resulted in the considerable extension of data on rare-earth mineral phases in the Kosyu carbonatites, and the given object seems very promising for further investigation.

The RHA mineral classification of rocks exemplified on nepheline syenite family

Krasnova, N.I.*, Petrov, T.G. & Korolev, N.M.
Saint-Petersburg State University, Saint Petersburg, Russia
(*nataly_krasnova@rambler.ru)

A new method of description of mineral composition, which will promote improved nomenclature, is offered. The practical absence of parallel chemical and mineral content analyses of alkaline rocks has compelled the use of their normative composition, calculated by means of the program Norm-4.

The normative compositions for 418 chemical analyses of many alkaline rock varieties taken from different sources have been calculated. The results are represented in volumetric %, that most corresponds to the visual definition of the rock. The full version of data is displayed on the web-site: http://geology.pu.ru/ the file Min comp_alkaline rocks.rar.

The classifications of chemical and mineral composition have been made using the rank-entropy RHA-method [1]. R – the rank formula – is the succession of components in the system ranged according to diminishing content in the analysis. As a result we receive a set of rank formulae (R-Min) – sequences of minerals e.g. of type AbNeOrt… that correspond to decrease of volume fractions (%) of minerals in rock Ab> Ne> Ort>….

The rank formula sets are ordered under a certain "alphabet". The "alphabet" is the sequence of these minerals received in their chemical R-classification (a file R-Min-Catalogue-2007.rar at the same web-site). The principle of mineral rank formulae ordering is shown in the table.

Rank formula mineral				Rock name	An%
Ne	Ort	Ab	Di	khibinite	0
Ne=	Ort	Ab	Di	syenite	0
Ne=	Ort	Di	Ab	syenite Ne	2
Ab	Ne	Ort	Aeg	lujavrite	0
Ab	Ort	Ne	Ol	miaskite	7
Ab	Ort	Ne	Ol	syenite Ne	4
Ab	Ort	Ne	Ol	foyaite	12
Ort	Ne=	Ab	Aeg	khibinite	0
Ort	Ne=	Ab	Aeg	foyaite	0
Ort=	Ne	Ab	Di	syenite Ne	0

Our data illustrate the well-known domination of Ne, Ort and Ab assemblages in the composition of main Ne-syenite types. The RHA-method allows creation of a uniform, unequivocal classification of mineral compositions not only of the nepheline syenite group, but also all sets of rocks. It is necessary to consider the real mineral composition, including micas, amphibole, cancrinite, etc, instead of some virtual components, received sometimes from norm calculation.

Rock classification based on mineral composition using the RHA-method earlier has also been done on an example of phoscorites and carbonatites [2].

Partitioning of trace elements between garnet, clinopyroxene and diamond-forming carbonate-silicate melt at 7 GPa

Kuzyura, A.V.[1*], Wall, F.[2], Jeffries, T.[3] & Litvin, Yu.A.[1]
[1]Institute of Experimental Mineralogy RAS, Chernogolovka, Moscow region, Russia ([*]shu25@rambler.ru)
[2]Camborne School of Mines, University of Exeter, Penryn, UK
[3]Dept. of Mineralogy, Natural History Museum, London, UK

A better understanding of the geochemical behaviour of trace elements at mantle conditions relevant to diamond formation may help to constrain the identity of the mantle medium from which natural diamonds can grow.

Our experimental work studied partitioning of trace elements under high pressure melting of a natural silicocarbonatite, to which representative set of trace elements had been added. Concentrations of trace elements in coexisting garnet, clinopyroxene and completely miscible carbonate-silicate melt were determined using LA-ICP-MS.

Light REE are partitioned favourably into the melt phase, and the rest REE go into garnet (Fig. 1). The Sm and Nd K_D values (for garnet/melt) are near to 1, as usually expected for REE when garnet is present [1]. LILE (Rb, Sr, Ba), Sc, and also Zn, Ta, Pb, Th, U have an affinity for carbonate-silicate melt.

Comparison with published data for garnet, clinopyroxene and carbonatite melt, and garnet, clinopyroxene and silicate melt [2-4] shows that the trace element partitioning is not significantly altered by changes in melt composition, with HREE always concentrated similarly in the garnet (Fig. 1). Carbonate-silicate melt as a diamond-forming medium and carbonatite or silicate melt equilibrated with mantle silicate minerals behave similarly in respect of trace element distribution. This makes it difficult to choose between the two melts as potential diamond-forming media if only the garnet is available for measurement of trace element concentration.

[4]Institute of Geological Sciences, Masaryk University, Brno, Czech Republic
[5]Dept. of Earth and Environmental Sciences, Karel Englis College, Czech Republic
[6]Geological Survey of Canada, Ottawa, Canada

A large suite of fresh and metasomatically modified carbonatites from the Lugiin Gol (a.k.a. Lugingol'skiy) complex in South Gobi, Mongolia, was examined. The samples chosen represent not only rare carbonatite outcrops, but also drill-core material (down to a depth of 1200 m) that has not been previously studied. The Lugiin Gol carbonatites may have some economic potential due to their overall high content of rare-earth elements (REE). Their chondrite-normalized REE profiles have a steep negative slope and lack any anomalies. In addition, these rocks are characterized by extremely high abundances of Ba and Sr, coupled with low levels of Nb, Ta, Ti, K, Rb and Cs. Their age of emplacement has been determined by U-Pb dating of zircon as Triassic (ca. 240 Ma, i.e. post-orogenic).

The carbonatites are represented predominantly by coarse-grained sövite, consisting of magmatic calcite, minor to accessory Na-Sr-REE-bearing apatite, and a plethora of rare-earth carbonates whose modal content locally reaches several per cent. The latter group is paragenetically diverse and includes both primary carbonates (burbankite–calcioburbankite series and REE fluorocarbonates) and hydrothermally or metasomatically formed phases associated with strontianite, fluorite, barite, celestine and quartz. The primary fluorocarbonates are represented by zoned synchysite-(Ce) crystals (synchysite I) with lamellae of bastnäsite-(Ce), parisite-(Ce) and röntgenite-(Ce).

The primary textures and parageneses are modified and overprinted by such late-stage processes as recrystallization of calcite, alteration of apatite, break-down and replacement of burbankite and other early-crystallized carbonates, followed by precipitation of secondary carbonate parageneses. The primary burbankite is pseudomorphed by an assemblage of synchysite II, calcite and strontianite, and the Na released at this stage is incorporated in khanneshite, carbocernaite and cordylite-(Ce). A careful study of the minerals associated with the REE mineralization and their structural relations shows that most of the carbonatites underwent subsolidus metasomatic processes of two types: (1) high-temperature (max. T ca. 450°C) fluoritization, accompanying the precipitation of REE carbonates and strontianite; and (2) low-temperature ($T \leq 150$°C) precipitation of barite, celestine and quartz.

Our data demonstrate the complexity of magmatic and subsolidus processes involved in the evolution of carbonatites in post-orogenic settings.

Lamprophyres of Middle Timan, Russia

Makeev, A.B.[*] & Bryanchaninova, N.I.
Dept. of Petrography, Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry RAS, Moscow, Russia ([*]abmakeev@mail.ru)

Subalkaline basic rocks of the dike series are widespread in Timan and belong to the lamprophyre group. These rocks are confined to deep-seated, long-lived faults striking NE, transverse to the general Timan northwestern extension of plicative and disjunctive structures. The host rocks are sandstones and clay shales of the Chetlas and Bystrin groups. In the area of lamprophyres, the sediments of the Chetlas Group form a gently SW-dipping monocline complicated by small gentle folds. Beds commonly dip 10°–20°, becoming steeper near Middle Timan fault zone. The rocks of the Bystrin Group are deformed into simple folds whose limbs dip up to 40°. The lamprophyres comprise hundreds of bodies (predominantly dikes and a few stocks) that show no spatial relation to intrusive magmatism. They form several fields with the area of approximately 1000 km^2 in the southeastern part of the Chetlas Kamen. Postcrystallization transformations of the lamprophyres were caused by autometasomatism (phlogopitization, amphibolization) and hydrothermal processes. Carbonatites spatially related to the lamprophyres and localized in the same fault zones are the younger rocks. Their possible age established by phlogopite K–Ar dating is 600 ± 30 Ma.

Two isochrons were obtained from Rb-Sr dating of the lamprophyres. The first is 819 ± 19 Ma, and the initial Sr ratio $(^{87}Sr/^{86}Sr)_0$= 0.70421 ± 16, definitely indicates the mantle source of the protolith and the absence of post-crystallization alteration. The second isochron hash practically the same age parameter 826 ± 31 Ma but more radiogenic Sr isotopic composition $(^{87}Sr/^{86}Sr)_0$ = 0.70693 ± 24 and is caused by significant crustal contamination of the rock-forming protolith.

It is concluded that the lamprophyres were formed in the Neoproterozoic at 820 Ma, confirming their within-plate (pre-Timanian) origin. Local postcrystallization transformations of lamprophyres took place in the Early Cambrian (530 ± 10 Ma) after the Timanide orogeny.

The sub-alkaline basalts of the dyke series that are widespread in Chetlassky Kamen are typical lamprophyres – they are holocrystalline rocks of porphyritic texture, containing phenocrysts of brown mica, clinopyroxene, amphibole, and a little olivine without any phenocrysts of feldspar at all. Their characteristic structural feature is a fine-grained base made of femic and salic minerals, with roundish, sometimes fused or corroded colored minerals phenocrysts, autoliths and xenoliths. The bodies of Chetlassky Kamen lamprophyres consist of an autonomous row of dikes, not bound to any intrusive massif spatially. According to chemical and mineralogical features the rocks are members of the kersantite – spessartite lamprophyre series. A certain typomorphism is characteristic for the rock-forming and accessory minerals of these rocks. The series of accessory minerals in lamprophyres and metasomatites around them is similar to the accessory minerals in the diamond-bearing Middle Devon conglomerate-breccia of Ichetju that testifies to the genetic closeness of lamprophyres to the rocks of the native source of Timan diamonds.

Rare earth-rich carbonatites at Lofdal, Namibia

Niku-Paavola, V.N.[1], Wall, F.[2*], Ellmies, R.[2,3] & Sitnikova, M.A.[3]
[1]Geological Survey of Namibia, Ministry of Mines and Energy, Windhoek, Namibia
[2]Camborne School of Mines, University of Exeter, Penryn, UK ([*]f.wall@exeter.ac.uk)
[3]BGR, Geozentrum Hannover, Germany

The carbonatites at Lofdal, Namibia are highly unusual in that they contain significant amounts of the the heavy REE mineral, xenotime-(Y). They are under active exploration for REE. The xenotime-(Y) occurs highly oxidised iron-rich calcite carbonatite dykes where it mantles and replaces zircon, forms aggregates in ankerite carbonatite, some of which are associated with hematite, and and forms crystals associated with monazite-(Ce) and synchysite-(Ce). The paragenetic sequence places the xenotime-(Y) at the end of magmatic activity and certainly into the hydrothermal stage [1]. Although the xenotime-(Y) is heavy *REE* enriched, the whole rock compositions are light *REE*-enriched in common with most carbonatites, although they are less enriched in light REE that most other published carbonatite data [1]. The light REE minerals present at Lofdal are also of potential economic interest.

Recent exploration work and mapping at Lofdal has revealed that there is a calcite carbonatite intrusion present in addition to the dyke swarm. This contains apatite and magnetite (but not in high enough quantities to be of economic interest) and is devoid of any significant quantity of rare earth minerals. This is consistent with observations at many carbonatite complexes that REE are concentrated in Fe-rich calcite and dolomite dykes rather than the earlier calcite carbonatite.

Trace-element variations in clinopyroxene from calcite carbonatites

Reguir, E.P.*, Chakhmouradian, A.R., Halden, N.M. & Yang, P.
Dept. of Geological Sciences, University of Manitoba, Winnipeg, Manitoba, Canada (*umreguir@cc.umanitoba.ca)

Clinopyroxene is a common constituent of carbonatitic rocks (sensu lato). Variations in major-element chemistry of clinopyroxenes from carbonatites have been addressed in a number of studies and shown to reflect the changes in temperature, pressure and chemistry of their crystallization environment [1-3]. By contrast, there is virtually no published data on the trace-element composition of these minerals. In this work, we examined the major- and trace-element variations in clinopyroxenes from calcite carbonatites from Murun (Aldan), Prairie Lake (Ontario) and Afrikanda (Kola) using wavelength-dispersive X-ray spectrometry and laser-ablation inductively-coupled-plasma mass-spectrometry.

Strongly zoned clinopyroxene from Murun ranges in composition from $Ae_{64}Di_{14}Hed_{22}$ in the core to $Ae_{78}Di_{11}Hed_{11}$ in the rim. This zoning pattern is accompanied by a decrease in Mn (from 1200 to 5000 ppm), V (from 7000 to 2000 ppm), Zn (from 600 to 160 ppm), Sr (from 350 to 120 ppm), Zr (from 2300 to 100 ppm), Hf and REE (both from 50 to 5 ppm) contents towards the rim. The LREE/HREE ratio also tends to decrease rimward. Clinopyroxene from Afrikanda and Prairie Lake corresponds to Fe-, Al- and Ti-poor diopside (80-86 mol. % and 75-88 mol. % of $CaMgSi_2O_6$, respectively). The zoning pattern of the Afrikanda clinopyroxene (decreasing Mg coupled with increasing Fe content toward the rim), differs from that observed in the Prairie Lake samples. However, the trace-element composition of the Afrikanda and Prairie Lake clinopyroxene shows a similar variation pattern, where the rim is enriched in Mn and REE and, to a much lesser extent, Sc, V and Zr relative to the core (up to 1900 and 4300 ppm Mn, 140 and 130 ppm ΣREE, 145 and 160 ppm Sc, 190 and 220 ppm V, 700 and 600 ppm Zr in the rim, relative to 1100-1400 and 2500-3700 ppm Mn, 25-115 and 35-80 ppm ΣREE, 75-130 and 45-100 ppm Sc, 40-170 and 100-170 ppm V, 110-500 and 85-480 ppm Zr in the core, respectively). The rims of clinopyroxene crystals from Afrikanda and Prairie Lake are characterized by higher LREE/HREE ratios relative to their cores. The observed compositional differences clearly indicate that the clinopyroxene/carbonatite distribution coefficients of Mn, V, Sc, REE and Zr are strongly influenced by the major-element chemistry of clinopyroxene, in particular by its aegirine content.

[1] Kapustin, Yu.L. (1987) *Novye Dannye o Mineralakh*, **34**, 63-70 (in Russ.). [2] Andersen, T. (1988) *Lithos*, **22**, 99-112. [3] Chakhmouradian, A.R. & Zaitsev, A.N. (2002) *Can. Mineral.*, **40**, 1347-1374.

Contrasting trends of trace-element zoning in phlogopite from calcite carbonatites

Reguir, E.P.*, Chakhmouradian, A.R., Halden, N.M. & Yang, P.
Dept. of Geological Sciences, University of Manitoba, Winnipeg, Manitoba, Canada (*umreguir@cc.umanitoba.ca)

Phlogopite is a ubiquitous accessory mineral in carbonatitic rocks and, owing to its large capacity for atomic substitutions and long crystallization span, can be used as a sensitive petrogenetic indicator. In the literature, zoning in phlogopite crystals from carbonatites has been suggested to reflect variations in crystallization conditions (e.g., T and fO_2) in the course of carbonatite evolution. In this work, we examined the major- and trace-element composition of phlogopite in calcite carbonatites from Iron Hill (Colorado), Kovdor (Russia), Prairie Lake and Oka (Canada). The composition of the mineral was determined by wavelength-dispersive X-ray spectrometry and laser-ablation inductively-coupled-plasma mass-spectrometry.

The Iron Hill and Oka samples exhibit similar core-rim evolutionary trends of enrichment in kinoshitalite, $BaMg_3Al_2Si_2O_{10}(OH)_2$, component. The rims also contain higher levels of Sr, Sc, Zr and Nb relative to the cores. The Mn and Rb contents generally decrease rimward, but their variation trend is not as pronounced as the Ba, Sr, Sc, Zr and Nb trend. The Kovdor and Prairie Lake phlogopite shows a strong enrichment in Fe in the rim, and an inverse pattern of Sr, Ba, Mn, Sc and Zr variation relative to that observed in the Iron Hill and Oka samples. There is significant overlap in Rb values in the Kovdor and Prairie Lake phlogopite, although the cores typically contain somewhat higher levels of this element. In common with the Iron Hill and Oka samples, the rims of phlogopite from Prairie Lake are enriched in Nb relative to the cores, whereas the Kovdor material shows an inverse trend. The core-to-rim trend of increasing Co/Ni ratio observed in the Prairie Lake phlogopite contrasts with that of the Kovdor material, whereas crystals from Iron Hill and Oka are Co- and Ni-poor. The V concentrations decrease rimward in the Iron Hill and Kovdor phlogopite, but increase in the Prairie Lake and Oka samples. The ∑REE concentrations do not exceed 14 ppm in any of the samples.

Conclusions. (1) Phlogopite does not contribute significantly to the REE budget of carbonatites, but is the principal host for K, Rb and Cs in feldspar-free carbonatite types. (2) There appears to be no universal pattern of zoning that could be explained by a consistent pattern of trace-element partitioning between phlogopite and carbonatitic magma. (3) Two major trends of trace-element variation can be recognized in zoned phlogopite from calcite carbonatites: (i) kinoshitalite trend, involving a concomitant increase in Sr, Zr, Nb and Sc and a decrease in Mn and Rb; and (ii) Fe-enrichment trend involving a rimward depletion in Ba, Sr, Zr and Sc at an increasing Mn content. (4) Intragranular variations in such trace elements as V, Nb, Ta, Co and Ni lack consistency, which is probably due to competitive

Carbonatitic zircon – geochemical analysis

Savva, E.V.[1], Belyatsky, B.V.[2*] & Antonov, A.V.[3]
[1]IPGG RAS, St.-Petersburg, Russia
[2]VNIIOkeangeologia, St.-Petersburg, Russia
([*]bbelyatsky@mail.ru)
[3]CIR, VSEGEI, St.-Petersburg, Russia

It is well-known that in magmatic systems undersaturated in silica, such as alkali-ultramafic and carbonatite melts, if there is sufficient zirconium, baddeleyite and other zirconium minerals (zirconolite, calzirtite, zirkelite etc) crystallize in preference to zircon, which should be dissolved [1]. However, for many carbonatite–alkali-ultramafic massifs zircon is the prevailing accessory mineral both in silicate and carbonatite rocks. Very often it forms large, up to centimeter, crystals of pseudo-octahedral habit [2]. The following characteristics have been assumed as typical for "carbonatite" zircons basing on restricted data from the Mud Tank carbonatite complex (723 Ma) in Central Australia and the Kovdor complex (380 Ma), Kola Peninsula, Russia: average REE content 600-700 ppm at comparatively flat distribution, (Yb/Sm)n: 3÷30, Th/U up to 100 and more, 2.3<Lu<20.7 ppm, Ta>0.5 ppm, Hf>0.62 % [3]. We tested the plausibility of these characteristics on zircons from carbonatite massifs of different ages and origins, including zircons from the Archean Siilinjärvi massif, Proterozoic Tiksheozero and Elet'ozero massifs, Paleozoic Lovozero and Khibiny massifs and Mesozoic carbonatitic dyke from Antarctica.

We have analyzed more than 100 zircon grains for rare and trace elements. The morphology of the zircons studied repeats the known features of zircons from the other carbonatite massifs [2]. REE patterns of the zircons are characterized by extreme variability – from weakly fractionated flat chondrite-normalised REE distribution with generally low rare elements to fractionated patterns with prominent enrichment in heavy REE and well pronounced negative Eu and positive Ce anomalies, but there are distributions with distinctly increased REE content with positive Eu and weak Ce anomalies: (Sm/La)n: 2÷738, (Lu/Gd)n: 1÷58, Ce/Ce*: 1.2÷194.1, Eu/Eu*: 0.7÷1.78, (La/Gd)n: 0.0005÷0.5, (Pr/Gd)n: 0.01÷1.0, (Gd/Yb)n: 0.03÷0.9. Noteworthy in our case are the wide variations in (Yb/Sm)n: 0.9÷180, Th/U: 0.2÷512; [Hf]: 1020÷8700; [Lu]: 1÷94, [Nb]: 3÷ 2675; [Ta]: 4.7÷68 ppm and only about 45% of the studied zircons could be convincingly classified as carbonatitic according suggested characteristic ratios and element contents [3]. Moreover, variations in zircon composition within the single complex could be compared with general variations and even in some grains there have been observed fluctuations in content of some elements of more than one order of magnitude: [Th] – from 4.7 to 270, [Lu] from 1 to 11, [Y] – from 15 to 430 ppm. Zircons from carbonatitic dykes and veins showed the least variations. Crystallization temperatures of the zircons by Ti geothermometer correspond to a rather narrow interval of 570°–850°C. Surprisingly the elements which are greatly accumulated in carbonatites [4] – REE, HFSE, P, Y, Sr, Ca, vary widely in the zircons and do not demonstrate essential enrichment in comparison with zircons from the other rock types. It is obvious that zircon composition is predominantly determined by evolution of fluid composition due to interaction of carbonate fluids enriched in lithophiles with the matrix minerals. The single geochemical type of "carbonatitic zircon" related to a genetic link with the host carbonatites seems rather ill-founded.

Ba-Ti-rich oxymica from olivine nephelinites of the Udokan lava field (Russia)

Sharygin, V.V.
V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (sharygin@uiggm.nsc.ru)

Ba-Ti mica was found in olivine nephelinites from oldest (14 Ma) volcanoes of the Udokan field (Ingamakit, Munduzhyak and others). The rocks contain phenocrysts of olivine (Fo_{75-85}), augite (Mg# - 0.95-0.85) and groundmass consisting of olivine (Fo_{70-75}), Ti-rich augite (Mg# - 0.85-0.80), Ti-magnetite (TiO_2 - 12-24 wt.%), fluorapatite, Ba-Ti-mica, nepheline, leucite, rarely ilmenite, K-feldspar or glass. Ba-Ti-mica forms xenomorphic grains in the groundmass and rarely occurs as a daughter phase in olivine-hosted melt inclusions. This mineral is an oxymica (EMPA and SIMS data) and contains low H_2O (0.1-0.3 wt.%), Li (30-50 ppm) and high BaO (6.7-11.5 wt.%), TiO_2 (10-13.3 wt.%), F (to 3 wt.%), Nb (460-920 ppm), Cr (180-420 ppm), Sr (940-1970 ppm), Zr (60-150 ppm) and REE (100-120 ppm) (Table 1). The core-to-rim variations are not significant occasionally showing weak enrichment in K_2O and depletion in BaO. Similar Ba-Ti-rich micas were previously described in olivine nephelinites and related rocks around the world [1-3].

Table 1: Chemical composition (wt.%) of the Udokan Ba-Ti-micas

Sample	Munduzhyak		Ingamakit		Ingamakit	
	core	rim	core	rim	core	rim
SiO_2	30.95	31.19	31.03	32.82	31.93	33.46
TiO_2	13.25	12.96	11.52	11.27	12.75	12.46
Nb_2O_5	0.17		0.21		0.15	
Cr_2O_3	0.11		0.05		0.05	
Al_2O_3	14.55	14.57	13.99	13.65	13.51	13.46
Fe_2O_3	2.11	2.88	0.57	2.09	0.48	3.19
FeO	11.18	10.20	11.15	9.84	11.68	9.67
MnO	0.09	0.08	0.08	0.06	0.07	0.06
MgO	10.67	10.90	12.51	12.42	12.10	12.42
CaO	0.02	0.13	0.01	0.10	0.09	0.11
BaO	9.37	9.14	11.20	8.98	9.83	6.68
SrO	0.23		0.11		0.12	
Na_2O	0.77	0.73	0.57	0.57	0.64	0.53
K_2O	5.33	5.34	5.10	5.63	5.43	6.71
Li_2O	0.01		0.02		0.02	
F	1.28	1.29	1.91	1.80	1.70	1.80
H_2O	0.11		0.29		0.19	
Total	100.22	99.41	100.33	99.23	100.74	100.55

Nb_2O_5, Cr_2O_3, SrO, Li_2O and H_2O were analyzed by SIMS, others - by EMPA. Fe_2O_3 are calculated only as tetrahedral Fe^{3+} in formula.

Oxymica varies from $K_{1.5}Ba_{0.5}(Mg,Fe)_{4.5}Ti_{1.5}[Al_{2.5}Si_{5.5}O_{20}]O_3F$ to $K_{1.25}Ba_{0.75}(Mg,Fe)_{4.5}Ti_{1.5}[Al_3Si_5O_{20}]O_{3.25}F_{0.75}$ and $K_{1.5}Ba_{0.5}(Mg,Fe)_4Fe^{3+}{}_{0.5}Ti_{1.5}[Al_{2.75}Si_{5.25}O_{20}]O_{3.25}F_{0.75}$. It notes that studied micas are related to intermediate members of the theoretical solid solution $K_2(Mg,Fe)_6[Al_2Si_6O_{20}]F_4$ - $KBa(Mg,Fe)_4Ti_2[Al_3Si_5O_{20}]O_4$ via complex isomorphic scheme $K+2(Mg,Fe^{2+})+2Si+4F \rightarrow Ba+2Ti+Al+4O$. In general, the Udokan oxymica strongly resembles oxykinoshitalite $KBa(Mg,Fe)_{3.5}Fe^{3+}Ti_{1.5}[Al_3Si_5O_{20}]O_3F_{0.5}(OH)_{0.5}$ [1] differing in lower Ba, Fe^{3+}, H_2O and higher K and F. Minor substitutions $K+2Si+(Mg,Fe^{2+})+F \leftrightarrow Ba+2Al+Ti+O$ and $K+2Fe^{3+}+O \leftrightarrow Ba+2(Mg,Fe^{2+})+F$ are not excluded in the Udokan micas. All the above schemes do not lead to the appearance of vacancy sites in the structure of these micas.

Low H_2O content in Ba-Ti-mica suggests that the Udokan olivine nephelinite magma and its derivates were essentially "dry". The presence of Fe^{3+} in mica possibly indicates the gradual increasing in fO_2 during nephelinite melt evolution.

Potassium-rich carbonatite magma: mechanism of formation and mineralogy as a result of examination melt inclusions (eastern Pamir)

Solovova, I.* & Girnis, A.
Institute of Geology of Ore Deposits, Petrography, Mineralogy, and Geochemistry, Russian Academy of Sciences, Moscow, Russia (*solovova@igem.ru)

Almost all known cases of magmatic carbonatites are related to sodium-type alkaline rocks, phonolites and nephelinites. Carbonatites very rarely associate with potassium igneous rock and this makes the carbonatite-bearing potassic basaltoid complex of the Eastern Pamirs especially interesting. The conditions of formation of primary silicate and carbonate melt inclusions in the clinopyroxene of the fergusite of this complex and their chemical and mineralogical compositions has been the object of our study.

At heating melt inclusions the complete dissolution of daughter minerals were observed at 1120–1150°C. The silicate matrix of the inclusions contains carbonatite melt globules and gas bubble (fluid phase). A gas bubble disappeared at 1150–1180°C (the homogenization temperature). The phase boundary between the silicate matrix and carbonatite melt globules did not disappear up to 1210°C; i.e., the initial melt already passed the stage higher-temperature unmixing at the moment of liquidus mineral crystallization (phlogopite, clinopyroxene, apatite). The pressures estimated using fluid inclusions and mineral geobarometers were 0.5–0.7 GPa.

At 1180°C concentration of SiO_2 in the carbonatite melt does not exceed 10 wt%. Note the very high concentration of alkalis (up to 20 %) at K_2O/ Na_2O up to 2.5, which is not typical for natural carbonatites. Chemical compositions of daughter phases and silicate glasses indicate the high contents of volatiles (F, Cl, and S) in the magma. The melts are characterized by high sums of REE and enrichment in Ba, Th, U, Li, and B. According to our research, SiO_2 undersaturated minerals dominated in the crystallized carbonatitic inclusions. Reflecting ultrapotassic nature of melt, the first phases were kalsilite and K-Ba-rich alkali feldspars (up to 9 wt% BaO). The earliest minerals are also Ca-Ti-bearing phases - titanite, perovskite and zoned garnet schorlomite (core is enriched in TiO_2 and rim zones are enriched Fe_2O_3). Among the phase of melt inclusions were determined extremely rare silicate minerals fresnoite and delindeite containing up to 59 and 30 wt% BaO, 13 and 15 wt% TiO_2, respectively. These minerals are characterized by appreciable concentrations of SrO, FeO, CaO, F and H_2O. The carbonate is calcite with up to 0.3 wt % K_2O, 2 wt % SrO, and up to 0.5 wt % FeO, MgO. Ore minerals are mainly K–Cl-bearing sulfide (djerfisherite), typical mineral of lamproites, Fe-sulfide and rare magnitite. Accumulation of volatile components, Ca, Na and Fe in the residual melts leads to crystallization aegirine, scapolite, cuspidine, cancrinite, and H_2O-bearing K-Ba- and Ca-Sr zeolite on the late stages of the magma evolution. Thus, we showed some geochemical and mineralogical sequence of crystallization of high-temperature alkali carbonatite melt in closed conditions: *K+Ba+Si – K+Ba+Ti+Si – K+Fe+Ca+Na+Si - K+Sr+F+Cl+H_2O+S (Si) – Ca+CO_2.*

Amphibole-bearing upper mantle xenoliths from the Perşani Mountains (Transylvania, Romania)

Szabó, Á.[1,2*], Tóth, A.[2,3], Nédli, Zs.[2], Szabó, Cs.[2], Harris, N.[4] & Tindle, A.[4]
[1]Dept. of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania
[2]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (*sz_abel@yahoo.com)
[3]Dept. of Environmental Sciences, Sapientia University, Cluj-Napoca, Romania
[4]Dept. of Earth & Environmental Sciences, Open University, Milton Keynes, United Kingdom

In the Carpathian–Pannonian Region (CPR) there are five major volcanic areas where basalt volcanoes, active during the Neogene – Quaternary period, brought to the surface large numbers of xenoliths [1]. The easternmost and youngest Plio-Pleistocene alkaline basaltic volcanic field of the CPR developed in the Perşani Mountains (Eastern Transylvanian Basin) where the alkaline basalt contains numerous peridotite and pyroxenite xenoliths, as well as clinopyroxene and amphibole megacrysts. Eight amphibole-bearing xenoliths were selected for this study of mineral chemistry and petrography comprising seven composite xenoliths (six spinel lherzolite/hornblendite and one amphibole-pyroxenite/harzburgite) and one amphibole-clinopyroxenite were classified. All xenoliths have significant amphibole content; in the lherzolite part of the spinel lherzolite/hornblendite composite xenoliths, amphibole is present interstitially to the other silicates, whereas in the hornblendite portion amphibole is a rock-forming mineral.

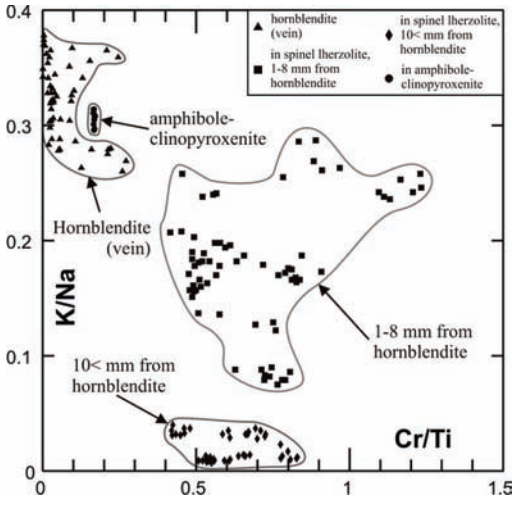

Fig. 1: Cr/Ti vs. K/Na variation diagram for amphibole occurring in different textural position.

Geochemical features of the studied amphiboles show systematic differences relating to their textural position. The interstitial amphiboles are enriched in Na, Cr, Mg, depleted in incompatible trace elements and LREE, whereas amphiboles in hornblendites and amphibole-pyroxenites show elevated K, Ti, Fe, incompatible trace element and LREE content (Fig. 1). The chemical variations of the texturally defined amphiboles indicate a complex history of lithospheric metasomatism at shallow depths beneath the Perşani Mountains. The main aim of this study is to shed light on the details of the general evolution of the lithospheric mantle beneath the studied area by textural and major and trace element geochemical data of amphibole and coexisting clinopyroxene, as well as to constrain metasomatic reactions in the mantle between a suspected mafic melt and peridotitic wall rock.

A mineralogical study of REE minerals from the Higashimatsuura basalt, Kyushu, Japan

Takai, Y.* & Uehara, S.
Dept. of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, Fukuoka, Japan
(*takai@geo.kyushu-u.ac.jp)

The Higashimatsuura basalt which distributes throughout Higashimatsuura peninsula, Kyushu, Japan is neogene alkali olivine basalt. REE minerals are reported and three new REE minerals are found from this basalt (*e.g.* kimuraite [1]).

Samples were collected from 36 localities and REE minerals are found in 13 localities. Eleven REE minerals are identified; kimuraite, lokkaite, tengerite, lanthanite-(Nd), lanthanite-(La), kozoite-(Nd), kozoite-(La), calcio-ancylite-(Nd), rhabdophane-(La), rhabdophane-(Ce) and rhabdophane-(Nd). Furthermore, three candidates of new minerals are found; "hizenite", "calcio-ancylite-(La)" and "rhabdophane-(Y)".

According to the mineralogical features, crystallization of REE minerals in the Higashimatsuura basalt has four stages.

(1) At the first stage, rhabdophane crystallizes in high temperature condition. Due to the high temperature, difference of ionic radii of REE ions do not affect and rhabdophane can contain larger amount of HREE. Therefore, rhabdophane in this basalt has variety in chemical composition and Y can be predominant REE in some rhabdophane.

(2) Spherical crystal of kozoite crystallizes. This type of kozoite has chemical composition which centers to boundary among kozoite-(Nd), kozoite-(La), calcio-ancylite-(Nd) and calcio-ancylite-(La). In this stage, temperature is lower than the first stage, but it still keeps high temperature on some level. Therefore, spherical crystal of kozoite incorporates higher content of Ca and Y than kozoite which alters after lanthanite.

(3) Tengerite family minerals (tengerite, lokkaite and kimuraite) and lanthanite crystallize in the third stage. In this stage, temperature should be low because these minerals are very weak in heat. Tengerite can keep its crystal structure even in 200°C, however, lanthanite become amorphous in only 80°C. Distribution by ionic radii occurs in this time. LREE incorporates in lanthanite, and HREE incorporates in tengerite family minerals (Fig. 1). Ca^{2+} is contained into tengerite family minerals because lanthanite can not contain Ca^{2+} due to its crystal structure [2].

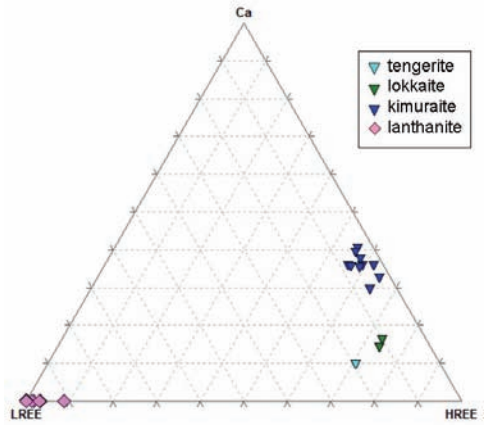

Fig. 1: Miscibility gap between tengerite family minerals and lanthanite.

(4) Some of lanthanite alters to kozoite-(Nd) by heating in the last stage. Because of lower temperature than the second stage, this type of kozoite almost does not contain HREE, and Ca is also contained only a part of aggregate.

Nb and REE minerals from the Virulundo carbonatite (Namibe, Angola)

Torró, L.[1*], Villanova, C.[1], Castillo, M.[1], Campeny, M.[1], Gonçalves, O.A.[2] & Melgarejo, J.C.[1]
[1]Dept. Cristal·lografia, Mineralogia i Dipòsits Minerals, Universitat de Barcelona, Catalunya, Spain
(*lisardtorro@hotmail.com)
[2]Depto. de Geologia, Universidade Agostinho Neto, Luanda, Angola

The Virulundo carbonatite is located in SW Angola, in the Namibe province, and is one of the biggest carbonatite outcrops in the world. It is a Cretaceous subvolcanic plug, which belongs to the Parana-Namibia-Angola alkaline-carbonatitic province. It is found intruding Early Archean granitoids, which are fenitized on the contact.

The structure consists of a central circular body of massive carbonatites, 1.5 km in diameter, surrounded by concentric ring dikes of carbonatitic breccia. The central body is made up of a sequence of calcitic, dolomitic and ankerite intrusions. Finally, some microtrachytic dikes crosscut the ensemble.

Pyrochlore is widespread in all the above mentioned units. It occurs as euhedral crystals, less than a millimetre in size. The crystals show a complex texture with 2 main generations of pyrochlore: a) primary magmatic, displaying concentric zoning, and b) secondary, found in irregular replacements along grain borders, small fractures and other discontinuities. Zoning in primary pyrochlore mainly reflects changes in the F content and the cation filling in the A position (Fig. 1). The secondary pyrochlore is strongly enriched in Ba and Sr, and depleted in F, Ca and Na (Fig. 1). The vacancies also increase in the secondary pyrochlore. Secondary pyrochlore is intimately associated with barite, thus suggesting that the hydrothermal alteration of pyrochlore takes place in oxidizing conditions.

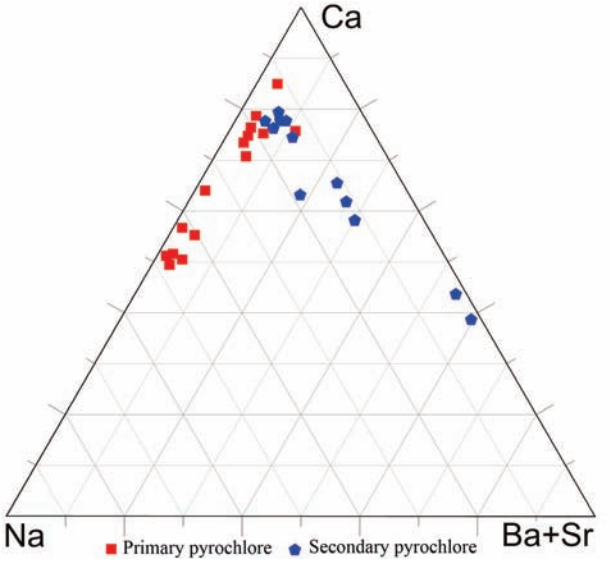

Fig. 1: Distribution of chemical analyses of primary and secondary pyrochlore in the diagram Na-Ca-(Ba+Sr) (a.p.f.u.)

REE minerals are also very common as small crystals and are produced as late replacements of the primary mineral associations, filling porosity in close association with barite. They consist of fluorocarbonates (bastnäsite-(Ce), parisite-(Ce), synchisite-(Ce)) and silicates (britholite-(La), cerite, tritomite-(Ce)).

A fluid-dynamical model of carbonatite-silicate magma interaction

Valentini, L.[1*], Moore, K.R.[2] & Chazot, G.[3]
[1]Dept. of Geosciences, University of Padua, Italy
([*]luca.valentini@nuigalway.ie)
[2]Dept. of Earth and Ocean Sciences, NUI Galway, Ireland
[3]Institut Universitaire Europeén de la Mer, Université de Bretagne Occidentale, Plouzane,France

In a recent work [1] 527 worldwide carbonatite occurrences were catalogued, with approximately 80% of them being associated with silicate rocks. The great majority (~90%) occur in intrusive complexes, where field relations show that emplacement of the carbonatites is generally late with respect to the associated silicate rocks. In contrast, evidence from the 49 extrusive centres [2] reveal that carbonatite and silicate magma extrusion can be contemporaneous, such that interaction processes between the two types of magmas may occur. Nonetheless, the modes of interaction between carbonatite and silicate magmas are still poorly constrained.

In this study, the mechanisms of interaction between a carbonatite magma and a silicate magma are inferred on the basis of the textural, geochemical and rheological features of a carbonate-bearing tuff from the Velay Province (Massif Central, France) characterized by the presence of dolomite globules within a silicate glass matrix.

The results of EPMA transects and elemental maps show that no chemical re-equilibration occurred between the two liquids, although major element compositions rule out the possibility that the two magmas may represent an immiscible equilibrium pair.

In order to explain the observed geochemical and textural features, a two-fluid-dynamical model consisting in the occurrence of an incipient viscous fingering instability, subsequent to the injection of a carbonatite magma into a trachyte magma residing within a chamber, is envisaged. The observed emulsion-like texture resulted from the quasi-instantaneous fragmentation and solidification of the developing fingers. The replenishment event triggered immediate evacuation of the magma chamber such that interaction between the two magmas occurred over a short time scale and large-scale mixing was prevented.

The composition of phlogopites from laprophyric dykes and syenites (South-Eastern Altai)

Vasyukova, E.A.[*] & Sukhorukov, V.P.
IGM SB RAS, Novosibirsk, Russia
([*]helena.yukova@gmail.com)

Lamprophyric dyke complexes are the largest magmatic occurrence from Mesozoic period, in South-Eastern Altai. Lamprophyric magmatism is close to the large ore occurrences in location and age [1]. Two different lamprophyre areas are separated: South-Chuya and Yustyd. The first one is related with Ni-Co-As, U, Cu-Hg-Sb-Ba and hematite mineralization, while in the second area Ag-Sb and Ni-Co-As ore occurrences are located. Tarkhata syenite massive of the same age is placed in the South-Chuya area.

The main rock minerals of lamprophyres are phlogopite (in phenocrysts and in matrix) and K-Na feldspar and carbonate. Some of dykes contain clinopyroxene as phenocrysts. In spite of some differences in petrogenetic elements (for example amount of silica in dykes varies from 40 to 60 wt.%), the character of REE distribution of syenites and dykes are absolutely similar. This chemical resemblance, additional to that of space and time nearness, is evidence of genetic correlations between dykes and syenitic rocks. Changes in composition of phlogopite can be evidence of melt evolution and show us the difference in crystallization conditions in dykes of different area.

The analyses of phlogopites of more then 100 dykes from South-Chuya and Yustyd areas and syenitic massif are carried out. Phlogopites differ in TiO_2 and *f* (*f*=Fe/(Fe+Mg)) (see table 1). Micas of the South-Chuya area contain the lowest *f* (<20%) and TiO2 (<4 wt.%). There is no any correlation between *f* and TiO_2 in syenite micas. Their compositions are located on the *f*-TiO_2 diagram in the area of Yustyd phlogopite. Besides they have the highest Cl and lowest Cr_2O_3 in comparison with dyke phlogopites.

Table 1: Analytical results for phlogopites from studied areas

	South-Chuya lamprophyres	Tarkhata syenites	Yustyd lamprophyres
TiO_2	1-4	3-5.5	3-7
f	<20	20-40	10-50
MnO	<0.2	<0.22	<0.4
Cl	0.05-0.02	~0	~0
Cr_2O_3	0-2.5	<0.5	0-2.5

Determining depth of lamprophyre magma generation and emplacement: mica thermobarometry revisited

Woodard, J.[1*] & Boettcher, I.[2]
[1]University of Turku, Finland ([*]jdwood@utu.fi)
[2]TU-Clausthal, Clausthal-Zellerfeld, Germany

Lamprophyres are mafic to ultramafic dyke rocks, which commonly contain macrocrystic grains of mica (biotite or phlogopite) together with olivine, clinopyroxene, amphibole or apatite. Rock [1] outlined a six-tier hierarchy of lamprophyre mineralogy from fully cognate groundmass grains to fully xenocrystic grains. Zoned grains are common, representing overgrowth crystallisation from the magma onto xenocrystic or earlier-formed phenocrystic cores. Using the mica thermobarometer developed by Righter and Carmichael [2], systematic analysis of multiple generations of mica from lamprophyres may provide depth estimates for both magma generation and emplacement.

For this study, we have analysed macrocrystic and matrix mica from Palaeoproterozoic shoshonitic lamprophyre dykes in the Fennoscandian Shield. These lamprophyres represent low-volume partial melts derived from an enriched lithospheric mantle. Macrocrysts occur as pseudohexagonal laths, typically around 1 mm but up to 1 cm across. Compositional zoning and castellated textures are common. Many grains contain crystallographically oriented, needle-shaped inclusions of titanite. In some grains, strongly pleochroic inclusion-free rims surround sharply defined inclusion rich cores, while in other cases inclusion-rich rims grade into inclusion free cores. Matrix grains are typically smaller than 0.2 mm, inclusion-free and strongly pleochroic.

Biotite macrocrysts typically exhibit core-to-rim zoning, appearing progressively brighter towards the rims in BSE images. The cores have low Mg# (65-75) and are relatively enriched in Si, K and F. A gradational increase outwards in Mg#, Ti, Al and Ba is observed near the rims. Matrix biotite/phlogopite has similar composition to the inclusion-free outer rims of the macrocrysts, with high Mg# and strong enrichment in both Ti and Ba.

Thermobarometric results from the matrix micas indicate crystallisation at temperatures of 1100-1150°C at 0.2-0.3 GPa, corresponding to an emplacement depth of 7-10 km. This is in accordance with previous depth/exhumation estimates from this area [3]. Thermobarometric results from the macrocrysts form a well-defined trend toward T = 1200°C and P = 2.5 GPa. Still higher values (up to P = 4.5 GPa) were obtained from the core zones of many macrocrysts, however these data become scattered such that a distinct path of decompression is no longer discernable. This uncertainty could reflect a lack of equilibrium between the macrocryst cores and the lamprophyric melt. Another consideration is that the thermobarometer used [2] has not been experimentally calibrated at such high pressures. Nonetheless, source temperatures in excess of 1000°C, the closure temperature of zircon [4], are implied by the presence of mantle zircons [5]. These conditions correspond to pressures >4.5 GPa according to the geotherm of Kukkonen and Peltonen [6], implying that the highest pressures obtained in this study could also be real.

Chrome spinels in ophiolites: from micro-analyses to large-scale plate tectonic interpretations

Pearce, J.A.
School of Earth and Ocean Sciences, Cardiff University, Cardiff UK (pearceja@cf.ac.uk)

Like zircon, chrome spinel [$(Mg,Fe^{II})(Cr,Al,Fe^{III})_2O_4$] is an alteration-resistant accessory phase which carries global tectonic information. Unlike zircon, however, it can be used to investigate mafic–ultramafic rocks and their weathering products (e.g. [1,2]). In ophiolites, chrome spinel in mantle peridotites has proved most informative. Because the divalent (X) site has its closure temperature well below the mantle solidus, the trivalent (Y) site carries the more useful information about petrogenesis and hence tectonic setting which may be obtained by micro-analysis using a combination of EMA and LA-ICPMS. Of the major elements in the Y site, the proportion of Cr, expressed as Cr#, is sensitive to melting history, while Fe^{III} can be used to calculate oxygen fugacity. The plot of oxygen fugacity against Cr# [3-6] remains one of the most effective ways to distinguish mantle protoliths from mid-ocean ridge (MOR), supra-subduction zone ridge (SSZ) and plume-related (P-MOR) ridge settings: SSZ peridotites have high fO_2 and high Cr# resulting from high degrees of wet melting, whereas P-MOR peridotites have low fO_2 and high Cr# resulting from high degrees of dry melting, and MOR peridotites have low fO_2 and relatively low Cr# resulting from lower degrees of dry melting. Of the analysable minor elements in the Y site, Ti and Ga are particularly useful: the incompatibility of Ti makes it particularly sensitive to melt-rock interaction (e.g. [5]); and Ga has the ionic radius of ferric iron but no redox dependency, so providing a way of correcting for the effects of magmatic differentiation on Fe^{III} [6]. Thus the Ti-Ga-FeIII systematics of chrome spinel provide additional tectonic information [6].

Application of these methodologies to ophiolites and their modern analogues demonstrates their chrome spinels may carry a record of more than one setting. For example, many spinels from SSZ ophiolite analogues in the Izu-Bonin forearc have compositions that span the MOR and SSZ fields [3]. Significantly, these follow a vector representing interaction between a MOR peridotite protolith and a SSZ boninite magma. This may be interpreted tectonically in terms of pre-subduction MOR mantle, which reacts with boninite magma following subduction initiation. Interestingly, many SSZ ophiolites follow similar trends (e.g., Semail, Pindos, Zambales), so providing new or supporting evidence of their subduction initiation settings and validating the view that this setting is the one in which most ophiolites form. Chrome spinels from many MOR ophiolite analogues also indicate complex origins, for example the interaction of orogenic peridotites with MOR magma at the Galicia margin during Atlantic opening. Many MOR ophiolites (e.g., Othris) have similar characteristics. On a plate tectonic scale, therefore, chrome spinel micro-analyses indicate that a high proportion of ophiolites form at a time of global tectonic change, specifically during and just after subduction initiation and continental breakup.

Similarity and difference between abyssal and back-arc basin peridotites: inference from xenolith suites from the Sea of Japan

Arai, S.* & Tanaka, C.
Dept. of Earth Sciences, Kanazawa University, Kanazawa, Japan (*ultrasa@kenroku.kanazawa-u.ac.jp)

Petrologic characteristics of the upper mantle peridotite beneath the back-arc basin have not been thoroughly understood because of very limited availability of deep-seated rocks there. We have a few mantle peridotite xenolith localities within or along the Sea of Japan, one of the back-arc basins in the Western Pacific [1].

Peridotite xenoliths captured by alkali basalt dredged from a small seamount (Takeshima Seamount tentatively), ca. 230 km to the north of Oki islands, are possibly representative of the Japan-Sea mantle. They are spinel-bearing lherzolite to harzburgite, which show equigranular to porphyroclastic textures. They can be classified into two types (Type 1 and Type 2) in terms of REE patterns of their Cpx [2]. Type 1 peridotites (Cr# of spinels, 0.4-0.5) are similar in major element chemistry and MREE to HREE concentrations of Cpx to abyssal peridotites. The Cpx in the former shows slight enrichment of LREE. In contrast, Type 2 peridotites have high-REE Cpx with flat to slightly LREE-enriched patterns, and are quite similar to subcontinental peridotites obtained as xenoliths from China. The southern half of the Sea of Japan was formed mainly by thinning and rifting of the continental lithosphere. Type 2 peridotites were derived from a possible remnant of the continental lithospheric mantle.

Harzburgite xenoliths from Oshima-Ôshima volcano in the Sea of Japan off Hokkaido, northern Japan, may represent the upper mantle beneath the Sea of Japan [3]. The Oshima-Ôshima harzburgite (olivine of Fo_{90-91}, spinel Cr# = 0.52) is similar to the Type 1 peridotite from Takeshima Seamount. This type of harzburgite is possibly a residual mantle peridotite of BABB (back-arc basin basalts) of the Sea of Japan because its northern half represents an oceanic basic formed by accretion of BABB through spreading [4].

BABB are very similar in spinel chemistry to MORB, indicating the residual peridotite (or the degree of partial melting) is basically similar between the back-arc basin and mid-ocean ridge. Some of BABB drilled from the Sea of Japan, however, contain high-Cr# (> 0.6 up to 0.8) chromian spinel, indicating the presence of highly refractory peridotite in the mantle. High degree of mantle melting occurs when the spreading rate is high as in the case of the Sea of Japan (up to 60 cm/year) [5]. The high degree of partial melting to produce BABB and Type 1 peridotites may be formed by open-system melting affected by a flux from the downgoing slab.

Variable mantle section in Albanian Ophiolites: evidences from mineral and bulk rock composition

Koller, F.[1*], Hoeck, V.[2], Ionescu, C.[3] & Onuzi, K.[4]
[1]University of Vienna, Austria ([*]friedrich.koller@univie.ac.at)
[2]Paris Lodron University, Salzburg, Austria
[3]Babes-Bolyai University Cluj-Napoca, Romania
[4]Instituti i Gjeoshkencave, Universiteti Politeknik i Tiranes, Tirana, Albania

In the classical view, the Albanian Ophiolites were divided in an eastern SSZ and a western MORB belt. This genetic view should be reflected in the mantle section as well, by the predominant occurrence of harzburgites in the eastern and lherzolites in the western belt, respectively. Recent investigations in the western belt revealed a different and more complex picture, with a wide compositional variation of peridotites, at regional scale.

The southern massifs of Voskopoja, Rehove and Morava are dominated by fertile lherzolites and contain, if any, only minor harzburgite bodies. By contrast, the next two massifs further in the north, Devolli and Vallamara, are almost exclusively composed of highly depleted harzburgites.

In turn, the massifs situated in central Albania, such as Shpati, Kuterman and Skenderbeu are built up of almost equal proportions of harzburgites and lherzolites. In all these massifs, harzburgites are dominating in the western parts, while lherzolites are restricted towards the east. The Puka and Gomsique massifs located in the northern part of Albania, are similar to those in the southern part, i.e. dominated by highly fertile lherzolithes. The Krrabi massif, positioned in between the western an the eastern belt, is formed by both harzburgites and lherzolites, thus fitting better into the eastern belt. The latter is more homogeneous and contains only harzburgite- dominated massifs, such for example the Shebenik and the Bitincka.

The Al_2O_3 values in peridotites show accordingly a high variability, ranging from 0.3 to 3.8 wt.%. This is consistent with fertile peridotites on one hand, and extremely depleted peridotites, on the other hand. Likewise, the composition of typical ultramafic minerals such as olivine, chromian spinels and pyroxenes reflect this lithological variability. Both orthopyroxene and clinopyroxene show a wide range of Al_2O_3 content, ranging from 0.5 to 4.5 wt.% and from 0.8 to 5.5 wt.%, respectively. The X_{Mg} values of olivine range from 0.895 in lherzolites to 0.915 in depleted harzburgites. These values are accompanied by Cr# in spinels ranging from 10 to 73, spanning the composition from lherzolites to depleted harzburgites.

A similar wide variation can be found in the Cr# in spinels vs. Cr# of both clinopyroxene and orthopyroxene. The spinels composition range from 11 to 60 wt.% Al_2O_3.

The mantle composition in the Albanian western ophiolite belt, which extends for more than 140 km in N-S direction, changes several times from a lherzolitic composition close to primitive mantle to a highly depleted harzburgite. By contrast, the eastern ophiolite belt seems to have been formed from a more homogeneous harzburgitic mantle.

Spinels in ophiolitic sediments in southern and central Albania: a provenance study

Hoeck, V.[1*], Koller, F.[2], Ionescu, C.[3], Robertson, A.[4] & Onuzi, K.[5]
[1]Paris Lodron University, Salzburg, Austria
([*]volker.hoeck@sbg.ac.at)
[2]University of Vienna, Austria
[3]Babes-Bolyai University, Cluj-Napoca, Romania
[4]Edinburgh University, UK
[5]Polytechnical University Tirana, Albania

The ophiolites in Albania are part of the Dinaric Hellenic ophiolite Belt which extents from Croatia to Greece. In Albania it is built up by two zones, a western MOR-type dominated ophiolites and an eastern SSZ-type. Mantle tectonites form commonly large bodies of lherzolite and/or harzburgite. Crustal sections are mostly restricted to cumulates and gabbros. Sheeted dykes and volcanics are rare in central and southern Albania. Sediment piles on top of the ophiolites are more common and consist of ophiolitic conglomerates and breccias, sandstones with prevailing ophiolite material and calcareous rocks with ophiolitic detritus [1]. The calcareous sediments are most likely Early Cretaceous in age as inferred from the fossil content. Spinels from sediments covering the Luniku, Stravaj, Shpati, and Morava massifs were analysed by EMP. The results were compared with spinel analyses from harzburgites and lherzolites from the ultramafics, cumulates, gabbros and basalts.

Spinels in sediments from the top of the Luniku massif display a wide range of compositions ranging from high to intermediate Cr# (0.85-0.50) and an X_{Mg} between 0.35 and 0.65. These compositions overlap to a certain extent with those of spinels from harzburgites in Shebenik and Shpati massifs, located nearby. Spinels from the sediments higher Cr# could be derived from massive chromite ores. Spinels with lower Cr# and high X_{Mg} common in harzburgites, are missing in the sediments.

The sediments of Stravaj show spinels with a wide variation of the Al_2O_3 content from 5 to 40 wt.%. Low Ti and Al spinels could be associated with a possibly eroded(?) boninitic source, but most spinels are compositionally compatible with those from harzburgites and possibly lherzolites.

Spinels collected from calcareous sediments from the inner part of the Shpati massif show a bimodal distribution. Al and Ti poor spinels with a high Mg# are probably derived from boninites. By contrast, the source of Ti and relatively Al rich spinels are most likely MOR basalts.

The calcareous sediments on top of the Morava Massif in the south of Albania contain at least two spinel populations: one with high Cr# and low Ti content and a second one, with Ti > 0.5 wt.%. The former is indicative for a harzburgitic source, the latter for a MORB source. Harzburgites are rare in Morava, but occur frequently in the massif of Bitinska to the NE of Morava.

Our results imply that in the early Cretaceous mantle and crustal fragments of ophiolites were emplaced onto a shallow marine platform environment where they underwent erosion and mass wasting. These processes delivered the spinels as heavy mineral and, more rarely, as components of mafic and ultramafic clasts into shallow water sediments as recently pointed out by Robertson et al. [1].

[1] Robertson, A. et al. (2010) *Int. J. Earth Sci.* (submitted).

Plagioclase-free harzburgite in equilibrium with MORB from the uppermost mantle of the northern Oman ophiolite

Akizawa, N.[1*], Arai, S.[1] & Tamura, A.[2]
[1]Dept. of Earth Sciences, Kanazawa University, Kanazawa, Japan ([*]nori.plus.x@gmail.com)
[2]Frontier Science Organization, Kanazawa University, Kanazawa, Japan

We have found plagioclase-free harzburgites that are in equilibrium with MORB in terms of clinopyroxene (cpx) and chromian spinel chemistry, which have not been recorded from the current ocean floor, from the uppermost mantle from the northern Oman ophiolite (along Wadi Fizh) (Fig. 1). They are from beneath the wehrlite-dunite layer (= Moho transition zone; MTZ) just under the layered gabbro. The MORB-saturated harzburgites slightly enriched mineralogy (spinels with higher Ti and ferric iron, and cpx with higher Ti), and contain slightly but clearly more abundant in modal cpx (up to 3.5 %) than ordinary Oman depleted harzburgites (with less than 1 % cpx), which are also common as abyssal harzburgite.

The MORB-saturated harzburgite was formed from the ordinary Oman harzburgite in equilibrium with depleted MORB (melt increments by fractional fusion) by impregnation of a MORB-like melt, which has left cpx (not cpx + plagioclase as in plagioclase-impregnated abyssal harzburgite). This may mean that the involved MORB-like melt is not equal to MORB, which precipitates plagioclase after olivine, in that clinopyroxene, instead of plagioclase, is precipitated after olivine. The harzburgites just under the MTZ wehrlite/dunite of Wadi Fizh are highly varied in terms of modification (of cpx) by the MORB-like melt, from the harzburgite only modified in light REE (LREE-enriched) to the MORB-saturated harzburgite via the harzburgite modified in LREE to MREE. Only depleted harzburgites are found in deeper part of the mantle section. This is a result of interaction between the MORB-like melt and depleted harzburgite beneath a spreading center, which is possibly situated not at a mid-ocean ridge but in a back-arc basin.

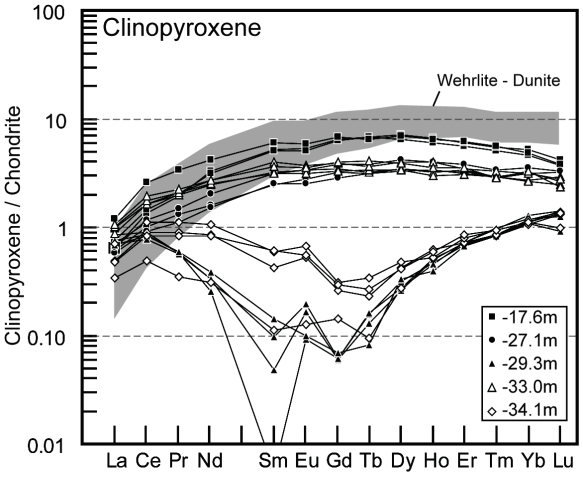

Fig. 1: Chondrite-normalized rare earth element (REE) patterns of clinopyroxenes (cpxs) in wehrlite-dunite (shaded area) and harzburgite. The numbers (in meters) indicate depths of samples from the lower end of the layered gabbro. Note that some of harzburgite cpxs are enriched in M- to HREE, and are possibly in equilibrium with MORB.

Heterogeneity of mantle source for arctic basalts revealed by olivine compositions and isotopic signatures

Sushchevskaya, N.M.[1*], Belyatsky B.V.[2] & Sobolev, A.V.[1]
[1]Vernadsky Institute of Geochemistry, Moscow, Russia ([*]nadyas@geokhi.ru)
[2]Dept. of Antarctic Geology, VNIIOkeangeologia, St.-Petersburg, Russia

Evolution of the Norway-Greenland basin, in general, is connected with Knipovich Ridge formation and the magmatic activity in the Svalbard Archipelago region (about 20 Ma ago), frequently developed in the form of plateau basalts. The process of magmatic activity continued till 10 Ma. In Quaternary time this process caused formation of three volcanoes, alkaline by the main composition of lavas, situated at the northern edge of Breibogen fault.

On the base of the studied Spitsbergen Island basalts and Knipovich ridge lavas it has been shown that in the source of both continental basalts and rift tholeiites there is marked a similar enriched mantle component. Enriched component of Arctic province has high radiogenic isotope signature: $^{207}Pb/^{204}Pb$ – 15.6, $^{206}Pb/^{204}Pb$ – 18.6, $^{208}Pb/^{204}Pb$ – 38.6 and $^{87}Sr/^{86}Sr$ – 0.7048 [1]. Its share in the melts decreases from Neogene trap intrusions via Quaternary alkaline lavas to insignificant admixture in the depleted and weakly enriched magmatism of the Knipovich ridge. On the base of Ni, Mn and Ca olivine contents [2] it was established that this component for Svalbard Archipelago and Knipovich Ridge basalts is approximated to pyroxenite. The amount of this pyroxenite in mantle sources changes from 2% for ridge tholeiites to 80% for Neogene trap of Spitsbergen Island.

Enriched rift basalts were formed during transformation of paleo-Spitsbergen fracture zone into Knipovich ridge. This process is connected with magmatism of west part of Spitsbergen during its separating from the northern Greenland. Enriched melts could be formed as a result of involvement of the lower parts of adjacent continental blocks into the melting process within the spreading zones at the early stage of Norwegian-Greenland Sea opening.

Petrogenetic and geotectonic significance of Neoproterozoic suprasubduction mantle as revealed by serpentinites from the Wizer ophiolite complex, Central Eastern Desert, Egypt: geochemical and mineralogical constraints

Farahat, E.S.[1*], Hoinkes, G.[2] & Mogessie, A.[2]
[1]Dept. of Geology, Minia University, El-Minia, Egypt
([*]esamfarahat1@yahoo.com)
[2]Institute of Earth Science (Mineralogy and Petrology), Karl-Franzens University, Graz, Austria

Ophiolite complexes, formed in a suprasubduction zone environment during Pan-African orogeny, are widely distributed in the Eastern Desert of Egypt. The mantle sections of these ophiolites provide important information on the origin and paleo-tectonic history of ocean basins these complexes are thought to represent. The geochemistry and mineralogy of the mantle section of the Wizer ophiolite complex, represented by serpentinites after harzburgite containing minor dunite bodies, are presented. The fact that the serpentine minerals are antigorite together with the incipient alteration of chromites and absence of chlorite implies most likely serpentinization in the mantle wedge above subduction zone. Significantly, the Wizer serpentinized mantle has a wide range of chromite compositions. The chromite Cr# [100Cr/(Cr+Al)], decrease gradually from dunite bodies (Cr# = 81-87) and their host highly-depleted harzburgites (Cr# = 67-79) to the less-depleted harzburgites (Cr# = 57-63). Such decrease in mantle refractory character is accompanied by enriched Al and Ti contents in their bulk rock compositions. The estimated parental melt compositions point to an equilibration with melts of boninitic composition for the dunite bodies (TiO_2= ~<0.07 to 0.22 wt.% and Al_2O_3= 9.4 to 10.6 wt.%), boninitic-IAT signature for the highly-depleted harzburgites (TiO_2= <0.09-0.28 wt.% and Al_2O_3= 11.2-14.1wt.%) and more MORB-like affinities for the less-depleted harzburgites (TiO_2= ~<0.38 to 0.51 wt.% and Al_2O_3= 14.5-15.3 wt.%). This is obviously comparable with the overlying volcanic crust, which shows a transitional MORB-island arc geochemical signature with few samples displaying boninitic signature. Comparison with experimentally determined residual spinel composition indicates >45%, 36-43%, and 33-35% equilibrium melting of fertile MORB mantle to form dunite bodies, highly-depleted harzburgites, and less-depleted harzburgites, respectively. Yet, the enrichment of some chromites in TiO_2 and identification of sulfides in these highly-depleted peridotites implies interaction with an impregnating melt. A two-stage partial melting/melt-rock reaction model is advocated. According to this model, melting of a depleted mantle source by reaction with melts of MORB-compositions is followed by a second stage melting by interaction with melts of IAT-boninitic affinities in a suprasubduction zone environment to generate the highly-depleted harzburgites and dunite bodies. The shift from MORB to island arc/boninitic affinities within the mantle lithosphere of the Wizer ophiolite sequence suggests generation in a protoarc-forearc environment. This, together with the systematic lateral (from north to south) change in geochemical character of ophiolites occurring in the Central Eastern Desert (CED) of Egypt from IAT-boninitic affinities to more MORB-like signature, imply that the CED could represent a complete forearc-arc-backarc system above a southeast-dipping subduction zone.

New structural data and ^{40}Ar-^{39}Ar ages from the Danubian ophiolitic sole (SE Europe): implications for the Variscan collision

Plissart, G.[1,2*], Monnier, C.[2], Mărunţiu, M.[3], Neubauer, F.[4], Demaiffe, D.[1] & Diot, H.[2]
[1]GIGC, Université Libre de Bruxelles, Brussels, Belgium & Aspirant du F.R.S – FNRS ([*]gplissar@ulb.ac.be)
[2]LPGN, Université de Nantes, France
[3]Geological Institute of Romania, Bucharest, Romania
[4]Dept. of Geography and Geology, Univ. of Salzburg, Austria

The Danubian ophiolite (~ 500 km^2) crops out in the Southern Carpathians and the Balkans Mountains and consists of four dismembered massifs belonging to the Upper Danubian Alpin unit: Tişoviţa Iuţi in Romania, Deli Jovan and Zaglavak in Serbia and Tcherni Vrah in Bulgaria. Although this ophiolite has been considered as Late Proterozoic [1], the Deli Jovan massif has been recently dated to the Lower Devonian (U-Pb zircon age of 405 ± 2.6 Ma; [2]). The principal feature of the Danubian ophiolite is the occurrence of uncommon metasomatic rocks (Zo + Cal + Cr-Chl + Cr-Ms) developed from metagabbros, under strongly hydrated conditions, at temperatures around 280°C and that could be related to listvenites [3].

This study is focused on deformations observed in the listvenitic gabbros (LG) from Romania and in their adjacent rocks (Corbu Unit - CU). The LG are located in a thin N-S band at the Eastern part of the Tisovita Iuti ophiolite, and present a recurrent mylonitic texture. Similarly, the CU crops out in a 2km N-S wide band, at the Eastern part of the LG, and consists of a mélange of various metamorphic rocks (volcano-sedimentary rocks, margin sediments, acid volcanic rocks and ophiolitic rocks) from low- to high-grade (Gt + St ± And assemblage), and in which the deformation is partitioned between highly deformed mylonites and juxtaposed slightly-deformed rocks.

Foliation planes measured in both LG and CU are oriented North-Southwards and are dipping steeply (Fig. 1a). Also, mylonites from both units are characterized by a strong subhorizontal stretching mineral lineation (Fig. 1b) and isoclinal folds parallel to this lineation. These two fabric elements appear to develop during the same event, giving evidence for components of both simple and pure shear. This implies a deformation phase affecting both LG and CU which probably occurred in a transpressive context.

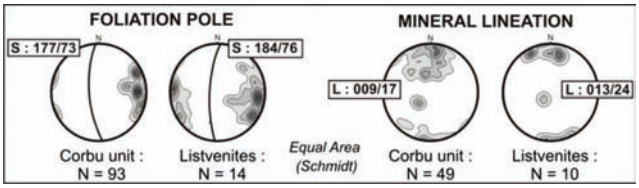

Fig. 1: Density distribution of foliation poles and mineral lineations measured respectively in Corbu Unit (CU) and listvenitic gabbros (LG).

New ^{40}Ar-^{39}Ar ages performed on two LG Cr-micas give plateau ages of 372.6 ± 1.3 Ma and 360.6 ± 1.2 Ma. These ages could represent the period of the listvenitic metasomatism, which occurred in a fluid-rich context certainly facilitating the pervasive deformation observed in the LG.

According to the ^{40}Ar-^{39}Ar results and to the similar deformation type encountered both in the Corbu mélange and in the listvenitic gabbros, we propose that these rocks correspond to the obduction sole of the Danubian ophiolite developed during a Variscan oblique collision.

Geochronology of ophiolites in Turkey: implications for Neotethyan geodynamics in Eastern Mediterranean

Parlak, O.[1,2*], Karaoglan, F.[1], Klötzli, U.[3], Koller, F.[3] & Rizaoglu, T.[4]
[1]Geology Dept., Cukurova University, Adana, Turkey
[2]Technology Faculty, Adiyaman University, Adiyaman, Turkey
([*]oparlak@adiyaman.edu.tr)
[3]Center for Earth Sciences, University of Vienna, Austria,
[4]Geology Dept., Sutcu Imam University, Kahramanmaras, Turkey

The Anatolian segment of the Alpine-Himalayan orogen comprises remnants of the Neotethyan oceanic basins, cropping out along E–W trending tectonic zones, between metamorphic massifs and/or platform carbonates. The remnants of the Neotethys, in a structural descending order, are characterized by ophiolites, metamorphic soles and ophiolitic melanges. These ophiolites and related subduction–accretion units were generated during the closing stages of the Neotethyan oceanic basins in Late Cretaceous. Well-preserved Neotethyan ophiolites in Turkey are of suprasubduction zone (SSZ) type. Late Cretaceous ophiolites in Turkey are mainly located in five zones; these are from north to south: a) Pontide ophiolites, b) Anatolian ophiolite belt, c) Tauride belt ophiolites, d) southeast Anatolian ophiolites and e) the peri-Arabian ophiolites. Important questions about the evolution of the ophiolites along the suture zones include: (i) the crystallization ages of oceanic crusts (ophiolites), (ii) the duration of magmatic activity and (iii) the timing of final emplacement.

The peri-Arabian ophiolites (Kizildag and Antalya), the southeast Anatolian ophiolites (Goksun, Ispendere and Komurhan) and the Tauride belt ophiolites (Mersin, Pozanti-Karsanti, Pinarbasi and Divrigi) were dated by LA-ICP-MS zircon U-Pb. The peri-Arabian ophiolites yielded 92.7±2.9 Ma from the plagiogranites in Kizildag (Hatay) and 86.6±3.2 Ma from the plagiogranites in Antalya. The southeast Anatolian ophiolites yielded 82.2±1.9 Ma from the rhyolitic lavas in Goksun (Kahramanmaras), 89.9±1.6 to 87.2±3.1 Ma from gabbros and 74.6±4.4 Ma from rhyolitic lavas in Komurhan (Elazig). The Tauride belt ophiolites yielded 81.8±4.3 Ma from the gabbros in Mersin, 70.9±3.0 Ma from the gabbros in Pozanti-Karsanti (Adana), 65.4±3.3 Ma from the diabase dikes in Pinarbasi (Kayseri) and 90.6±4.7 Ma from the gabbros in Divrigi (Sivas). The measured ages on different parts of ophiolites along the Tauride belt indicate that the subduction-related magmatic activity started in Turonian and continued until the end of Maastrichtian before their emplacement onto the Tauride platform. Whereas the peri-Arabic belt ophiolites display relatively older ages for the timing of crystallization of the oceanic crust from Cenomanian to Coniacian. The southeast Anatolian ophiolites show crystallization ages of oceanic crust from Turonian to Campanian, that occupies a time span between the peri-Arabic and the Tauride belt ophiolites.

All the data shows that (i) the crystallization ages of the ophiolites are late Cretaceous in general, but display differences from one location to another, (ii) continuous magmatic activities were exist during the closure stages of Neotethyan oceanic basins in SSZ tectonic settings from 92.7±2.9 to 65.4±3.3 Ma, and (iii) emplacement of the ophiolites were in the latest Maastrichtian.

Tracing a fore-arc suture in the Central Eastern Desert of Egypt

Abd El-Rahman, Y.
Geology Dept., Faculty of Science, Cairo University, Giza, Egypt (*yassermedhat@hotmail.com)

The early stages of the evolution of the Eastern Desert of Egypt during the Neoproterozoic are characterized by the formation of intra-oceanic island arc system(s) that was accreted to the Saharan Metacraton. The nature of suture resulted from the accretion/collision between the intra-oceanic arc body and the Saharan Metacraton was obscured by the late Najd fault system-related deformation and post-tectonic magmatism. The present work try to infer the nature of the suture zone in the Central Eastern Desert (CED) based on the new available geochemical data on the Neoproterozoic ophiolitic rocks and the distribution of the major ophiolitic serpentinites masses.

The geochemical data from the Wadi Ghadir and Fawakhir ophiolite complexes, the best preserved Neoproterozoic oceanic crust in the CED, indicate formation in back-arc and fore-arc tectonic settings respectively. Geochemical traverses along the ophiolitic blocks in the mélange of the CED show a systematic variation from a fore-arc geochemical signature towards the west to a back-arc signature towards the east. These geochemical traverses suggest the formation and evolution of the early intra-oceanic arc system above an east-dipping subduction zone. Finally, the island arc system was thrusted and/or collided with the continental margin to the west, which is represented by the Saharan Metacraton.

The ophiolitic serpentinites of the CED represent fore-arc oceanic mantle fragments [1]. The spatial distribution of the large ophiolitic serpentinite masses is in harmony with the distribution of the ophiolitic crust that have an inferred fore-arc affinity. The distribution of the large ophiolitic serpentinite masses in the CED can be traced as a line defining a suture zone at which the fore-arc front of an intra-oceanic arc system was collided with the older continental crust.

Origin of Neoproterozoic ophiolites of the Arabian-Nubian Shield: evidence from mineral composition in the Eastern Desert of Egypt

Azer, M.K.
Geological Science Dept., National Research Centre, Cairo, Egypt (mokhles72@yahoo.com)

Neoproterozoic ophiolites are common in the central and southern sectors of the Eastern Desert of Egypt, where they occur as tectonized bodies and mélanges. In the complete ophiolitic sequence, the base of most ophiolites consists of ultramafic rocks overlain by gabbros, sheeted dykes and pillow basalt with associated deep-sea sediments at the top. The upper part of the gabbros is isotopic, but the basal part commonly contains cumulate layers. However, because of folding and shearing, the majority of the ophiolites lack one or more of their diagnostic lithologies. In the Egyptian ophiolites, low-grade greenschist facies metamorphism predominates, but in some places the rocks reach amphibolite grade. Alteration resulted in the development of listwaenite, particularly in shear zones. The origin of the Neoproterozoic ophiolites of the Arabian-Nubian Shield exposed in the Eastern Desert of Egypt is still a subject of controversially. Despite deformation and metamorphism, remnant olivine, pyroxene and spinels present and their composition provided important clues to their tectonic environments. The ophiolitic rocks of Egypt were interpreted to have developed mainly at ancient mid-ocean ridges. Now, there is general consensus that the Egyptian ophiolites are formed in the supra-subduction zone setting (fore-arc or back-arc basins). Based on the chemical compositions of primary silicate minerals as well as spinels, the Egyptian ophiolites mostly formed in a forearc during the beginning of subduction. Also, the presence of boninitic affinities of some Eastern Desert ophiolitic rocks supports fore-arc settings.

Clinopyroxene composition as a petrogenetic indicator for the distinction of MORB- and SSZ-affinities in Albanian ophiolites

Beqiraj, A.* & Shallo, M.
Dept. of Earth Sciences, Faculty of Geology and Mining, Polytechnic University of Tirana, Albania
(*ae_beqiraj@yahoo.com)

The Albanian ophiolite complex, that represents a well developed ophiolite unit with a mostly complete and undisturbed ophiolite succession between Pelagonian and Apulian microplates, spread out over a 250km long and 30-40km wide belt with a NNW-SSE strike.

Two different ophiolite belts were distinguished based on their geochemical and petrological features [1,2]: western and eastern-type ophiolite, showing MOR and SSZ signatures, respectively. Clinopyroxene represents one of the most interesting rock-forming minerals because it is present almost in the entire ophiolite section and its composition, that largely depends on the composition of the melt from which crystallizes, shows an extremely wide variation. Compositional differences of clinopyroxene allowed to distinguish cumulate rocks with MOR- and SSZ-affinities within Bulqiza massif [3].

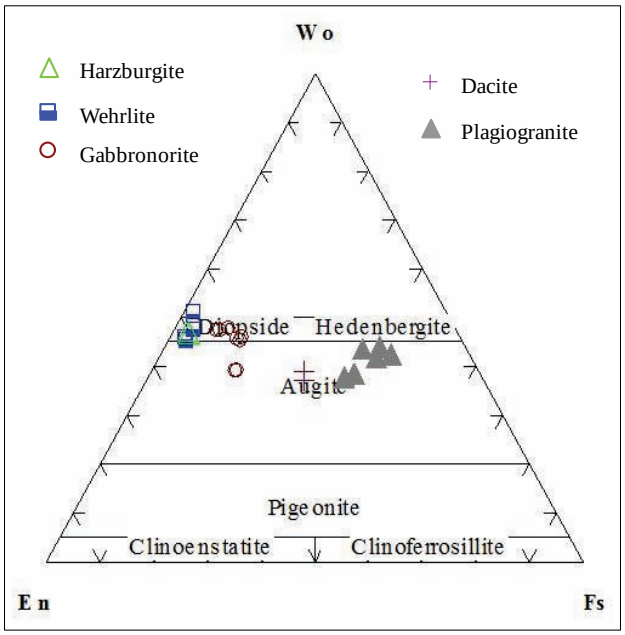

Fig. 1: Pyroxene quadrilateral diagram for the pyroxenes from the Eastern ophiolitic rocks (En-Enstatite; Wo-Wollastonite; Fs-Ferrosilite).

Clinopyroxene from eastern ophiolites shows a wider (Fs=5-45%) (Fig. 1) compositional range than clinopyroxene from western ophiolites (Fs=5-25%) (not shown). The Ti content of clinopyroxene, that ranges from 0.0 to 0.3 %TiO_2 and 0.3-0.9 %TiO_2 for eastern and western ophiolites, suggests their generation in supra-subduction zone (SSZ) and middle oceanic ridge (MOR) environment, respectively [4].

Mantle clinopyroxene is clearly lower in Ti, Fe and Na than magmatic analogue. This later indicates an apparent enrichment trend in iron (mol Fs) from the bottom (wehrlite) to the top (plagiogranite) of the ophiolite plutonic section, but this is not observed for the titanium.

Ophiolites in the Eastern Cordillera of the central Peruvian Andes

Castroviejo, R.[1*], Rodrigues, J.F.[2], Tassinari, C.[3], Pereira, E.[2] & Acosta, J.[4]
[1]School of Mines, Universidad Politécnica de Madrid, Spain (*ricardo.castroviejo@upm.es)
[2]Fac. Engenharia, Universidade do Porto, Portugal
[3]Institute of Geosciences, Universidade de Sao Paulo, Brasil
[4]INGEMMET, Lima, Perú

A discontinuous NNW-SSE trending belt of scattered ultramafic (UM) and subordinate mafic (M) rocks is exposed along some 250 km in the Eastern Cordillera of the peruvian Andes (Junín and Huánuco Departments, ~9º-12º S). New data question their previously assumed [1,2] intrusive origin. Work in progress shows that the essential geologic and tectonic features are common to most of them, as will be shown on the southernmost occurrences: Tapo and Acobamba (Tarma province). The Tapo massif is the most conspicuous and the only one with chromite mining history. It is a lens-shaped body, 5 km long (NW-SE direction) and 1-2 km wide, lying on detrital sediments of the Lower Carboniferous Ambo Group [3], and comprising extremely tectonised and serpentinised peridotites with subordinate podiform chromitite bodies, meta-gabbros or amphibolites. The Acobamba occurrences comprise serpentinites and subordinate meta-gabbros [4], in contact with phyllites of the Precambrian (?) Huácar Group (Marañón Complex).

In both cases, field work shows a strong shear deformation, with mylonites and phyllonites associated to the basal contact of the UM bodies with the siliciclastic sequences of the basement (either Huácar or Ambo Groups), which show no signs of thermal metamorphism. The interference patterns on the mylonites of these contacts point to a pre-Andean emplacement, followed by late tectonic reworking during the Andean cycle, also evidenced by folding of the basal thrust plane.

The mineralogy is strongly overprinted by metamorphism. The UM rocks are represented by serpentinites (with varying amounts of chromite and magnetite, but only scarce relics or ghosts from pyroxene or olivine) or chlorite-serpentine schists, and by chromitites. Secondary stichtite (Cr-bearing carbonate), kämmererite (Cr-bearing pennine), ilmenite and titanite are seen occasionally. Sulphides (as pyrite, pyrrhotite or millerite) are very scarce. Rodingites, usually grosularia- or andradite-rich rocks with varying amounts of epidote, zoisite, wollastonite or diopside, are present as boudins, and intensively deformed. Altered serpentinites, as listvenites (dolomite or magnesite-talc-antigorite) and birbirites (fine-grained silica), are also found near faults enhancing hydrothermal circulation. The M rocks are metagabros, amphibolites and amphibole-plagioclase mylonites, present in NW-SE trending bands, whose geochemistry strongly suggests an ocean rift or ocean island protolith. Preliminary results from on-going Sm-Nd geochronology point to a Precambrian age for the UM and M protoliths.

All these data preclude an intrusive origin for the UM-M bodies and support their interpretation as dismembered blocks of oceanic lithosphere (ophiolites) thrust on Andean siliciclastic sequences, as is the case for most of the occurrences of the UM belt farther north, thus defining a first example of Peruvian ophiolites (another example of thoroughly dismembered ophiolites along a 250 km belt is known in the Betic Cordillera, SE Spain [5]). Their origin may be related to the break-up of Rodinia and to the evolution of the NW Amazonian margin.

Geochemical fingerprinting of block-in-matrix structures to ophiolitic units in the Western Blue Ridge North Carolina (USA)

Collins, N.C.* & Ryan, J.G.
Dept. of Geology, University of South Florida, Tampa, USA
(*nccollin@mail.usf.edu)

The Blue Ridge province of the southern U.S. Appalachians includes extensive sequences characterized by olistostromal rocks that include blocks of highly metamorphosed mafic, ultramafic, and felsic rocks enclosed in metasedimentary rock matrices. The blocks range in size from a few centimeters across to mappable, >km-scale units, are strongly deformed, and sometimes extensively migmatized. Also, the southern Blue Ridge includes a number of Mafic-ultramafic massifs that, while highly metamorphosed, include lithologic sequences and preserve the geochemical signatures consistent with an oceanic, ophiolitic origin [1-3]. The ophiolitic rocks have been posited to be olistostromal mega-blocks [4-6], and as part of a sequence distinct from the olistostromal units [7]. However, clear petrologic linkages or distinctions between massif mafic units and olistostromal mafic blocks have not been established.

To better understand the connections between Blue Ridge block-in-matrix and ophiolitic units, we are examining the bulk geochemical and mineral chemistry signatures of amphibolitic blocks from parts of the Cullowhee/Cartoogechaye olistostromal terrane for comparison to published data for rocks from the Buck Creek mafic-ultramafic complex [1] and the Carroll Knob Complex [8,2], two of the largest Blue Ridge mafic-ultramafic massifs. Bulk geochemical data is being collected on the ICP-MS at the University of South Florida (USF), using digestion procedures from Kelley et al. 2003 [9]. Thin sections prepared at USF and mineral chemistry was analyzed on the remotely operable JEOL 8900 Superprobe electron microprobe facility at the Florida Center for Analytical Electron Microscopy (FIU).

The olistostromal blocks of the Cullowhee/Cartoogechaye terrane represent rocks with similar chemical trends as the Buck Creek mafic-ultramafic complex and Carroll Knob Complex. Mineral chemistry of amphiboles within the two massif units varies considerably in comparison to the sampled blocks. However, exclusion of high-Mg amphiboles from the massif units reveals chemical signatures within Carroll Knob Complex that are indistinguishable from the olistostromal mafic blocks, as well as areas surrounding the Buck Creek complex. It is our hypothesis that these blocks represent fragments of the upper level of the ophiolitic unit and are working to constrain this through trace and rare earth elemental abundances.

Protolith nature of Baijingsi eclogites from the North Qilian Mountains in NW China and its tectonic significance

Ker Choon-Muar[1*], Yang Huai-Jen[1], Zhang Jian-Xin[2], Tseng Chien-Yuan[1] & Meng Fan-Cong[2]
[1]Dept. of Earth Sciences, National Cheng-Kung University, Tainan, Taiwan (*kcmuar@gmail.com)
[2]Institute of Geology, Chinese Academy of Geological Sciences, Beijing, China

The WNW–ESE trending and ~1000 km long North Qilian suture belt (NQLS) is one of the major suture zones in NW China. It is composed chiefly of blocks of ophiolite mélanges, volcanic rocks and HP/LT metamorphic rocks in sedimentary formations. The protolith nature of these metamorphic rocks and its spatial relationship to the associate ophiolite are basic elements for reconstructing paleo-tectonic environment. In this study, abundances of major and trace element as well as Sr and Nd isotope ratios of 19 eclogite samples from Baijingsi (BJS) area in east part of the NQLS were determined. These data were critically evaluated to infer their protolith characteristics and tectonic significance.

All the analyzed BJS eclogites are of basaltic compositions containing 47–51% SiO_2, 14–20% Al_2O_3, and 6–10% MgO, except for two samples with low MgO contents of 2–4%. Seventeen samples show slight enrichment in LREE over HREE abundances with La/Yb ratio in the range of 1–40. Although consistent with derivation from lavas formed in ocean basins or arcs, such enrichments are not reliable protolith indicators given the mobile behavior of LREE during high-grade metamorphism. The abundances and ratios of relatively immobile Zr, MREE, and HREE are better parameters for deducing the nature of protoliths. The concentrations of these elements in the BJS eclogites are within the ranges for MORB, OIB, and arc lavas, pointing to extrusive, instead of cumulative, igneous precursors. Most significant is the depletions in the abundances of Zr, Hf, Nb, and Ta relative to that of REE with similar compatibility during igneous processes. This feature is the characteristics of lavas generated in arc systems. Collaborating evidence is the Nd isotope ratios. The metamorphic initial Nd isotope ratio, $\varepsilon Nd_{(450\ Ma)}$, of the BJS eclogites varies in the range of 1.5–7 (mostly 4–7), lower than that for MORB and most OIB but consistent with that for lavas formed in convergent zones. If the Nb/Th ratio remained intact during metamorphism, the values of 5–14 for 12 of 19 samples are over the range for North Luzon and Ryukyu arc lavas but within the range for lavas from Lau basin, favoring a back-arc environment. In contrast to the previously proposed MORB and/or OIB protoliths, our new data indicate that BJS eclogites were metamorphosed from lavas in an arc system, most likely back-arc basin lavas.

In developing a tectonic evolution model for NQLS, subduction polarity is a controversial issue. Both northward subduction and southward subduction have been proposed. In such models, a systematic spatial sequence of oceanic ophiolite–arc–back-arc is expected in the north-south direction. The BJS eclogites occur on the north of an oceanic ophiolite belt defined by the Yushiguo and Dongcaohe ophiolites. Consequently, a back-arc protolith for the BJS eclogites is consistent with northward subduction. The development of a back-arc basin also implies that a large ocean basin, instead of a marginal sea, was involved in NQLS subduction system. It is suggested this inferred mature ocean basin is the so-called "Paleo-Qilian Ocean".

Geochemistry and tectonic significance of ophiolites along the Ankara-Erzincan suture zone in northeastern Anatolia

Parlak, O.[1,2*], Colakoglu, A.[3], Donmez, C.[3], Sayak, H.[3], Turkel, A.[3], Yildirim, N.[3], Odabasi, I.[3] & Konak, N.[3]
[1]Adıyaman Üniversitesi, Teknoloji Fakültesi, Adıyaman, Turkey (*oparlak@adiyaman.edu.tr)
[2]Çukurova Üniversitesi, Jeoloji Müh Bölümü, Adana, Turkey
3MTA Genel Müdürlüğü, Ankara, Turkey

The northeastern Anatolia is characterized by two large tectonic units, namely the Eastern Pontides and the Eastern Taurides. These two tectonic units are separated by the Ankara-Erzincan suture zone. The Ankara-Erzincan suture zone includes large bodies of ophiolites and ophiolitic melanges in the northeastern Anatolia. The studied ophiolitic bodies are of (I) Refahiye (Erzincan), (II) Tekman-Pasinler (Erzurum), (III) Karadağ (Erzurum) and (III) Kırdağ (Erzurum). All of these ophiolitic bodies emplaced over the passive margin of the Tauride platform to the south of the suture zone during Late Cretaceous. The ophiolitic units in Refahiye region, except volcanics, are characterized by well-preserved oceanic lithospheric section (mantle tectonites, ultramafic to mafic cumulates, isotropic gabbro, sheeted dikes) and ophiolitic melange (recrystallized limestone, schist, gabbro, serpentinite, spilitic volcanics, sandstone and radiolarite), resting tectonically on the Munzur limestone of the Tauride platform. The ophiolitic units in Tekman-Pasinler region display a well preserved ophiolitic melange, including Triassic to Cenomanian various rock types in which traces of blueschist facies metamorphism were determined and lower part of oceanic lithosphere (peridotite, gabbro and isolated dikes in peridotites) remnants at the top. The Karadağ region displays almost an intact ophiolite succession such as serpentinized harzburgitic tectonites, gabbro, sheeted dike, plagiogranite and volcanics. The Kırdağ region displays a typical features of accretionary melange that includes chaotic mixture of peridotite, gabbro, diabase, limestone blocks, metasandstone, metasiltstone and slices of glaucophane schist. These ophiolitic units in northeast Anatolia are unconformably overlain by Campanian-Maastrichtian sediments that were in turn imbricated with the ophiolitic rocks, suggesting post-emplacement tectonic activity in the region.

Geochemical data for the oceanic crustal rocks along the Erzurum-Kars ophiolite zone (Refahiye, Tekman-Pasinler and Karadağ) display similar geochemical behavior such as (a) tholeiitic in composition (b) depletion of Nb, (c) enrichment in LIL elements, (d) parallel to slightly depleted HFS element patterns compared to N-MORB (e) slightly LREE-depleted to parallel REE patterns and (f) ratios of selected trace elements (Nb/Th, Th/Yb, Ta/Yb). These features suggest that the ophiolitic rocks in the northeastern Anatolia were derived from a island arc tholeiitic magma and formed above an intraoceanic subduction zone. In contrast, the volcanic rocks in the Refahiye ophiolitic mélange show variation in geochemistry (tholeiitic to alkaline nature, depletion & enrichment in REE and HFS elements). These suggest that seamount-type alkaline and subduction-related tholeiitic basaltic rocks were juxtaposed during subduction/accretion.

All the field and geochemical data from the ophiolitic rocks show that they formed along the northern Neotethyan ocean, bounded by the Sakarya Zone (Eastern Pontides) in the north and the Taurides in the south, as a result of north-dipping intraoceanic subduction during the Late Cretaceous. During the closure of the ocean, the rift/passive margin units and the distal edge of the Tauride Carbonate Platform were detached and emplaced together with the over-riding ophiolites. Subduction-accretion units and the leading edge of the northern margin of the Tauride Carbonate Platform were underthrust, deeply buried and metamorphosed under HP–LT conditions.

Petrology and geochemistry of Malakand ophiolitic complex, Pakistan

Sano, S.
Earth Science Laboratory, Faculty of Education, Ehime University, Matsuyama, Japan (sano@ed.ehime-u.ac.jp)

Malakand ophiolitic complex is exposed along suture zone in northern Pakistan [1]. The Malakand complex is a dismembered ophiolite formed with convergence of Neo-Tethyan Ocean by collision of the Indian plate against the Kohistan Arc. The main constituents are harzburgite and dunite, with minor wehrlitic, websteritic and gabbroic dikes. Small-scale chromitite deposits are frequently seen in the dunite zone. Harzburgite displays typical porphyroclastic texture, and clinopyroxene is rarely seen. Porphyroclastic and equigranular textures are observed in dunite. Chrome spinels in dunite and chromitite often include amphibole and clinopyroxene.

Harzburgites contain olivine with $0.906 < X_{Mg} < 0.925$. Olivine in dunites shows much wider X_{Mg} range of 0.911 to 0.943. The variation of Cr# depends on the rock and position of the body. Cr# of spinel in harzburgite ranges 0.50 to 0.75, while that in dunite shows 0.45 - 0.87.

REE concentrations of harzburgite and dunite are extremely low compared with those of mid-oceanic ridge (MOR) peridotites. Chondrite-normalized La, Gd and Lu contents are $(La)_N = 0.0013 – 0.017$, $(Gd)_N = 0.0015 – 0.0079$ and $(Lu)_N = 0.05 – 0.12$, respectively. The harzburgite and dunite display convex-downward REE patterns (Fig. 1). Dunite shows low HREE/MREE ratios, and higher LREE contents. On the other hand, REE patterns of dike rocks of hornblende-gabbro, leucogabbro and olivine-websterite, which intrude into harzburgite and dunite, display wide variety.

Harzburgites and dunites from the Malakand ophiolitic complex probably represent very depleted mantle after large degree of melting. Clinopyroxene-free harzburgite, high X_{Mg} of olivine, high Cr# of spinel and existence of hydrous minerals in chrome spinel indicate that the Malakand complex correspond to uppermost mantle beneath an island arc. Furthermore, it is expected that existence of high Cr# spinel (0.87) engage with a boninitic magma [2].

Very low concentrations of MREE to HREE in the harzburgite and dunite expect that they are residue after multi-stage extended melting at deeper garnet- to shallower spinel-fields [3]. Relative LREE enrichment of the peridotites is possibly resulted in any interaction [4] of circulating melt with harzburgite wall.

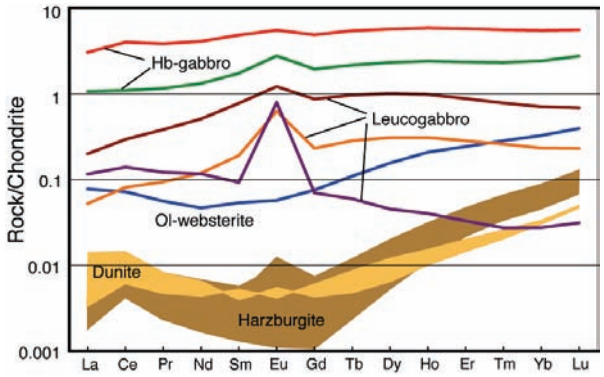

Fig. 1: Chondrite normalized REE patterns of rocks from the Malakand ophiolitic complex, Pakistan.

Petrology of the Singok ultramafic bodies in Hongseong area, Gyeonggi Massif, South Korea

Seo, J.[1], Rajesh, V.J.[1,2], Choi, S.-G.[1*] & Oh, C.W.[3]
[1]Dept. of Earth and Environmental Sciences, Korea University, Seoul, Republic of Korea ([*]seongyu@korea.ac.kr)
[2]Dept. of Earth and Space Sciences, Indian Institute of Space Science and Technology, Thiruvananthapuram, India
[3]Dept. of Earth and Environmental Sciences, Jeonbuk National University, Jeonju, Republic of Korea

Several isolated lensoidal serpentinized ultramafic bodies occur within the granitic gneiss in the Hongseong area in the western Gyeonggi massif, South Korea. Many of these bodies are highly deformed and metamorphosed under eclogite to greenschist facies conditions. The core compositions of chromian spinel and olivine are used to deduce the petrogenesis and tectonic environments of the Singok ultramafic rocks (one among the representative ultramafic bodies in the Hongseong area). The high Fo content of olivine with moderate to high Cr# (Cr/Cr+Al) of chromian spinel indicate the formation of the ultramafic bodies as mantle residues left after higher degrees of partial melting of a fertile MORB mantle. The data plot in an overlap area of the abyssal and suprasubduction zone peridotite fields in the olivine spinel mantle array (OSMA) diagram. The low TiO_2 content of the chromian spinel along with high Cr# suggest a suprasubduction zone environment. Further, the chromian spinel and olivine compositions are similar to those harzburgites formed in the mature back-arc basin in the Bibong area. We believe that the Singok ultramafic rock was a mantle part of the SSZ ophiolite and formed in the mature back-arc basin tectonic setting by high degrees of partial melting due to the increased supply of fluid or melt from the subducting oceanic crust. This finding substantiates the existence of a collision zone in the Hongseong area of the Gyeonggi massif.

Deciphering a complex geodynamic evolution of an orogen: what is the contribution of the metamorphic petrology?

Bousquet, R.[1*], Oberhänsli, R.[1] & Wiederkehr, M.[2] & Robert, Ch.[3]
[1]Institut für Erd- und Umweltwissenschaften, Universität Potsdam, Germany ([*]bousquet@geo.uni-potsdam.de)

[3]Laboratoire de Géologie, ENS Paris, France

Based on mineralogical works, Ernst [1] was able to use the plate tectonic concept for proposing a first modern model for the evolution of the Alps. In the meantime, [2], as well as [3], started to investigate metamorphism in isochemical systems provided by shales and siliceous carbonates, respectively. This allowed for quantitatively constraining the Cenozoic temperature evolution in the Central Alps. The regional distribution of the Permian and of Cretaceous-Tertiary metamorphic conditions, documented in post-Hercynian rocks across the entire Alpine belt from Corsica-Tuscany in the West to Vienna in the East, will be presented.

Based on metamorphic studies in metasediments, we evidence substantial differences in the metamorphic, and hence the geodynamical evolution along strike the Alpine orogen.

The Western Alps did not reach the mature stage of a head-on colliding belt as is indicated by a continuous metamorphic evolution, representing all the subduction related processes ranging from lower greenschist to UHP conditions. All the metamorphic rocks behind the Pennine frontal thrust were already exhumed to upper crustal level during ongoing oceanic and continental subduction and before collision with the Dauphinois domain from around 32 Ma onwards. Hence, the Western Alps represent a frozen-in subduction zone. Since then only exhumation by erosional processes affected the inner parts of the orogen. The rest of the Alpine orogen later underwent a more important collision process due to the ongoing head-on geometry of subduction and collision. It therefore often but not always shows a bimodal metamorphic evolution with two distinct P and T peaks. The intensity of the thermal overprint relates to the amount of crustal material incorporated to the orogenic wedge. Thermal overprint is primarily related to the amount of crust involved in the subduction and collision processes rather than to processes of shear or viscous heating. The latter mechanism, which suppose high deformation rate will not allow for the preservation of HP-LT assemblages within high-grade rocks. The recorded isotopic data reveal a significant time gap in the order of some 20 Ma between the subduction-related HP/LT event (42-40 Ma) and the later collision-related MP/MT Barrovian overprint (19-18 Ma) supporting the notion of a polymetamorphic evolution in the Centrtal Alps associated with a bimodal P-T path. Amphibolite facies Barrow-type overprint represents a clearly separated heating pulse that post-dates isothermal decompression after the early high-pressure stage. This considerable time interval is in accordance with the interpretation that it is the accretion of vast amounts of European continental crust (forming the present-day Lepontine dome) that provides high radiogenic heat production responsible for amphibolite facies metamorphism, being an entirely conductive and therefore rather slow process.

The relation between the volume of continental crust imbricated and intensity of high-temperature orogenic metamorphism can be generalized over the entire alpine edifice, except for Tuscany where the late thermal overprint is clearly related to lithospheric thinning.

Processes of extrusion and extension of the ALCAPA block as mirrored by mafic lower crustal xenoliths from the Bakony-Balaton-Highland basalts (Hungary)

Dégi, J.[1,2*], Török, K.[3], Abart, R.[4] & Belkin, H.E.[5]
[1]Research Institute for Solid State Physics and Optics, Budapest, Hungary ([*]julia.degi@gmail.com)
[2]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary
[3]Eötvös Loránd Geophysical Institute of Hungary, Budapest, Hungary
[4]Dept. of Lithospheric Research, University of Vienna, Austria
[5]U.S. Geological Survey, Reston, Virginia, USA

The Pannonian Basin (PB) is a Mediterranean type back-arc basin with thin crust (25–31 km) in thin lithosphere (60–70 km). The northern part, the ALCAPA block, was part of the Alps in the Upper Cretaceous. This block went through large scale juxtaposition and several drastic changes due to the tectonic processes during the Miocene extension/extrusion of the Pannonian Basin (18–11 Ma). The material of the deep lithosphere has been sampled by post-extensional alkali basaltic volcanism in the Bakony-Balaton Highland Volcanic Field, located in the central region of the Pannonian Basin. We have studied mafic lower crustal granulite xenoliths from this area in order to identify deep lithospheric processes acting associated with the geodynamic evolution.

Peak metamorphic conditions are shown by the granulite facies rock-forming mineral assemblage (clinopyroxene, plagioclase, garnet, ±orthopyroxene ±amphibole ±biotite). In most of the xenoliths, the peak metamorphic mineral assemblage shows equilibrated granoblastic microstructure, while in some samples non-equilibrium poikiloblastic microstructure is present. Petrographic observations and fluid inclusion studies of the latter samples suggest that biotite was destabilized in the presence of CO_2-rich fluids by the reaction Bt + Pl + Qtz = Opx + Grt + melt. Melt was extracted from the rock, and orthopyroxene, garnet and some plagioclase remained as restitic phases. Careful geothermobarometric investigations have shown that the granoblastic xenoliths represent a complete crustal section with equilibrium temperatures and pressures between 750–1070 °C and 1.0–1.6 GPa, which corresponds to 35–60 km depth. This corresponds to the overthickened orogenic root of the Alps, where CO_2-rich fluid input led to the partial melting of the lower crust may be at the beginning of the extension/extrusion of the Pannonian Basin.

According to mineral reactions observable in the rock, peak metamorphic conditions were followed by significant pressure decrease to 0.7–0.8GPa (25–28km), which corresponds to the depth of the present day lower crust. This suggests that the process took place due to significant crustal thinning during the extension/extrusion. Melting of high Ti amphiboles and reactions of rock-forming minerals with melts at lower pressures indicate that partial melting of the lower crust was continuous during the extension. Accessory Fe-Ti-oxides have preserved the traces of interaction of the xenoliths with the host basalt. By the modelling of diffusion profiles in the oxide grains we have estimated that the interaction lasted a few days.

Our results on the metamorphic evolution of lower crustal xenoliths have shown a series of lithospheric processes starting from an overthickened orogenic crust through the extrusion of the ALCAPA block and extension of the Pannonian Basin ending with sampling of the lower crust by late Tertiary basalts, which can be used for refining models of basin formation.

Different metamorphic records in the Western Kaoko Zone (NW Namibia) and their timing

Fuchs, P.[1*], Tajčmanová, L.[1,2], Milke, R.[1] & Konopásek, J.[2]
[1]Institute of Geological Sciences, Free University, Berlin, Germany ([*]parveen.fuchs@fu-berlin.de)
[2]Czech Geological Survey, Prague, Czech Republic

The Kaoko belt is situated in NW Namibia and represents a part of the Neoproterozoic orogenic belt system of western Gondwana developed between the Congo Craton, the Kalahari Craton and the Rio de la Plata Craton in southern Brazil. The metamorphic evolution of the eastern and central part of the Kaoko belt has already been well described by means of thermodynamic modelling [1]. On the contrary, well-constrained data on pressure-temperature (P-T) evolution of the western part of the Kaoko belt are still missing. The westernmost unit of the western Kaoko Zone, the so called Coastal Terrane (CT), is a unit with metamorphic ages of 650-630 Ma and an independent tectonic evolution prior to its collision with the Congo Craton at ~580-550 Ma. The CT consists of migmatitic metasedimentary rocks that are intercalated withfine -grained orthogneisses and amphibolites. Along its eastern margin, the Boundary Igneous Complex (BIC) is exposed and defines the suture between the CT and Congo Craton-related rocks of the Kaoko belt. The BIC is composed of various types of granitoids associated with isolated bodies of pervasively molten metapelites metamorphosed at 580-550 Ma. As the relationship of the CT with the rest of the Kaoko belt and the affinity of granitoids from the BIC is still a matter of debate, we have focused on the key metamorphic lithologies from both units in order to characterize the metamorphic evolution and partial melting in detail. This information combined with already existing geochronological, geochemical and structural data from the two units can help to a better description of the overall tectonic evolution of the area.

In this work, we have particularly focused on metasedimentary rocks from both units because they contain the most suitable assemblages for phase equlibria modelling. All phase equilibria calculations were carried out by using the thermodynamic software set Perple_X. The metasediments from the CT are characterized by a Grt-Bt-Pl-Kfs-Ms-Qtz mineral assemblage. The foliation is defined by biotite and muscovite bands alternating with a quartz-feldspatic matrix. Although the rock was affected by melting, the presence of muscovite documents that temperatures higher than 700°C have never been reached. Samples from the BIC underwent pervasive melting and have a strong stromatitic character. Three different assemblages have been described reflecting the slightly different pressure conditions of equilibration attained during the metamorphic evolution: Grt-Sil-Bt-Pl-Kfs-Qtz; Grt-Crd-Sil-Bt-Pl-Kfs-Qtz and Crd-Sil-Bt-Pl-Kfs-Qtz. Two different generations of garnet occur in the Grt-Sil-Bt samples. The First generation is characterized by medium grained garnets elongated parallel to the foliation and the second generation by undeformed porphyroblasts. This observation serves for more accurate description of the *P-T* path. The temperatures for all three assemblages exceeded 750°C. Regarding the *P-T* results from both units, the two different metamorphic events are characterized by different thermal evolution. The higher temperatures attained during the metamorphic event at 580-550 Ma are interpreted to be connected with an emplacement of a huge amount of granitoids within the BIC.

Island-Arc signature in amphibolites from the boundary between the Ossa Morena Zone and the Central Iberian Zone in Central Portugal

Henriques S.B.A.[1*], Neiva A.M.R.[2], Ribeiro M.L.[1] & Dunning G.R.[3]
[1]Dpt. of Geology, LNEG, Amadora, Portugal ([*]susana.henriques@ineti.pt)
[2]Dept. of Earth Sciences and Geosciences Centre, University of Coimbra, Portugal
[3]Earth Sciences Dept., Memorial University, St. John's, Canada

The Iberian Terrane contains an important tectonic boundary, the Tomar-Badajoz-Cordoba shear zone, between the Ossa Morena Zone and the Central Iberian Zone, where the Cabeço da Moura amphibolites (Pouchão Mafic Complex), crops out close to Abrantes, Central Portugal. It consists of a fine-grained amphibolite that comprises three main mineral assemblages: a) labradorite, magnesiohornblende, augite, diopside, quartz and ilmenite; b) bytownite rimmed by andesine, ferrohornblende, hedenbergite, diopside, epidote, titanite, quartz, magnetite and apatite; c) andesine, magnesiohornblende rimmed by actinolite, diopside, quartz and magnetite. Estimated P-T conditions, based on hornblende Al content [1] and hornblende-plagioclase equilibrium [2], are T=702-724º C, P=4.6-4.9 kb (± 0.6 kb) for the assemblage a); T=703-727º C, P=6.7-7.4 kb (± 0.6 kb) for the assemblage b), showing a progressive metamorphism and T=640-708º C, P=3.8-6.2 kb (± 0.6 kb) for retrograde crystallization evidenced by the formation of actinolite. The analyzed amphiboles have important coupled substitutions such as edenite in all the amphiboles, hastingsite-pargasite in ferrohornblende and magnesiohornblende, titanotschermakite in magnesiohornblende, ferrotschermakite in magnesiohornblende and actinolite and hastingsite in actinolite.

The Cabeço da Moura amphibolites are basic (SiO_2=45.68-50.03 wt %), subalkaline and tholeiitic. The MORB- normalized spider diagram shows enrichment in LILE relatively to HFSE (Rb_N/Y_N=2.67-15.76), a negative Th anomaly and a HFSE pattern (from P_2O_5 to Yb) parallel to MORB, but at a lower level, and in general LILE are enriched above MORB, suggesting an island arc setting. The chondrite normalized REE patterns display enrichments in MREE relatively to HREE (Sm_N/Yb_N=1.07-1.25) and do not show significant negative Eu anomalies (Eu/Eu*=0.92-1.05). The Th-Hf/3-Ta and Zr/4-2Nb-Y diagrams show N- and E-MORB affinities, supported by La_N/Sm_N (0.72-0.91) and La_N/Sm_N (1.29-1.51). Enrichment in LREE relatively to HREE only occurs in E-MORB samples (La_N/Yb_N=1.08 to 1.81), contrasting with N-MORB samples (La_N/Yb_N=0.85-0.87). The ID-TIMS U-Pb age of the metamorphic zircon, that has an equant multi-faceted morphology, is 539 ± 3Ma. These data suggest the presence of a Precambrian island arc that generated magmas from depleted and enriched mantle sources and were metamorphosed in the early Cambrian under amphibolite facies conditions.

Neoarchaean high-grade metamorphism of pelitic gneisses and ironstones in the Nhlangano area, SW Swaziland

Horváth, P.[1*], Reinhardt, J.[1], Hofmann, A.[1] & Nagy, G.[2]
[1]School of Geological Sciences, University of KwaZulu-Natal, Durban, Republic of South Africa ([*]horvathp@ukzn.ac.za)
[2]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary

Within the broader perspective of an investigation of Archaean geodynamic processes along the southern margin of the Kaapvaal Craton, we quantitatively evaluated pressure and temperature conditions recorded in supracrustal rocks overlying the Kaapvaal basement in southwest Swaziland. The uniqueness of the area is expressed by the occurrence of intensely deformed, high-grade metamorphic rocks of the c. 2900 Ma Pongola Supergroup. Elsewhere, this volcano-sedimentary cover sequence is relatively undisturbed and typically shows no more than low-grade metamorphic overprint.

Metapelitic gneisses of the Nhlangano area have a peak metamorphic assemblage of garnet-cordierite-sillimanite-K-feldspar-plagioclase-quartz-ilmenite. Restitic varieties lack sillimanite, but contain more garnet and cordierite. Silica-undersaturated rocks contain corundum and spinel with garnet, plagioclase, K-feldspar and biotite. These assemblages indicate high-temperature (granulite facies) conditions involving partial melting and, in case of the restitic rocks, melt loss. Meta-ironstones can be divided into two groups, according to petrographic and compositional parameters. The group 1 ironstones contain orthopyroxene with garnet, quartz and magnetite. The group 2 ironstones have no orthopyroxene. Instead, amphiboles are present. Another significant difference between the two groups is the bulk MnO content which is high in the group 2 ironstones. This is reflected in the high MnO content of the major rock-forming minerals (garnet, amphibole). Phase equilibria modelling of metapelites and ironstones indicate metamorphic peak pressure and temperature conditions around 6-8 kbar and 850°C.

Dating of metamorphic monazite in metapelites yielded ages between 2500 and 2700 Ma, suggesting peak (or post-peak) metamorphism during Neoarchaean times.

Distinguishing garnet grains using textural analysis on the pelitic schists of the Sanbagawa metamorphic belts, Shikoku, Japan

Inui, M.
School of Science and Engineering, Kokushikan University, Tokyo, Japan (inui@kokushikan.ac.jp)

The occurrence of garnet grains in the higher grade pelitic schists of the Sanbagawa metamorphic belt (Albite-biotite zone and Oligoclase-biotite zone) exposed along the Asemigawa-river, central Shikoku, Japan, was reexamined for the evidence of disequilibrium and of multiple generation. Those garnet grains play a very important role in constraining the pressure-temperature history of the Sanbagawa metamorphism.

Chemical mapping analysis was carried out on garnet grains in 13 pelitic schist samples to find some grains displaying weak intrasectoral zoning, which was an evidence of disequilibrium. It seemed reasonable to divide the garnet into two groups. Group A grains were porphyroblasts with 0.2 to 1 mm diameter, generally distributed evenly throughout a thin section. They exhibited normal chemical zoning. Group B grains were distinctly smaller and most of them were located in the muscovite-rich layers or included in the albite porphyroblasts. Group B grains often showed intrasectoral chemical zoning.

Group A garnet occurred in the Oligoclase-biotite zone and the upper Albite-biotite zone (the highest grade Oligoclase-biotite zone rocks are sandwiched by the upper and lower Albite-biotite zone rocks). Group B garnet occurred in the Oligoclase-biotite zone and the lower Albite-biotite zone. Group A and B grains were observed in the same thin section of rocks from the lower Oligoclase-biotite zone on the south of the proposed detachment fault [1]. The result of the crystal size distribution analysis supported that they were of two different populations.

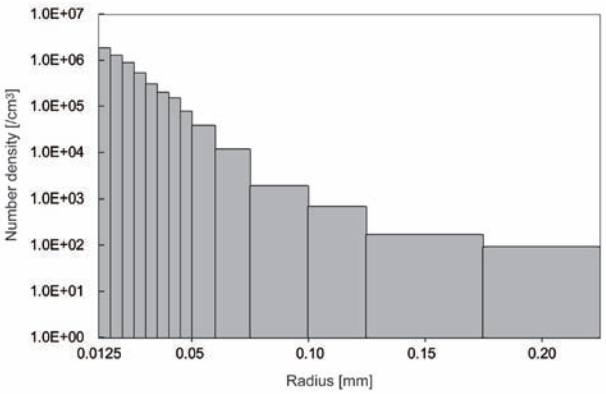

Fig. 1: Crystal size distribution of garnet in sample M19A.

Group A grains included in the albite porphyroblast had the same chemical profile compared to those not included in albite. Group A garnet seemed to have grown during the prograde metamorphism, which predated the formation of the albite porphyroblasts. The group B garnet included in the albite porphyroblasts lacked the rim which the group B grains in the matrix had (middle Oligoclase-biotite zone), or, on the contrary, the rim of the included grains were more preserved compared to the resorbed grains in the matrix (lower Albite-biotite zone). It is indicated that formation of the group B garnet was roughly contemporaneous with that of the albite porphyroblasts, the timing of which is probably after the peak metamorphism. It is possible that garnet grains of post peak generation (group B) are more widely distributed than previously thought.

Metamorphic *P-T-t* evolution of the Trans-Angarian region, Yenisey Ridge, as a consequence of geodynamic events in the western margin of the Siberian craton

Likhanov, I.I.*, Reverdatto, V.V., Kozlov, P.S. & Popov, N.V.
Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia (*likh@uiggm.nsc.ru)

We report new isotopic and petrological data on the evolution of polymetamorphic complexes of the Trans-Angarian region, Yenisey Ridge, which allowed us to constrain several major stages in the Riphean geological history of the study area that were controlled by different geodynamic settings.

The first stage was marked by the formation of zoned (LP/HT) metamorphic complexes of the andalusite-sillimanite type over a wide range of temperature and pressure conditions (T=400°C-650°C, P=3.5-5 kbar), suggesting a normal metamorphic field gradient with dT/dP ca. 40°C/km [1]. The inferred relationships between these processes and the Grenville orogeny can be supported by SHRIMP-II U-Pb and ^{39}Ar-^{40}Ar dating of metapelites from the Teya polymetamorphic complex (953-973 Ma) [1]. In the vicinity of thrusts, within the Tatarka deep fault, these rocks underwent medium-pressure metamorphism which resulted in the progressive replacement of andalusite by kyanite and the formation of new mineral assemblages and deformation structures [2]. Some specific features of the kyanite-sillimanite metamorphism include a small thickness of the medium-pressure metamorphic zoning (2.5-7 km) and a gradual increase in pressure from 4.5-5 to 6.5-8 kbar in approaching the thrusts, with a less pronounced temperature zoning, which is indicative of a low metamorphic field gradient with dT/dP ranging from 1-7 to 12°C/km [3]. These specific features are typical of collision-related metamorphism, which can be well substantiated using a model of crustal thickening at high thrusting rates and subsequent rapid exhumation and erosion [4]. Using the calculated exhumation rate (0.368 mm/yr) and the proposed model, we placed age constraints on the five areas and timing of collision-related metamorphism with the peaks at 849-862 and 798-802 Ma. The older metamorphic rocks (Angara, Mayakon, Teya, and Chapa areas) were formed as a result of thrusting of Siberian cratonal blocks onto the Yenisey Ridge that is evidenced by geophysical data and provenance studies. Subsequent collision-related metamorphism was caused by opposite movements of smaller eastward-trending blocks in the zone of higher-order splay faults (Garevka area). On a regional scale, this can be linked to accretion and collision processes when the microcontinent split off the craton at the Early-Middle Riphean boundary and dock onto the Central Asian terrane [5].

Cr-staurolite - bearing rocks from the Valea Someşului Unit (Rodna Mountains, East Carpathians, Romania)

Mosonyi, E.* & Forray, F.L.
Dept. of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania (*emilia.mosonyi@ubbcluj.ro)

Cr- staurolite is described from the Valea Somesului Group gneisses of Alpine Infra-Bucovinian Unit in the Rodna Mountains (East Carpathians). This is a first record of a Cr-staurolite from the polymetamorphic crystalline basement in the East Carpathians. The aim of the study was to characterize a chemically zoned staurolite, the metamorphic evolution of the staurolite- bearing rocks and to compare their evolution with those from overthrusted Sub-Bucovinian Rebra Group gneisses. The Cr- staurolite formed under Barrovian-type metamorphic conditions. As revealed by the microprobe measurements in the staurolite zoning profile three main zones could be delimited, that record three phases in staurolite evolution: two blasthesis phases in prograde, and one resulted during retrogression transformations.

About the Cr origin in these rocks we suppose either a bimodal magmatic event during a cratonic rifting or an accretionary wedge material in convergent plate setting. Using different geothermometers and geobarometers (Ti in biotite [1] and biotite-muscovite geothermometers [2] and phengite geobarometer [3]) it could be outlined that Cr-staurolite-bearing gneisses from Valea Somesului Group/ Bretila Group (BG) a medium pressure metamorphism in amphibolite facies conditions (T_{max}= 580°C, P =5-6.6 kb) suffered during the M_1 (during this collision BG was a part of an upper plate) with two deformation phases (the D_2 phase was associated with some migmatic processes). The Sub-Bucovinian Rebra Group gneisses were metamorphosed in medium pressure amphibolite facies conditions (640ºC, 6kb [4]) in the M_1. During M_2 event in an uplift tectonic setting both groups processed together (parallel, transposed rock fabrics), but in different pressure conditions.

Tertiary eclogites in the lower tectonic unit of East Rhodope (Kechros Complex, NE Greece)

Mposkos, E.* & Baziotis, I.
Section of Geological Sciences, Dept of Mining and Metallurgical Engineering, National Technical University of Athens, Greece (*mposkos@metal.ntua.gr)

The Rhodope Metamorphic Province is one of the major tectonic units in northern Greece. It consists of different tectonometamorphic complexes involved in the Alpine collisional history between the Eurasian and African plates. In eastern Rhodope a Jurassic UHP metamorphism is documented in the uppermost Kimi Complex by the presence of microdiamond inclusions in garnets from pelitic gneisses [1]. Partially or completely amphibolitized eclogites are common recording P-T conditions >1.8 GPa and 750°C for the eclogitic stage [2].

In the underlying Kechros Complex lenses of kyanite eclogites in orthogneisses with Permian ages of their gabbroic protoliths [3] and of common eclogites within metapelites associated with serpentinized peridotites occur.

The mineral assemblage of the kyanite eclogites is Grt + Omp(Jd_{35-55}) + Ky + Tr + Hbl + Zo/Czo + Phg + Qtz + Rt. Garnet shows growth zoning with core composition $Grs_{0.19}Prp_{0.15}Alm_{0.63}Sps_{0.03}$ and rim composition $Grs_{0.20}Prp_{0.27}Alm_{0.52}Sps_{0.01}$. Inclusions in garnet are abundant; they are clinozoisite, kyanite, omphacite (Jd_{45-55}), quartz, actinolite, hornblende and very rare albite and paragonite. Matrix omphacite is in textural equilibrium with kyanite, but commonly it is replaced by Ca-amphibole. A decrease in jadeite component from the core to the rim indicates a re-equilibration tendency during exhumation. Temperatures of 550-600°C and minimum pressure of 1.5 GPa are obtained with Grt-Cpx geothermometry and the jadeite component (Jd_{55}) in omphacite. However, the coexistence of matrix omphacite with kyanite constrains the minimum pressure to 2.1 GPa assuming H_2O activity equal to unity.

In the common eclogites the HP mineral assemblage is Grt + Omp + Rt ± Phg ± Czo ± Gln + Hbl ± Mrg ± Pg. Garnet shows compositional zoning with $Grs_{0.32}Prp_{0.03}Alm_{0.51}Sps_{0.14}$ in the core and $Grs_{0.26}Prp_{0.09}Alm_{0.65}Sps_{0.01}$ at the rim. It contains inclusions of glaucophane, actinolite, clinozoisite, paragonite, oligoclase/albite, omphacite (Jd_{29-41}), titanite and rutile. Glaucophane is present only as inclusions in garnet, omphacite and hornblende and paragonite as inclusions in garnet and hornblende. The paragonite component in margarite ranges from 30-37%. Temperatures of 500-530°C and minimum pressure of 1.4 GPa are obtained with Grt-Cpx geothermometry and the jadeite component in omphacite (Jd_{40}). Maximum pressure is constrained below 2.2 GPa by the presence of margarite and paragonite and the absence of kyanite. In retrogressed samples Ca-amphibole replaces garnet and omphacite. Anorthite-rich plagioclase (An_{55-95}) is formed replacing margarite+zoisite+quartz indicating isothermal decompression from the maximum pressure down to 0.7 GPa.

Ages for the HP metamorphism in the Kechros Complex are not available. A Rb-Sr white mica age of 37 Ma from an orthogneiss records probably a stage of exhumation. The HP event may occurred at the same time with the Eocene HP metamorphism (49-55 Ma) recorded in the Nestos Shear Zone (NSZ) in Central Rhodope [3,4]. The NSZ comprises lithologies of the overlying Sidironero Complex and the underlying Albite-Gneiss Series; the latter represents the westward continuation of the Kechros Complex.

Chemical zonation in Ca-amphibole from the Jubrique unit (Betic Cordillera, Spain), and metamorphic *P-T*-t path

Ruiz Cruz, M.D.
Facultad de Ciencias, Malaga University, Málaga, Spain (mdruiz@uma.es)

Zoned Ca-amphibole from metaclastic rocks and veins of the Jubrique area (Alpujárride complex, Betic Cordillera, Spain), and its significance on the metamorphic evolution of these rocks are described for first time. Typical Al-rich metapelites from this area show assemblages consisting of dominant white mica (muscovite and paragonite) and chlorite, with sporadic biotite, kyanite, and chloritoid. Nevertheless, in some Ca-richer phyllites, fine-grained quartzites, and quartz-rich veins, amphibole crystallized with plagioclase and K-feldspar, epidote, titanite, chlorite and quartz. Two main types of amphibole have been identified: Ca-amphibole, the most frequent, and Fe-Mg-amphibole (calcian cummngtonite). Ca-amphibole appears as intergrowths of dominant radial grains and as euhedral crystals. Ca-amphibole displays zonation with actinolite or Si-rich hornblende cores, overgrown by magnesiohornblende (and edenite) and minor tschermakite, indicating growth at increasing metamorphic physical conditions. Retrogressive rims are variably developed in the several lythotypes (Fig. 1 left).

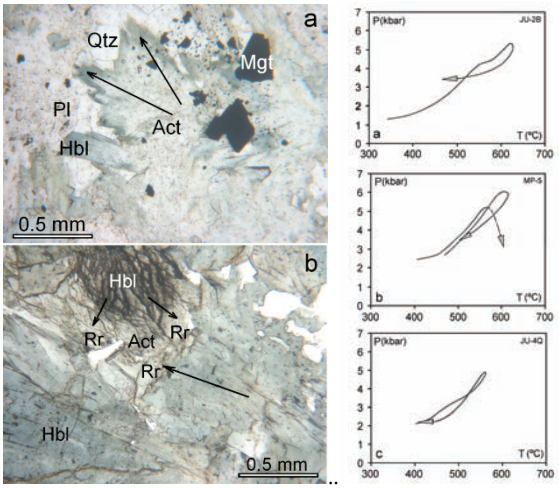

Fig. 1: Left - a) Radial amphibole from quartz-vein with an actinolite core and a narrow rim of hornblende. b) Sub-euhedral dark amphibole from quartzite showing an inverse zonation from hornblende to actinolite. Rr: retrogressive rims. Arrows mark some of the analyzed profiles. **Right** - General *P-T* trends defined by zoned amphiboles from quartz-rich veins (a), phyllites (b) and quartzites (c).

General zonation is well described in terms of the tschermak, the edenite and the $Fe^{3+}Al_{-1}$ and $MgFe^{2+}_{-1}$ exchanges. The Al-in-amphibole thermobarometer [1] provides a range of temperatures between 350ºC and 620ºC (Fig. 1 right), for a pressure range from 0.9 to 6.2 kbar, respectively. Amphiboles define a prograde pressure-temperature path from low pressure-low temperature to medium pressure-medium temperature, typical of Barrovian-type metamorphism.

Pumpellyite-bearing assemblages in metapelites and veins from the Federico Units (Internal Zone of the Rif): their application to reconstructing the metamorphic history

Ruiz Cruz, M.D.[1*], Sanz de Galdeano, C.[2], Alvarez-Valero, A.[2], Rodríguez Ruiz, M.D.[1] & Novak, J.[3]

[1]Facultad de Ciencias, Malaga University, Málaga, Spain ([*]mdruiz@uma.es)

[2]Instituto Andaluz de Ciencias de la Tierra, Facultad de Ciencias, CSIC-Universidad de Granada, Granada, Spain

[3]Institute of Geology, Academy of Sciences CR, Prague, Czech Republic

Pumpellyite has been found for the first time in phyllites and synfolial veins of Permo-Triassic units from the Beni Mezala 1 unit (Federico units, Internal Zone of the Rif belt). Two main assemblages were identified in different microdomains: 1) pumpellyite-actinolite-epidote (Fig. 1a & 2) pumpellyite-muscovite-epidote (Fig. 1b). Epidote is Fe-rich; actinolite contains very low Na_2O and Al_2O_3; and white mica has mean Si content of 3.13 *apfu*, all these characteristics being typical of low-*P* conditions.

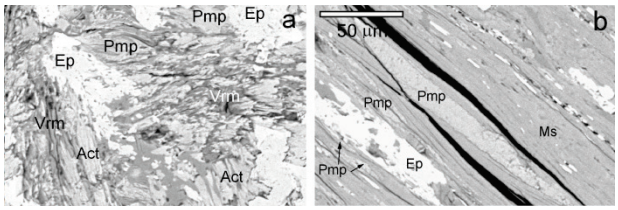

Fig. 1: Back-scattered images of the assemblages pumpellyite-actinolite-epidote (a) and pumpellyite-muscovite-epidote (b).

Assemblages in pumpellyite-bearing rocks indicate *P*≅2 kbar and *T*≅250ºC, in agreement with the estimates deduced from white mica and chlorite from the enclosing phyllites. Nevertheless, peak conditions reached c. 400ºC–5 kbar, as indicated the presence of kyanite-bearing veins (Fig. 2).

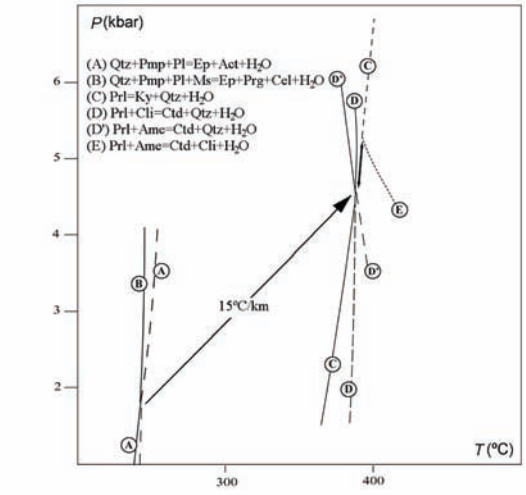

Fig. 2: Schematic *P-T* diagram showing the calculated metamorphic conditions in pumpellyite- and kyanite-bearing parageneses.

The deduced geothermal gradient (15ºC/km) is characteristic of collisional geotectonic settings but the mineral assemblages indicate low-to medium grade metamorphic conditions, which contrasts with previous H*P* estimates.

Acknowledgements: This study has received financial support from the Project CGL 2006-02481 (Ministerio de Educación y Ciencia) and from the Research Group RNM-199 (Junta de Andalucía).

Jadeitites and the subduction factory: progress and questions

Harlow, G.E.[1*] & Sorensen, S.S.[2]
[1]Dept. of Earth & Planetary Sciences, American Museum of Natural History, New York, NY, USA ([*]gharlow@amnh.org)
[2]Dept. of Mineral Sciences, Smithsonian Institution, Washington, DC, USA

Jadeitites are rocks composed principally of jadeitic pyroxene found in serpentinite mélanges with HP/LT tectonic inclusions such as blueschists and eclogites. In recent years it has been increasingly accepted that jadeitites are the product of dehydration fluid interactions in the subduction channel at the boundary or into the hydrating mantle wedge. Lack of protolithic remnants and veinous crystallization textures argue for primary crystallization from the channel fluid. However, some occurrences document encapsulation of eclogite fragments (West Sayan, Syros) by jadeitite or relics of feldspar replacement and inherited zircon (particularly at Mie, Japan) incorporated in jadeitite, indicating a true metasomatic origin. Possibly a spectrum exists between these end members with varying populations in different sources. Mineral assemblages provide poor constraint on crystallization conditions, so presence or absence of quartz has been used with the Jd + Qtz = Ab reaction to constrain *P* and zoisite/lawsonite/pumpellyite (if present) to constrain *T*, yielding brackets from 300-~500ºC and 6 – 20? kbar. However, coexisting Jd-Omph can yield both higher and lower *T* than other assemblages indicate.

Compositions of jadeitite and component minerals indicate large enrichments in the most fluid-mobile elements (Cs, Tl, Rb, Ba, K, Pb, Sn, Li), moderate enrichments of U, Th, Be and LREE and little to no enrichment of HFSE and HREE [1]. Particularly Li concentrations and isotopes argue for jadeitite crystallizing from fluid derived from altered oceanic crust with perhaps 5-15% sediment; variation among different jadeitite point to variation of material entering the subduction zone. Jadeitites appear to record well the transport of trace elements travelling from subduction channel to arc volcanism, now the focus is on light and volatile such as N (as NH_4), Li, S, C, and probably B for which research progress has barely started. The hottest topic in jadeitite research is the origin and dating of zircon. Good arguments for both inheritance (high Th/U ratios, mineral inclusions, zoning) and for primary crystallization from a fluid (low Th/U, mineral and fluid inclusions, zoning), with the latter demanding greater fluid transport of "immobile" elements than expected. The limited number of dates from zircons that are interpreted as crystallized in jadeitite show ages greater than those of related lithologies (e.g., eclogite) by 10-20 Ma with a considerable range. This difference or asynchronism may reflect the growth of jadeitite veins and bodies in the static mantle wedge (or oscillating fragments in the channel) prior to collision and exhumation that metamorphosed downgoing oceanic fragments record.

Jadeitites clearly contain an important record of fluid transport from the subduction channel into the overlying mantle wedge that should help develop a fuller understanding of the subduction factory.

Understanding of the mineralogy of jadeitites: natural and theoretical studies from a new occurrence of blue jade (Sorkhan area, Iran)

Bousquet, R.[1*], Oberhänsli, R.[1] & Moazzen, M.[2]
[1]Institut für Erd- und Umweltwissenschaften, Universität Potsdam, Germany ([*]bousquet@geo.uni-potsdam.de)
[2]Dept. of Geology, University of Tabriz, Iran

The beauty and wide-ranging expression of jade have held a special attraction for mankind for thou- sands of years. Jade is, strictly speaking, a generic term for two different types of rocks, nephrite or jadeitite, dominated either by amphibole or jadeite, respectively. Nephrites range mainly from medium to dark green or grey-green, but can also be white, yellowish or reddish. Rarer, somewhat harder, and therefore regarded as more precious, jadeitites display hues that include green, but also white or pink, and red, black, brown, violet, lavender and blue. In both rock types, the way the color is distributed varies considerably

Jadeitites, and especially blue jadeitites, are rather uncommon rocks. Generally, they are associated with subduction- related serpentinites along fault zones [1] and generally interpreted as crystallizing from hydrous fluids derived from dehydration of subducted slabs at high P and T [2]. Truly blue and lavender jadeitites are reported from only a few localities around the world. Among the most renowned occurrences, some contain only one clinopyroxene (pure jadeite) as the Olmec blue jade (Quebrada Seca, Guatemala), the blue jade from Ohmi–Kotaki in Japan or the lavender jadeitite from Tavsanli in Western Anatolia, Turkey. Others as the green and bluish jadeites from Burma contain two clinopyroxenes (jadeite and omphacite).

We report here a new locality of clear, sky-blue jadeitite occurring near Sorkhan, in a blueschist belt of southeastern Iran. Jadeitite occur in a vein system along a serpentinite – magnesite contact. The veins are composed of almost pure jadeite, 90 to 99.5 mol.% Jd, contain minor amounts of Ba-bearing K-feldspar, lawsonite and katophoritic amphibole.

The jadeitite veins formed at HP-LT conditions, around 1.6 GPa and 420°C. Thermodynamic studies show that the mineral assemblage within the blue jade is strongly pressure- and temperature-dependent. Jadeitites containing two clinopyroxenes (jadeite and omphacite) are stable at high pressure (0.8 GPa) and low temperature ($\leq$430°C) conditions, whereas blue jade with only one clinopyroxene (jadeite) forms at higher temperature or lower pressure. On the basis of these new calculations, P–T conditions of formation are re-examined for all occurrences of blue jade. From this study, we discuss the composition and the stability of one-and two-pyroxene-bearing jadeitites

Jadeitite, omphacite rocks, and albitite as a metasomatic series in a serpentinite melange from the Nishisonogi metamorphic rocks, western Kyushu, Japan

Nishiyama, T.[1*], Shigeno, M.[2] & Mori, Y.[2]
[1]Dept. of Earth & Environmental Sciences, Kumamoto University, Kumamoto, Japan ([*]tadao@sci.kumamoto-u.ac.jp)
[2]Kitakyushu Museum of Natural History and Human History, Kitakyushu, Japan

This contribution presents an overall view of peculiar metasomatic rocks such as jadeitite, omphacite rocks, and albitite which occur as tectonic blocks in a serpentinite melange from the Nishisonogi metamorphic rocks, epidote-blueschist subfacies metamorphic rocks of Cretaceous in age, western Kyushu, Japan. Companion works (Shigeno et al. and Mori et al.) will discuss further details of fluid – rock interaction and mass transfer, and relict igneous zircon in jadeitite as an indicator of the protolith, respectively. There are two localities of jadeitite in this region, Tone and Mie, both of which belong to the same serpentinite melange.

Tone jadeitite [1] is almost a monomineralic rock with small amounts of albite, analcime, muscovite, phlogopite, paragonite, clinozoisite and titanite. Jadeite includes a lot of quartz in its core, of which volume fraction is very close to that produced by the albite breakdown reaction. Thus Tone jadeitite strongly suggests a solid-state transformation from an albite-rich rock. The protolith is estimated to be a plagiogranite by REE pattern of the relict zircon (Mori et al.). The *P-T* condition is estimated to be about 1.5 GPa and 500°C. Mie jadeitite [2] consists mainly of jadeite rimmed by omphacite with small amounts of albite, epidote, muscovite and paragonite. Jadeite rarely includes quartz. Omphacite-bearing metagabbro and monomineralic omphacite rocks also occur in Mie [3]. Such omphacite-bearing rocks consist mainly of omphacite, albite, epidote and actinolite in various amounts. Albite includes a lot of tiny omphacite crystals. Quartz is rarely but jadeite is never found in the rocks. We recognize two metasomatic series, prograde and retrograde series, in these rocks. Various amounts of omphacite in metagabbroic rocks may suggest a series of metasomatic formation of omphacite-bearing rocks from omphacite-poor rocks to nearly monomineralic omphacite rocks, leading to final formation of jadeitite. Retrograde series is represented by zoned omphacite rocks. Some omphacite rocks are enclosed in an albitite with an actinolite-rich selvage between them, which grows towards the omphacite rocks. It clearly shows a metasomatic replacement of the omphacite rocks by albitite during the retrograde stage. Further evidence of the retrograde metasomatic series comes from a zoned jadeitite with the following zonation: jadeitite core, omphacite-albitite, epidote-albitite and the outermost metagabbro (actinolite-albitite). Isocon analysis based on bulk compositions of each zone combined with SVD (singular value decomposition) analysis using mineral compositions show the following characteristics in the metasomatic reactions. SiO_2, Na_2O and K_2O are removed from the jadeitite towards serpentinite, whereas CaO and MgO come from serpentinite to the jadeitite, if the immobility of Al_2O_3 is assumed. Formation of albitite by the process clearly shows that the retrograde metasomatism occurred in the albite stability field. Thus the complicated textures and structures recorded in jadeitite, omphacite rocks and albitite from the Nishisonogi metamorphic rocks are products of prograde and retrograde metasomatic reactions.

Ba minerals in jadeitites and related rocks: implications for Ba recycling in subduction zones

Shi, G.H.[1*] & Cui, W.Y.[2]
[1]China University of Geosciences, Beijing, China ([*]shiguanghai@263.net.cn)
[2]School of Earth and Space Sciences, Peking University, Beijing, China

Sediment recycling at destructive plate margins is one of the most important issues in the scientific debate on the genesis of arc magmas [1-5]. Recently, attention has been paid to the Ba flux and Ba minerals in high pressure and low temperature (HP/LT) rocks at shallower depth [6-8], for example, in jadeitites [9-11]. Thus, the problem of barium might be better addressed in jadeitites and linked to the international discussion.

Jadeitite is found in serpentinites associated with high-pressure rocks such as eclogite and blueschist and regarded as a marker of subduction zones [9,12-15], occurring at < 15 locations worldwide [4,13,16,17]. Barium minerals identified in clinopyroxene rocks from the Myanmar jadeitite area include celsian, hyalophane, and hydrated barium aluminum silicate (HBAS). The hyalophane and HBAS occur as interstitial phases and sometimes crosscut jadeite crystals. The celsian has two modes of occurrence: i) in association with jadeite in jadeitite; ii) as a single-phase mineral forming part of multi-phase pseudomorphs in chromian omphacite rock (omphacitite). The latter rock type was formed predominantly during the same episode as the jadeitite. The pseudomorphs, with hexagonal form mostly, contain celsian and kaolinite, with or without quartz, graphite and diaspore. The P-T condition constraints on celsian suggest that a precursor phase, probably cymrite, once existed and decomposited into celsian under decreasing pressure [18].

Barium minerals have also been reported at various jadeitite localities [9,10,19,20], appearing that all the well-documented jadeitite localities have Ba silicates. The frequent occurrence of Ba silicates in jadeitites worldwide reflects a Ba-enriched environment for the formation of jadeitite. Therefore, the jadeitite records metasomatism and metamorphism, as well as fluid interactions and phase changes in the BaO-Al_2O_3-SiO_2-H_2O system. Taken together with previous results [21-24], we further suggest that jadeite-forming fluids are derived from the dehydration of the altered oceanic slab containing deep-sea sediments.

"Jadeitites" of the Escambray Massif, Central Cuba: an evaluation

Maresch, W.V.[1*], Grevel, C.[1,2], Stanek, K.P.[3], Schertl, H.-P.[1] & Carpenter, M.[4]
[1]Institute of Geology, Mineralogy and Geophysics, Ruhr-University Bochum, Germany ([*]walter.maresch@rub.de)
[2]TÜV Rheinland, Cologne, Germany
[3]Institute of Geology, TU Bergakademie Freiberg, Germany
[4]Dept. of Earth Sciences, University of Cambridge, UK

Millán & Somin [1] reported petrographic descriptions of jadeitite as pebbles, cobbles and boulders in isolated fluvial deposits of the Escambray highlands, Cuba. It has been suggested [2] that this is a first but "overlooked" report of jadeitite in Cuba. Although access to the localities is now difficult, we emphasize here that analytical data on samples from these occurrences conforming to the original petrographic descriptions have been available [3-5] for some time.

These macroscopically featureless, massive, dense, grey-green rocks are jadeite-bearing metagabbros of basaltic bulk composition with a "spilite fingerprint" (49 - 54wt% SiO_2; 1 - 1.3wt% TiO_2, ~15wt% Al_2O_3, 8 - 10wt% FeOtot, 6 - 8wt% MgO, 4 - 9wt% CaO, 4 - 6.5wt% Na_2O). Relics of magmatic augite preserving an ophitic texture are common. Completely recrystallized rocks are homogeneous, fine, felty intergrowths of predominantly pale glaucophane and jadeite, the latter with rims and patches of omphacite. Late development of Ca-amphibole, chlorite, epidote and albite is observed. Samples with large (up to 1.5mm) grains of augite show several types of sodic clinopyroxene development, which are well-documented by hot-cathode CL-microscopy. 1) Topotactic replacement of magmatic pyroxene by jadeite and some omphacite. This type of jadeite shows no optical CL. 2) A jadeite + omphacite + pumpellyite + chlorite assemblage dominates in the rock matrix. 3) Jadeite + omphacite + pumpellyite intergrowths occur as lamellae enclosed within and in sharp contact with augite (no diffusion profiles are observed), whereby lamellae and augite clearly mimic an original ophitic texture. 4) Jadeite + omphacite + chlorite assemblages, in which monomineralic jadeite aggregates can occur, fill very thin (500 - 1000 µm) fractures criss-crossing the sample at ~ 2 cm spacing (including type 3 "ophitic augite grains"). CL in types 2 and 3 is similar. Type 4 CL is clearly different; these jadeite grains show features indicative of crystallization from fluid. In all cases omphacite develops irregularly along jadeite rims; however, both may also show straight grain boundaries suggestive of phase equilibration. Late phases are albite, taramite, epidote and additional chlorite.

This unusual occurrence of jadeite in a metabasic rock suggests two contrasting sources. The first, in the rock matrix, is most easily explained as due to local domain equilibration in a rapidly subducted "spilitized" basic rock. The second, in fracture fillings, conforms to an origin as a crystallization product from a pervasive fluid [e.g. 6]. Conceivably, "pooling" of the fluids flowing through the fractures in larger cavities could lead to larger masses of jadeitite. These have not yet been documented in the Escambray Massif.

Jadeitite from the Monviso meta-ophiolite, western Alps: occurrence and genesis

Compagnoni, R.[*], Rolfo, F. & Castelli, D.
Dept. of Mineralogical and Petrological Sciences, University of Torino, Italy ([*]roberto.compagnoni@unito.it)

Fine-grained massive jadeitites were known long since by archaeologists because all over western Europe some Neolithic ceremonial stone axes are made of this rock type. However, although at the end of 19th century some alpine geologists suggested that the only possible primary source area should have been the Monviso in the western Alps [1], only recently the first in place occurrence has been reported from this area [2,3]. A further search in the same area allowed a dozen of other jadeitite outcrops to be found, all of them in the westernmost part of the Monviso Basal Serpentinite Unit (cf. [4]), which forms a sheet, a few hundred meters thick, exposed between Val Varaita and Valle Po at the contact with a peculiar banded "smaragditic" (Cr-omphacite bearing) metagabbro. This sheet of sheared antigorite serpentinite, which is characterized by the presence of rounded blocks of different lithologies, including eclogite, metagabbro, omphacitite and jadeitites, has been interpreted as a serpentinite mélange.

The studied jadeitites are fine-grained and typically consist of zoned jadeite and tiny zircons, together with local minor amounts of phlogopite, garnet, Mg-chlorite, allanite, rutile, local retrograde albite, and quartz. A rounded boudin, a few dm across, resulted especially interesting to infer the jadeitite genesis. The boudin consists of a quartz+jadeite+accessory zircon core and a quartz+accessory zircon rim, with gradual transition from core to rim. Both boudin core and rim have been chemically analysed. The core composition matches well with that of a plagiogranite, i.e. the extreme differentiation product of a basaltic magma. Metamorphic plagiogranites of similar composition, interpreted as late-magmatic dikes, have been recently reported from a metamorphic plagiogranite - FeTi-oxide gabbro association exposed in the southern Basal Serpentinite Unit on the northern side of Val Varaita [5], not far from the locations of the jadeitite boudins. Therefore, on the base of geologic, petrologic, and geochemical evidence, it is concluded that the Monviso jadeitite is derived from an original plagiogranite, where the igneous quartz has been totally consumed during serpentinization by reactions altering the original peridotite to serpentinite.

[6]Instituto de Geología y Paleontología, La Habana, Cuba

Jadeitite from the subduction mélange of the Sierra del Convento (eastern Cuba) occurs closely associated with albitite, talc, and chlorite rocks and with tectonic blocks of garnet-epidote amphibolite and tonalitic-trondhjemitic epidote gneiss, in a serpentinite matrix. Samples of jadeitite can be classified in two groups according to geochemical and petrographic characteristics. Group A is predominantly composed of jadeite and omphacite with minor to trace amounts of other constituents such as epidote, biotite, albite, sphene and apatite. Group B is impure and mainly consists of jadeite, omphacite, albite and epidote with minor to trace amounts of paragonite, muscovite, sphene and apatite. Textures (including oscillatory zoning) of group A jadeitites show evidence of crystallization from fluids in veins triggered upon episodic infiltration of fluids at >550 ºC. The contents of SiO_2 vary from 58 to 60 wt%, and from 52 to 53.5 wt% in groups A and B, respectively. Group A has lower Al_2O_3, CaO and K_2O contents and higher Na_2O and P_2O_5 contents than group B. In group A, Rb and Ba contents fluctuate between 0.4–1.6 and 7.5–27.7 ppm respectively, being much lower than in group B (1.8–17.5 and 57–764 ppm). Y and Yb contents are slightly higher in group B (<11 and 0.9 ppm, respectively). The higher values of Zr in group A (90 – 180 ppm) compared to group B (<110 ppm) are noteworthy. Both groups display REE abundances similar to those in pegmatites of the Sierra del Convento mélange. These and other geochemical characteristics suggest a genetic link between pegmatitic H_2O-rich melts and jade-forming fluids deep in the subduction channel. The relatively high temperature of formation of jadeitite and the early Cretaceous SHRIMP zircon 206Pb/238U ages of 105-110 Ma from jadeitite, probably corresponding to the isobaric (at ca. 15 kbar) cooling stage of trondhjemitic liquids of the mélange, strengthen this view. We suggest that two types of pegmatite-derived fluids were involved in the formation of jadeitite jade rocks: a fluid rich in K, Ba, and Rb with a strong sedimentary component evolved from K-rich pegmatites (group B), and a depleted fluid with a strong mantle component evolved from K-poor pegmatites (group A), as indicated by Rb/Sr and Sm/Nd isotopes. This new occurrence of jadeite in Cuba opens important perspectives for archaeological studies of pre-Columbian jade artifacts in the Caribbean region.

Geochemistry of Guatemalan HP-LT rocks: jadeitites as proxies for the shallow subduction fluid?

Simons, K.K.[1*], Harlow, G.E.[2] & Sorensen, S.S.[3]
[1]RSMAS, University of Miami, FL, USA
([*]ksimons@rsmas.miami.edu)
[2]American Museum of Natural History, NY, USA
[3]Smithsonian Museum, Washington D.C., USA

High-pressure, low-temperature (HP-LT) rocks occur as tectonic blocks in slivers of serpentinite mélange within and adjacent to the Motagua fault zone in central Guatemala. These blocks (lawsonite eclogite, amphibolite, jadeitite, albitite) are thought to represent a Cretaceous age (~120 Ma) subduction complex exhumed during the collision of the Maya and Chortís continental blocks. Jadeitite and albitite occur as veins and blocks, and are interpreted to be the crystallization products of subduction fluids at relatively shallow depths (< 400°C @ 0.4-1.4 GPa). The extremely low geothermal gradient (~5°C/km), and abundance of hydrous phases and fluid inclusions in the rocks, indicate that metasomatism was likely achieved via an aqueous fluid.

Trace element patterns for these rocks resemble those of arc lavas, with similarities to global subducted sediment (GLOSS). Jadeitites and eclogites lie to the right of the mantle array, indicating fluids sampled had a seawater and/or sediment component. Modelling of $^{143}Nd/^{144}Nd$, $^{87}Sr/^{86}Sr$ and δ^7Li in jadeitites suggests metasomatism by a fluid with up to 10% sediment component [1]. Trace element patterns are thought to be primarily controlled by 1) mineralogy and 2) element concentrations present in the fluid. For example, lawsonite eclogites have the greatest proportion of phengite for the metabasites, and thus have the highest LILE concentrations. Enrichment of Zr and Hf is controlled by the presence of metasomatic zircon, which is best seen in the jadeitites (Fig. 1). LREE and Th enrichment is controlled by the epidote group minerals. Thus the saturation of specific key minerals controls the trace element patterns for these rocks. Increasing the mobility of HFSE like Zr, Hf and Th in aqueous fluids may be facilitated by high water/rock ratios, increased solubilities and increased concentrations of silica, aluminium and alkalis which can act as polymerizing agents [2]. Together these mechanisms serve to dissolve and transport trace elements out of the slab and into the mantle wedge. Because Guatemalan HP-LT rocks were metasomatized close to the interface between the slab and mantle wedge (jadeitites formed the wedge itself), they provide a unique window into the composition of subduction fluids at depth.

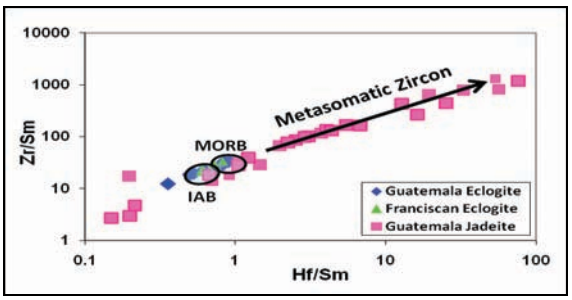

Fig. 1: Enrichments in Zr and Hf relative to Sm demonstrate addition of metasomatic zircon to Guatemalan jadeitites.

Relict igneous zircon in jadeitite from the Nishisonogi metamorphic rocks, Kyushu, Japan: an indicator of protolith characteristics

Mori, Y.[1*], Orihashi, Y.[2], Miyamoto, T.[3], Shimada, K.[3], Shigeno, M.[1], Gouzu, C.[4], Hyodo, H.[5] & Nishiyama, T.[6]
[1]Kitakyushu Museum of Natural History and Human History, Kitakyushu, Japan ([*]mori@kmnh.jp)
[2]Earthquake Research Institute, University of Tokyo, Japan
[3]Dept. of Earth and Planetary Sciences, Kyushu University, Fukuoka, Japan
[4]Hiruzen Inst. for Geology and Chronology, Okayama, Japan
[5]Research Institute of Natural Sciences, Okayama University of Science, Okayama, Japan
[6]Dept. of Earth and Environmental Sciences, Kumamoto University, Kumamoto, Japan

The Nishisonogi metamorphic rocks (Kyushu, Japan) are a Late Cretaceous subduction complex and include jadeitite as tectonic blocks within serpentinite melange. There are two localities of jadeitite, Mie and Tone. The Tone jadeitite consists mainly of jadeite including a lot of quartz inclusions, suggesting a solid-state transformation from an albite-rich protolith [1]. The aim of this study is to reveal the protolith of the Tone jadeitite based on the U-Pb ages and trace element compositions of relict zircon.

The Tone jadeitite contains euhedral zircon grains, both as inclusions in jadeite and as a matrix mineral. The zircon grains are divided into three types: homogeneous zircon, oscillatory zoned zircon and altered zircon. The homogeneous zircon and the core of zoned zircon yield mean U-Pb ages of 126 ± 7 Ma (± SD, n = 64). This age is clearly older than $^{40}Ar/^{39}Ar$ ages of muscovite in the Tone jadeitite (80-90 Ma). The homogeneous zircon and the core of zoned zircon are considered relicts from the protolith. In contrast, the altered zircon and the rim of zoned zircon show a wide range of U-Pb ages (76-116 Ma). The U-Pb ages of these zircons show a positive correlation with Th/U values (Fig. 1). The y-intercept of this correlation at Th/U = 0 indicates a U-Pb age of 80-90 Ma, consistent with the $^{40}Ar/^{39}Ar$ ages of muscovite in the Tone jadeitite. The altered zircon and the rim of zoned zircon may be the products of recrystallization, resulting in the expulsion of Pb and Th from the lattice.

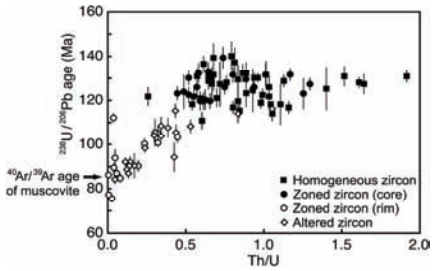

Fig. 1: Relationship between ^{238}U-^{206}Pb ages and Th/U values of zircon grains from the Tone jadeitite. Error bars represent 2SD.

The relict zircons in the Tone jadeitite have high Ti content of 4.89-20.7 ppm, yielding crystallization temperatures of >680°C. These temperatures are higher than the granite solidus and strongly suggest an igneous origin for the relict zircons. The zircon grains contain inclusions of muscovite, biotite, quartz and plagioclase that are likely to have crystallized from melt. The Hf, Y and REE contents of the relict zircons are similar to those of zircon from plagiogranites and indicate light-REE enrichment and no (or minor positive) Eu anomalies in their equilibrium melt. Taken together, the most likely protolith of the Tone jadeitite is plagiogranite with TTG-like REE patterns.

In-situ jadeitite in blueschist country rocks from the Dominican Republic: mode of occurrence and genesis

Schertl, H.-P.[1*], Maresch, W.V.[1], Stanek, K.-P.[2] & Krebs, M.[1]
[1]Institute of Geology, Mineralogy and Geophysics, Ruhr-University Bochum, Germany ([*]ans-peter.schertl@rub.de)
[2]Institute of Geology, TU Bergakademie Freiberg, Germany

The Rio San Juan Complex (RSJC) of the northern Dominican Republic consists of subduction-related mafic schists cut by diapir-like serpentinite mélanges. These mélanges contain blocks of various metamorphic rock types such as blueschist, eclogite, lawsonite blueschist, jadeitite, cymrite-bearing rock, and orthogneiss.

Comprehensive petrological studies demonstrate a broad diversity of PTt-paths which, however, are closely interrelated: In the early stages of development of the subduction zone, the PTt-paths typically are anticlockwise with shallow ("hot") P/T-gradients. Maximum PT-conditions derived from eclogites are 750°C/28 kbar; the related Lu-Hf-age is 103.9 Ma (Grt-Ep-Amp-Omp-WR isochron). Continuous cooling and steepening of the subduction zone PT-gradient is documented by omphacite blueschists, which experienced peak metamorphic conditions of 500-550°C/16-18 kbar at 80.3 Ma (Rb-Sr on Phe-Amp-WR). Jadeite-blueschists typically are constrained to very steep "cold" P/T-gradients; Rb-Sr-ages (Phe-Amp-WR isochrons) of 62.1 Ma date the peak metamorphic conditions of about 380°C/18 kbar.

Although commonly found as allochthonous blocks, some jadeitite occurrences appear unique and critically important in that they are directly associated with lawsonite blueschists. Two main types of contact relationships can be distinguished. In the first the jaedeitite veins are clearly discordant, whereas the second type is characterized by concordant and intimate, gradational interlayering with the surrounding blueschist.

The jadeitites are fine-grained, whitish-green, and contain jadeite as the main constituent; the amount of jadeite may exceed 90 vol.%. Phengite, omphacite, epidote, Na-amphibole, plagioclase, calcite, lawsonite, pumpellyite, stilpnomelane, garnet and quartz can occur in minor amounts. Titanite, zircon, and rutile are accessories. The homogeneous cores of the jadeite crystals reach 98% jadeitite end-member composition; in some cases these are surrounded by very thin omphacitic rims. In general, the jadeite grains contain numerous microinclusions of quartz and lawsonite (especially within the core regions), leading to a cloudy to dirty appearance. Cathodoluminscence (CL) studies contribute to a better understanding of structural characteristics and genetic relationships. The most important result from these studies is the distinctive oscillatory zoning pattern of the jadeite, which is reminiscent of "magmatic" zonation in zircon. Several jadeites were found to be characterized by a patchy olive-green inner core surrounded by a bluish-red oscillatory mantle and an outermost bright-green luminescent oscillatory rim.

The petrographic character of the jadeitites suggests that many are analogous in both mineralogy and fabric to jadeitites described from the serpentinites of the Motagua Fault Zone in Guatemela. In the light of the two clearly different types of jadeitite contact relationships - discordant versus concordant - the possibility of two different origins is discussed: metamorphism of an appropriate pre-metamorphic protolith vs. formation by fluid-driven mass transfer.

Formation of jadeitite in the Nishisonogi metamorphic rocks, Kyushu, Japan: prograde albite-decomposition and retrograde fluid-jadeitite interaction

Shigeno, M.[1*], Mori, Y.[1], Shimada, K.[2] & Nishiyama, T.[3]
[1]Kitakyushu Museum of Natural History and Human History, Kitakyushu, Japan (*sjfmt461@yahoo.co.jp)
[2]Dept. of Earth and Planetary Sciences, Kyushu University, Fukuoka, Japan
[3]Dept. of Earth and Environmental Sciences, Kumamoto University, Kumamoto, Japan

Current models of jadeitite formation include (1) solid-state transformation from protoliths and (2) direct precipitation from fluids [1]. Although both of the processes may represent possible origins for jadeitite, the jadeitite from the Nishisonogi metamorphic rocks (Kyushu, Japan) supports the former model [2].

The Nishisonogi metamorphic rocks are epidote-blueschist subfacies metamorphic rocks and include jadeitite as tectonic blocks within serpentinite melange. There are two localities of jadeitite, Tone and Mie in Nagasaki City. Primary mineral assemblage of these jadeitite is jadeite/omphacite + paragonite + phlogopite + muscovite ± clinozoisite/epidote. Jadeite grains in the Tone jadeitite have cores including a lot of quartz inclusions and clear rims. Volume fraction of the quartz inclusions within the cores is close to that of quartz produced by isochemical decomposition of albite, suggesting solid-state transformation of the jadeitite from an albite-rich protolith.

The Tone and Mie jadeitites are typically surrounded by reaction zones of albitite and muscovite rock. Mineral assemblage of the albitite is albite + clinozoisite/epidote ± muscovite ± omphacite ± phlogopite ± actinolite ± chlorite, and that of the muscovite rock is muscovite + clinozoisite ± chlorite. The reaction zones represent retrograde products, because albite is stable. Clinozoisite and phlogopite in the reaction zones contain large amounts of Sr and Ba, respectively. Isocon analysis indicates that Sr and Ba have been added to the reaction zones during fluid-jadeitite interaction, which is consistent with the mineralogical observation. Clinozoisite grains in the reaction zones have allanitic cores and exhibit skeletal shapes. REE-rich veinlets emanate from such clinozoisite grains, suggesting REE mobility during the fluid-jadeitite interaction.

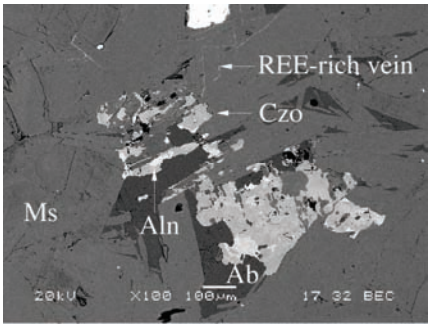

Fig. 1: BSE image from metasomatic reaction zone of Tone jadeitite showing REE mobility during retrograde fluid-jadeitite interaction. Ab, albite; Aln, allanite; Czo, clinozoisite; Ms, muscovite.

Taken together, the jadeitites in the Nishisonogi metamorphic rocks have recorded two stages of formation, prograde albite-decomposition and retrograde fluid-jadeitite interaction.

Genesis of jadeitite: a case study from Guatemala

Yui Tzen-Fu[1*], Maki Kenshi[1], Usuki Tadashi[1], Lan Ching-Ying[1], Martens, U.[2], Wu Chao-Ming[3], Wu Tsai-Way[4] & Liou G. Jung[2]
[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC (*tfyui@earth.sinica.edu.tw)

[3]Dept. of Applied Arts, Fu-jen Catholic University, Hsinchuang, Taiwan, ROC
[4]Dept. of Earth Sciences, University of Western Ontario, London, Ontario, Canada

One Guatemala jadeitite sample was collected from north of the Motagua fault, Guatemala, to examine the possible formation mechanisms/conditions. Zircons were also separated for age dating and REE analysis. The sub- to anhedral crystal form, the lack of typical magmatic oscillatory zoning, the presence of fluid and albite/quartz/jadeite inclusions, and the low Th/U ratios (<0.005) clearly demonstrate that zircons in this particular jadeitite sample would have been precipitated from an aqueous solution. It is concluded that, in addition to "metasomatic replacement", "vein precipitation" is a feasible process for jadeitite formation. The U–Pb concordia intercept age of these zircons is 95.1±3.6 Ma.

Both the whole-rock jadeitite and its zircons have very low REE contents, ~1 ppm and 0.5–42 ppm, respectively. The whole-rock jadeitite shows a flat and slightly concave REE pattern and a positive Eu anomaly (Eu/Eu*=1.24). Zircons are enriched in HREE and their REE patterns can be divided into two groups: one with negative Eu anomaly and one with positive Eu anomaly. The latter tends to have smaller positive Ce anomalies. The fluid from which jadeitite formed probably evolved over time, becoming more reducing and more dominated by plagioclase decomposition reactions. Alternatively, trace element compositions of zircons simply demonstrate complicated variations of fluid chemistry during jadeitite formation.

A reducing fluid with high pH values capable of mobilizing Al, Na, Zr and Hf is inferred to be the media during jadeite/zircon formation. If jadeitites are genetically related to serpentinization of ultramafic rocks, as suggested by the common jadeitite–serpentinite association, then three conditions for jadeitite formation under a proper P–T regime in subduction zones must be fulfilled. (1) The ultramafic rocks, whether partially altered, must contain olivine as the major primary phase subjected to serpentinization. Serpentinization of such ultramafic rocks would produce fluids with geochemical characteristics capable of mobilizing Al, Na, Zr and Hf in precipitating/forming jadeite and zircon. (2) A protolith, such as a tectonic block within ultramafic rocks, is needed to provide Al and Na. The block would have escaped earlier alteration reactions (such as rodingitization) and contains feldspars/micas as its major constituents. And (3) the presence of fluid channels and pulses of fluid supply would be the triggers for jadeitite formation reactions. These prerequisites may at least partly, in addition to the possible tectonic controls, explain the worldwide scarcity of jadeitite occurrences in high-P metamorphic belts.

Mineralogy and petrogenesis of the gem-bearing pegmatites of the Shigar valley, Skardu, Northern Pakistan

Agheem, M.H.[1*], Shah, M.T.[2] & Khan, T.[3]
[1]Centre For Pure and Applied Geology, University of Sindh, Jamshoro, Pakistan ([*]mhagheem@yahoo.com)
[2]National Centre of Excellence in Geology, University of Peshawar, Pakistan
[3]Advanced Geosciences Research Laboratories, GSP, Pakistan

Shigar valley is located about 32 km north of Skardu, the head quarter of the Baltistan, and is the gateway for most of the expeditions to the K-2 in the northern areas of Pakistan. This valley has the plenty of pegmatite intrusions, hosting the various types of gemstones, which are being excavated by the local miners for aquamarine, goshenite, topaz, tourmaline and fluorite etc. These gemstones, especially aquamarine, are now marketed internationally.

These pegmatites were mapped and sampled during two field seasons for the sack of their mineralogy, internal structure, and petrogenesis. The field and various analytical techniques have revealed that these pegmatites are not only diverse in their mineralogy, classification, internal structure but on the basis of present data their petrogenetic linkage is also in ambiguity. On the basis of field features and petrographic studies, these pegmatites have been classified into two types as: (1) simple and (2) complex or zoned pegmatites. These pegmatites have further been classified into four sub-classes on the basis of presence or absence of various accessory minerals and gemstones.

Petrogenetic studies of the Shigar valley pegmatites have been carried out on the basis of major, trace and rare earth elements chemistry. These studies suggest that these pegmatites are the separate magmatic pulses generated probably from the metapelites of the Karakoram Metamorphic Complex (KMC) along the axis of the active thrust fault known as the Main Karakoram Thrust (MKT). Although, other post-collisional plutonic units of the Karakoram Batholith such as the Baltoro Plutonic Unit and the Mango Gusar Unit are exposed in the vicinity of the Shigar valley but the aerial extent, field features, and the geochemical data suggest that these pegmatites have no correlation with the off shoots of above-mentioned plutonic units. These pegmatites are of collisional tectonic settings and have been formed after the collision of Indian plate with the Eurasian plate.

Mineralogy and petrography of phosphate minerals from pegmatites of the Conselheiro Pena district, Minas Gerais, Brazil

Baijot, M.[1*], Hatert, F.[1] & Philippo, S.[2]
[1]Laboratory of Mineralogy, University of Liège, Belgium ([*]mbaijot@student.ulg.ac.be)
[2]Section of Mineralogy, National Museum of Natural History of Luxembourg

In Brazil occurs one of the most important pegmatite provinces in the world, the Eastern Brazilian Pegmatite Province (EBPP). This province is located at the Eastern side of the Saõ Francisco craton, mainly in the state of Minas Gerais, as well as the states of Bahia, Espírito Santo and Rio de Janeiro. The Conselheiro Pena district forms part of the EBPP where two intrusions crosscut the basement rocks and its cover: the Galiléia and Urucum magmatic suites which belong to the G1 and G2 supersuites, respectively. In September 2008, we visited several pegmatites located in the Conselheiro Pena district, between Galiléia and Mendes Pimentel, in order to investigate the petrography of phosphate minerals and their relationships with associated silicates. All the pegmatites intrude the garnet-, biotite-, and sillimanite-bearing schists of the São Tomé Formation (Rio Doce group, Late Proterozoïc). Preliminary results obtained from this study will be presented in this paper and allow to better characterize the chemistry and petrography of phosphates and to elaborate the genetic sequence of these minerals.

Phosphate minerals form nodular masses which can reach 2 meters in diameter. Two kinds of phosphate associations occur:

I) Masses showing dendritic or/and skeletic textures involving feldspar and several secondary phosphate minerals.

II) Fresh massive triphylite only altered by vivianite, which give its bluish colour to the phosphate.

Petrographic observations, X-ray diffraction measurements, and electron-microprobe analyses were performed on the phosphates, to confirm their identification, calculate their unit-cell parameters and to characterize their chemistry. The only primary phosphate mineral is triphylite, $Li(Fe^{2+},Mn^{2+})PO_4$, which progressively oxidizes to ferrisicklerite, $Li_{<1}(Fe^{3+},Mn^{2+})PO_4$, and heterosite, $(Fe^{3+},Mn^{3+})PO_4$, following the so-called "Quensel-Mason" sequence. In association I, ferrisicklerite is frequently replaced by several secondary phosphates like barbosalite, tavorite, hureaulite, cyrilovite, leucophosphite, phosphosiderite, minerals of the jahnsite group and minerals of the rockbridgeite-frondelite series. In association II, triphylite is directly replaced by vivianite along cleavage planes. A similar genetic sequence is generally observed in pegmatites of the Conselheiro Pena district, except in the northern part where brazilianite-bearing pegmatites occur. In this area, qingheiite-(Fe^{2+}) (IMA 2009-076), $Na_2Fe^{2+}MgAl(PO_4)_3$, has been described and is produced by reaction between triphylite and albite.

Even if triphylite is the only primary phosphate mineral, it shows interesting chemical variations within the district, with $Fe_{tot}/(Fe_{tot}+Mn)$ ranging from 0.56 to 0.74, and $Fe_{tot}/(Fe_{tot}+Mg)$ ranging from 0.83 to 1.00. A correlation between the chemical composition and the unit-cell parameters of triphylite-type phosphates will also be discussed, with an emphasis on the incorporation of Mg into triphylite from Sapucaia.

Fluid and melt inclusion: windows to hidden pegmatite-forming processes

Thomas, R.[1*] & Davidson, P.[2]
[1]GeoForschungsZentrum Potsdam, Germany
([*]thomas@gfz-potsdam.de)
[2]ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Australia

For more than 260 years pegmatites have fascinated scientists, amateur mineralogists and artists by their beauty and diversity of minerals, their extraordinary paragenesis and often very strong enrichment of rare elements. We should also remember the thorny path of the discovery of the rare-earth elements, starting in summer of 1787 with the find of an unknown, heavy and black mineral by the Swedish army lieutenant Carl Arrhenius, a student of Berzelius, in an abandoned quarry near Ytterby on the skerry island Resarö in NE of Stockholm. For the REE's journey's end was reached in 1945 by the American chemists Jacob Marinsky, Lawrence Glendenin, and Charles Coryell with the isolation of promethium. The list of pegmatite minerals which have had a profound influence on science is extensive. Here we only review the minerals tantalite and zircon from pegmatites. They were the godparents for the elements Nb, Ta, Zr and Hf. As an example, element number 72 was predicted by Niels Bohr, who advised György von Heversy and Dirk Coster to search for this element in zircon from Norway. They found traces of this element by its characteristic X-ray emission lines in January 1923 in Copenhagen. About 40 years later the mineral hafnon with 72.5 % (g/g) HfO_2 was found in a pegmatite.

The last mentioned element, mostly at low concentration camouflaged in Zr minerals brings us to a central problem of explanation: how is it possible to explain the "inverse" element arrangement in the mineral hafnon, where Hf is the main element and Zr is present only in traces? To understand the appearance of such "abnormal" element enrichment – hafnon is only one example of many, we have to understand much more about the pegmatite-forming media and processes working in nature.

We can not stop with such statements as "Melt solutions in which water is plentiful as an essential volatile component besides large amounts of non-volatile components are called pegmatitic solutions" [1], we have to more accurately constrain the answer based on real facts, directly derived from nature.

An important tool in this intricate task has been developed within the last 150 years, although often simply ignored or underestimated: Fluid and melt inclusions in minerals as media for the deciphering of mineral-forming processes, first on the temperature and pressure and then on the compositions of the long-gone fluids that were actively involved in many environments [2].

Using fluid and melt inclusions is not a simple tool, it requires insight into the processes of trapping, as well as those which modify an inclusion post-trapping, such as recrystallization.

In this presentation we will show important steps in the solution to fundamental questions regarding the pegmatite-forming media and processes, including water concentration in real melts, melt-melt immiscibility, main and trace element distribution in different phases, extreme enrichment of boron and its consequences, and the suggestion that the gel stage may play an important part in pegmatite formation, especially during the formation of the quartz core.

Anomalous, LCT-type, Ta enrichment in NYF-type pegmatites of the Nine Mile pluton in the Wausau syenite complex, Marathon County, Wisconsin, USA

Falster, A.U.[1*], Simmons, W.B.[1] & Buchholz, T.W.[2]
[1]Dept. of Earth and Environmental Sciences, University of New Orleans, LA, USA ([*]afalster@uno.edu)
[2]1140 12th Street North, Wisconsin Rapids, Wisconsin, USA

The anorogenic, NYF-type, Wausau syenite complex is located in central Marathon Co., Wisconsin. The Proterozoic (ca. 1.5 Ga) complex consists of 4 intrusive centers, from oldest and most alkalic to youngest and most silicic: Stettin complex, Wausau pluton, Rib Mountain pluton, and the Nine Mile pluton. The Nine Mile pluton is the best exposed of the 4 intrusives, a result of extensive mining of weathered rocks (grus) for road metal and landscaping. Numerous pegmatite bodies exist throughout the complex. The pegmatites are of modest size, rarely reaching 100 m in maximum dimension. Pegmatites are well-zoned with distinctive wall zones, intermediate zones and core zones. Replacement units (usually albite) occur in some. The mineralogy of the pegmatites is rich in REE-bearing species such as monazite-group minerals, xenotime, bastnaesite-group species and numerous pyrochlore-group minerals. Be minerals occur sporadically, and B minerals are essentially absent, whereas F is widespread as fluorite and other F-bearing minerals. In late-stage primary and secondary miarolitic cavities (left by dissolution of pre-existing quartz or fluorite), a highly-evolved mineral association is seen consisting of tantalite-(Mn), microlite, tantalian rutile, tantalian cassiterite, and tapiolite. In some non-miarolitic pegmatites, Ta-rich minerals (tantalite-(Mn), microlite, tanteuxenite-(Y)) occur embedded in feldspar and quartz mainly along the inner intermediate zone and core margin. Typically, the Ta/Nb ratio steadily increases from the core of the crystals toward the rim, such that significant Ta-dominance is achieved. Sometimes, Ta-rich microlite forms as a late overgrowth on and/or replacement of columbite-group minerals. Zircons found in this assemblage also reflect a similarly high enrichment trend expressed as very low Zr/Hf ratios. The abundance of fluorite suggests that F complexing is the controlling mechanism causing the late enrichment of Ta which produced a late-stage mineral association similar to that seen in highly evolved LCT-type pegmatites.

Geochemical evolution of K-feldspar and muscovite in the pegmatitic field of Giraúl, Namibe (Angola)

Gonçalves, A.O.[1*], Melgarejo, J.C.[2], Alfonso, P.[3], Paniagua, A.[4], Yusta, I.[5] & Velasco, F.[5]
[1]Dept. de Geologia, Universidade Agostinho Neto, Luanda, Angola ([*]tonyolympio72@hotmail.com)
[2]Dept. de Cristal·lografia, Mineralogia, Dipòsits Minerals, Universidad de Barcelona, Spain
[3]Dept. d'Enginyeria Minera i Recursos Minerales, Universidad Politècnica de Catalunya, Manresa, Spain
[4]Dept. de Ciencias de la Tierra, Universidad de Zaragoza, Spain
[5]Dept. Mineralogía y Petrología, Universidad del Pais Vasco, Spain

Diverse pegmatite types crop out in the pegmatitic field of Giraúl (Namibe, Angola). These pegmatites are, from less to more evolved: type I (barren, intrabatholitic and grading to the leucogranite host), type II (barren, peribatholitic); type III (beryl-columbite); type IV (beryl-columbite-phosphate); type V (spodumene).

Two main trends of geochemical fractionation are distinguished in K-feldspar and muscovite: at field scale and at the pegmatite body scale.

At the scale of pegmatitic field, the K/Rb ratio in microcline decreases from type I to type V pegmatites, which have up to 7100 ppm Rb. Cs (2 to 2000 ppm), Ga (7 to 22 ppm), Sn (0.1 to 29 ppm). The P content (450 to 6150 ppm) tends to increase progressively from the more primitive pegmatites to the most evolved ones. Ba, Sr and Pb have opposite evolution trends.

Similar trends are found in muscovite. The next variations are appreciated from type I to V: Rb (263 to 8700 ppm), Li (51 to 4340 ppm), Cs (7.6 to 2000 ppm), Zn (50 to 760), Ga (28 to 183 ppm), Sn (5 to 822 ppm), P (70 to 990 ppm), Nb (33 to 364 ppm), Ta (6 to 170 ppm); inverse correlations are found in Ba (384 to 2 ppm) and Pb (6.4 to 1.3 ppm).

Similar enrichment trends, although not so important, are appreciated in these minerals when comparing their compositions at the scale of the different units of a single pegmatite body. In these cases, fractionation increases from the early-formed zones (border, first and second intermediate zones) to the late replacement units (albite bodies and quartz-muscovite veins).

The concentration of LILE and HFSE elements in the muscovite structure increases at the same time that minerals of these elements start to develop, which suggests that muscovite might have remained saturated in these elements in some stages of crystallization of the pegmatites. Hence, in the late stages of crystallisation of the most evolved pegmatites Cs- and Li-rich muscovite coexists with pollucite, nanpingite, a Cs-rich mica, and with spodumene.

In the same way, the concentration of LILE, HFSE and other incompatible elements increases gradually with the evolution of the pegmatites of the Giraúl field, from the types I and the II (geochemically very similar) up to the types IV and V. This fact suggests that all the pegmatites of the field have a common origin and are linked by a process of magmatic fractionation from the parental leucogranites.

The concentrations of some elements, such as Rb and Cs in muscovite, approach to the economic levels in the most evolved pegmatites, though these values are found only in some of the internal units.

Mn-rich yellow tourmaline: conditions of formation and implications for pegmatite petrogenesis

Simmons, W.B.[1*], Falster, A.U.[1] & Laurs, B.M.[2]
[1]Dept. of Earth and Environmental Sciences, University of New Orleans, LA, USA ([*]wsimmons@uno.edu)
[2]*Gems & Gemology*, Gemological Institute of America (GIA), Carlsbad, CA, USA

Mineralogically, yellow tourmaline is dominantly Mn-rich elbaite and "fluor-elbaite" although very rare yellow rossmanite and "fluor-rossmanite are known. Yellow tourmaline samples from pegmatites (or alluvial deposits inferred to be from pegmatites) in Zambia, Mozambique, Congo, Madagascar, Russia, Nepal, and the United States were analyzed. The composition of these tourmalines from all locations is remarkably similar. Most are elbaite with very low Fe and Mg and with elevated Mn and Ti. A few yellow samples from Mozambique are rossmanite or "fluor-rossmanite". Overall, MnO ranges from 1.50 to 8.90 wt.%, FeO contents are very low (<0.03 wt.%) and TiO_2 contents range from 0.1 to 0.7 wt.%. The yellow coloration is due to Mn^{2+}-Ti^{4+} intervalence charge transfer interaction [1]. Thus, both Mn and Ti are essential for the formation of yellow tourmaline. Analyses reveal that small increases in Fe darken these tourmalines toward brownish colors. The substitution scheme is confirmed to be $2Mn^{+2} = Li^{+1}+Al^{+3}$.

Yellow tourmaline is quite rare because most pegmatites that contain sufficient B to produce tourmaline also contain significant Fe during tourmaline crystallization and most tourmaline-producing pegmatites with low Fe contents don't contain elevated levels of Mn or sufficient Ti. Commonly, in evolved LCT-type pegmatites, Mn is associated with high Li and is incorporated into Li-micas and Li-Mn-phosphates, making the late-stage melts relatively depleted in Mn. Tourmaline forming from these melts will be the more typical colorless, pink, blue or green elbaite, which generally contain less than 2 wt.% MnO. A peraluminous pegmatite melt high in B will preferentially crystallize tourmaline rather than biotite or garnet. Thus, high-B will impede the formation of spessartine and biotite that would remove Mn from the melt. A common sink for Ti is biotite, and with high B contents preventing its formation during the early stages of pegmatite crystallization, Ti will be available to be incorporated into late-stage, low-Fe tourmaline.

Tourmaline is a sensitive recorder of the changing chemical conditions during late-stage crystallization. In pegmatite pockets with color-zoned tourmaline crystals, the chemical conditions of low Fe, high Mn and elevated Ti are achieved only during part of the crystallization history of tourmaline growth, during yellow tourmaline growth. Most zoned crystals in this study were Fe-rich (schorlitic) initially, and as Fe was depleted, the compositions became Mn enriched allowing the formation of yellow zones in the crystal. Subsequently, Mn and Ti typically became somewhat depleted, producing colorless or pink tourmaline or, as is often the case, there was a slight enrichment of Fe giving rise to darker yellow-green to green or blue terminations or rims.

Experimental crystallization of Li-B-pegmatites

Sirbescu, M.[1*], Wilke, M.[2], Veksler, I.[2] & Whittington, A.[3]
[1]Dept. of Geology, Central Michigan University, Mt. Pleasant, MI, USA ([*]sirbe1mc@cmich.edu)
[2]GeoForschungsZentrum, Potsdam Germany
[3]Dept. of Geological Sciences, University of Missouri, Columbia, MO, USA

Textural features of pegmatites are thought to be a consequence of the interplay between crystal nucleation and growth rates under conditions of undercooling, which are strongly influenced by water [1,2]. To better understand pegmatite texture in relation to the degree of undercooling and water concentration, we performed dynamic experiments of nucleation and crystallization of synthetic hydrous haplogranite with added 1% Li_2O + 2.3% B_2O_3 (composition C1) and 2% Li_2O + 4.6% B_2O_3 (C2). Time-series isothermal or programmed-cooling runs (from 1 to 30 days) were performed at temperatures ranging from 400 to 700°C at 300 MPa coresponding to variable degrees of undercooling between liquidus and glass transition. Viscosity data at 1 atm indicate that the glass transition of both melts containing 6.5 wt. % is just under 300°C. Moderately fluxed, hydrous melts are sluggish to nucleate. Both melts remained virtually crystal free at 400°C, about 100°C above glass transition, in 14 day-long experiments. At 500° C the incubation times were between 5 and 9 days for C1 and <5 days for C2. The maximum growth rates of ~250 μm/day were produced in composition C2 at 550°C. Reproducible mineral assemblages of alkali-feldspars, muscovite, stuffed β-quartz, petalite, and virgilite nucleated heterogeneously on the capsule wall and crystallized inward. C1 textures resembled fine grained, layered, and graphic outer zones of Li-rich pegmatites (Fig. 1). Hydrous C2 compositions (around or above fluid saturation) had low nucleation density and best resembled the coarse fabric found in highly fractionated inner zones of Li-rich pegmatites.

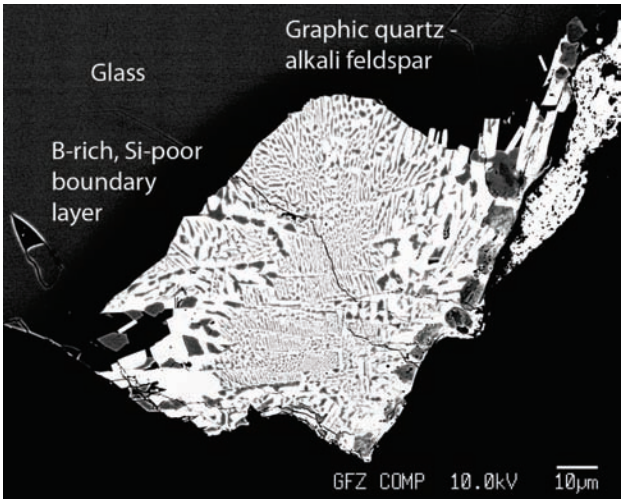

Fig. 1: Graphic intergrowth in composition C1 + 6.6 wt% H_2O, 9 days, programmed-cooling between 750 and 500°C, at 300 MPa.

Water concentrations of several wt. % below saturation lead to extremely high nucleation density, incompatible with typical coarse pegmatitic texture. Within a single charge, local water supersaturation lead to pegmatite texture by reducing nucleation and increasing crystal growth. Gradual textural coarsening by a factor of 3 was observed in areas surrounding large fluid cavities formed in a 200 MPa run similar to textures near "pockets" in shallower myarolitic pegmatites.

Production of large crystals in highly undercooled H_2O-rich granite melts

Nabelek, P.I.[1*], Whittington, A.G.[1] & Sirbescu, M.C.[2]
[1]Dept. of Geological Sciences, University of Missouri, Columbia, MO, USA ([*]nabelekp@missouri.edu)
[2]Dept. of Geology, Central Michigan University, Mount Pleasant, MI, USA

Granite pegmatites in the continental crust are characterized by large elongated crystals that often exhibit preferred directions of growth. There has been a shift in viewing pegmatites as products of very slow cooling of granite melts to viewing them as products of crystal growth in undercooled liquids, mostly because thermal considerations require rapid cooling of intrusive sheets. With this change there has been a renewed debate about the role of H_2O in the petrogenesis of pegmatites. On the basis of data on nucleation of minerals and new viscosity models for hydrous granite melts, it is argued that H_2O is an essential component in the petrogenesis of granite pegmatites. H_2O is key to reducing the viscosity of silicate melts, which enhances their transport within the crust. It also dramatically reduces the glass transition temperature, which permits crystallization of melts at hundreds of degrees below the equilibrium solidus. Crystallization of melts below the thermodynamic solidus is demonstrated by trapped fluid and melt inclusions and other features. Recent experimental data show that because H_2O drastically reduces the nucleation rates of silicate minerals, the minerals may not be able to nucleate until the melt is substantially undercooled. In a cooling melt sheet, nucleation starts at its highly undercooled margins, followed by inward crystal growth towards its slower-cooling, hotter core. Delay in nucleation may be caused by competition for crystallization by several minerals in the near-eutectic melts and by the very different structures of minerals and highly hydrated melts. Once a mineral nucleates, however, it may grow rapidly to a size that is determined by the distance between the site of nucleation and the point in the magma at which the temperature is approximately that of the mineral's liquidus, assuming components necessary for mineral growth are available along the growth path. The unidirectional textures and internal zoning that typify many pegmatites are determined by internal temperature gradients.

In contrast to rhyolites that degas prior to or during eruptions, granite pegmatites are apparently able to retain H_2O during most of their crystallization histories within the confinement of their wall rocks. Without retention of H_2O the conditions for pegmatitic textural growth may be difficult to achieve. Loss of H_2O due to decompression and venting leads to microcrystalline texture and potentially to glass during rapid cooling as seen in rhyolites. In contrast, slow cooling within a large magma chamber promotes continuous exsolution of H_2O from crystallizing magma, growth of equant crystals, and final solidification at the thermodynamic solidus. These are the characteristics of normal granites that distinguish them from pegmatites.

Evaluation of the use of fracture minerals for exploration for rare-metal pegmatites

Linnen, R.L.[1*], Galeschuk, C.[1], Halden, N.M.[2] & Lau, L.[1]
[1]Dept. of Earth and Environmental Sciences, University of Waterloo, Canada ([*]rlinnen@uwaterloo.ca)
[2]Dept. of Geological Sciences, University of Manitoba, Canada

Whole rock analyses of Li, Rb and Cs are used to locate hidden rare-metal pegmatite bodies. However, Li-bearing minerals may occur along fractures and cause false positive anomalies. The Dibs pegmatite was selected as a site to evaluate exploration methods because it is a completely buried LCT pegmatite in the Bernic Lake area, near the famous Tanco pegmatite in south eastern Manitoba. In this study, fracture minerals in metabasite around the Dibs pegmatite were analysed and compared to matrix mineral chemistry (both by LA-ICP-MS) and whole rock lithogeochemical data (total digestion ICP).

All three data sets show a progressive dispersion of Li and away from the pegmatite-metabasite contact. There are also less well developed Rb and Cs dispersion halos defined by whole rock and biotite analyses. At the upper pegmatite contact the metabasite contains up to 2954 ppm Li, 176 ppm Rb and 65 ppm Cs, but these values decrease to 28, 17 and 5 ppm, respectively, at a distance of 60 m above the pegmatite. Of the matrix minerals biotite contains the highest concentrations of Li, Rb and Cs. These range from 3264, 1406 and 753 ppm, respectively, at the contact to 150, 212 and 37 ppm, respectively, 60 m above the pegmatite. However it is fracture chlorite that may best reflect dispersion around the Dibs pegmatite. At the pegmatite contact Li values are similar to lithogeochemical and biotite values, at 1000-2000 ppm, but, at 45m above the pegmatite contact fracture chlorite contains approximately 300 ppm Li, which is an order of magnitude higher than whole rock values and 2 to 3 times the values in biotite. Consequently fracture chlorite is demonstrates promise as a recorder of fluid flow around pegmatites and as an exploration tool for rare metal pegmatites.

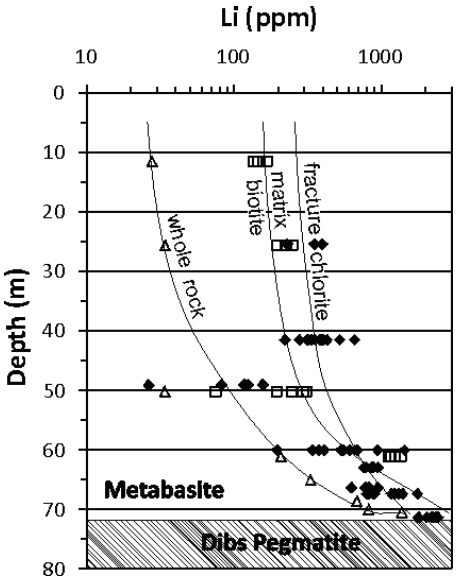

Fig. 1: Dispersion around the Dibs pegmatite. Open triangles represent whole rock lithogeochemistry, open square are matrix biotite and solid diamonds are fracture chlorite analyses.

The role of pegmatites in the Central Alps. Proxies of the exhumation history of the Alpine nappe stack in the Lepontine dome

Guastoni, A.[*], Artioli, G. & Pennacchioni, G.
Dept of Geoscience, University of Padova, Italy
([*]alessandro.guastoni@unipd.it)

The area of this study is located between the town of Domodossola (Western-Central Alps, Italy-Swiss) and the Masino-Bregaglia Oligocene intrusion (Central Alps, Italy). Most of the pegmatitic dikes are hosted by the Southern Steep Belt (SSB), an alpine migmatitic unit, which includes several Lepontine nappes like the Antigorio, the Monte Rosa, the Camughera-Moncucco-Isorno-Orselina and the Adula. Alpine metamorphism in Central Alps is poliphasic and characterized by high temperature greenschist and amphibolitic facies related to Barrovian metamorphism during Oligocene-Miocene age. Barrovian metamorphism is structurally related to D3 phase of backfolding of Alpine nappes in the Central Alps and it forms an asymmetric dome structure named Thermal Lepontine Dome characterized by metamorphic isograds which discordantly crosscut the Pennidic nappes [1-4]. The age determinations of a limited number of aplite-pegmatites dikes injections into the Isorno-Orselina and Monte Rosa nappes on monazite-(Ce) $^{206}Pb/^{238}U$-$^{207}Pb/^{235}U$, xenotime-(Y) $^{206}Pb/^{238}U$-$^{207}Pb/^{235}U$ and zircon $^{206}Pb/^{238}U$-$^{207}Pb/^{235}U$ are between 29-26 m.y [5].

Preliminary field studies based on textural, mineralogical observations and structural relationships of pegmatitic dikes with the hosting rocks which outcrop in the Central Alps allow them to be assigned to different families and classes as reported in the classification of Ćerný & Ercit [6]. Most of pegmatitic dikes (>90%) can be defined as "barren" being composed by K-feldspar and subordinate quartz + muscovite. A minor percentage can be assigned to a population of more "geochemically evolved" pegmatites respectively belonging to the two main LCT (lithium, cesium, tantalum) and NYF (niobium, yttrium, fluorine) families.

The changing from greenschists to amphibolites metamorphic grade in the Central Alps involves a main changing with depth in the fragile/ductile rheology of crustal rocks thrusted during the formation of the Lepontine Alps. Along SSB ductile deformations of pegmatites in amphibolitic facies are overprinted by fragile deformations in greenschists facies. Future studies will focus on:

- isotopic studies to establish relationships between pegmatites and host rocks to define age of crystallizations and rate of coolings of deformed and miarolitic pegmatites, the latter have not been affected by metamorphic overprinting;
- geochemical studies in order to establish whether the pegmatitic field of the Central Alps is genetically related to migmatites terrains of the Alpine Barrovian-type metamorphic belt [3] or related to granitic-tonalitic liquid melts of Masino-Bregaglia intrusion.

The rare elements-rich granitic body of Outeiro Mine (Northern Portugal)

Lima, A.[1,2*], Rodrigues, R.[1], Guedes A.[1,2] & Novák, M.[3]
[1]Centre of Geology, University of Porto, Portugal
([*]allima@fc.up.pt)
[2]Dept. of Geosciences, Environment & Territory Management - FCUP, Porto, Portugal
[3]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic

In Outeiro open-pit (Seixoso area) outcrops a granitic cupola that have been mined in the last decade for the ceramic industry. This structure belongs to the so-called Seixoso-Vieiros pegmatite field that is located in Northern Portugal and contains numerous pegmatite-aplite veins and rare element-rich granites. This field was known in the past for old mining of cassiterite and columbite-tantalite at least from the last century [1]. In Seixoso area the granitic intrusion outcrops as two main apices (Seixoso body and Outeiro body) and numerous, small apices or dike-like bodies. Seixoso and Outeiro granitic bodies are very heterogeneous and characterized by a horizontal magmatic layering, which was accentuated by post-magmatic pervasive albitization and greisenization, this latter being more intensive upwards. They evolved from a biotite-bearing facies at depth, through two-mica or muscovite tourmaline facies into the apex roof. Apical facies (apogranites) are highly evolved and locally (Seixoso granite) poorly mineralized in cassiterite. Biotite bearing facies, apogranites of Seixoso granite or Outeiro granite and the most evolved Seixoso pegmatites are considered to be members of a single differentiation series [2] characterized by a sodalithic-type evolution - a decrease in Si and K is accompanied by increase in Al, Na, Li, F (P, Sn, Ta, Nb, Be). During recent mining the lithium-bearing minerals, such as amblygonite-montebrasite, spodumene, petalite, cookeite became more abundant, although most of them in accessory quantity. They appear together with beryl, chrysoberyl, tourmaline, sekaninaite, eosphorite-childrenite, Th,U-rich monazite-(Y) (9.11 wt.% ThO_2; 7.57 wt.% UO_2), xenotime-(Ce), pretulite, zircon, Nb,Ta,Ti,Sn-oxide minerals - highly heterogeneous niobian rutile (≤3.38 wt.% SnO_2; ≤29.35 wt.% Ta_2O_5; ≤24.14 wt. % Nb_2O_5), Ti,Nb,Ta enriched cassiterite (≤3.67 wt.% TiO_2; ≤2.34 wt.% Ta_2O_5; ≤1.51 wt.% Nb_2O_5), Ti-enriched ferrocolumbite (≤1.66 wt.% TiO_2), ilmenite and ferronigerite and zincnigerite both Ti-enriched (≤5.31 wt.% TiO_2) [3]. This mineral assemblage typically matches the complex petalite or spodumene subtype pegmatites [4]. [5] referred for Seixoso surrounding mined pegmatite-aplite veins, an analogous and extensive list of minerals where also found lepidolite, zinwaldite and topaz.

Age and mineralogy of supergene uranium and manganese minerals - tools to unravel the supergene alteration in pegmatitic and granitic terrains (Bohemian Massif, SE Germany)

Dill, H.G.[1*], Gerdes, A.[2], Hansen, B.[3], Weber, B.[4] & Keck, E.[5]
[1]Bundesanstalt für Geowissenschaften und Rohstoffe, Hannover, Germany ([*]dill@bgr.de)
[2]J.W.Goethe University, Frankfurt, Germany
[3]Georg-August University, Göttingen, Germany
[4]Weiden i.d.OPf., Germany
[5]Etzenricht, Germany

Uranyl phosphates (torbernite, autunite, uranocircite, saleeite) and hydrated uranyl silicates (normal and beta-uranophane) as well as K-bearing manganiferous oxide-hydroxides met at various erosion levels and structures in the Late Variscan granites and pegmatites at the western edge of the Bohemian Massif, Germany, were the target of mineralogical investigations and age dating, using conventional K/Ar methods and more advanced techniques such as Laser-Ablation-Inductive-Coupled-Plasma Mass Spectrometry (LA-ICP-MS). Supergene U minerals have an edge over other rock-forming minerals, because of their inherent “clock” and their swift response to chemical and physical environmental changes on different scales. The azonal duricrusts, involving uraniferous phoscretes and silcretes, can be used to characterize the alkalinity/ acidity of meteoric/ *per descensum* fluids and to constrain the redox conditions during geomorphic processes. Moreover, uraniferous calcretes bearing uranyl vanadates are marker rocks for arid climatic conditions and for a desert depositional environment. This study aimed at deciphering the geomorphological and paleohydraulic history which granitic rocks of the Central European Variscides (Moldanubian and Saxothuringian zones) went through during the Neogene and Quaternary in the foreland of the rising Alpine mobile fold belt. The study provides an amendment to the current subdivision of the regolith by introducing the term “hydraulith” (percolation and infiltration zones) for the supergene alteration zone in granitic terrains. It undercuts the regolith at the brink of the phreatic to vadose hydraulic zones. Based upon the present geomorphological and mineralogical studies a four-stage model is proposed for the evolution of the landscape in a granitic terrain which might also be applicable to other regions of the Saxothuringian and Moldanubian zones of the European Variscides. Stage I (U mineralization in the infiltration zone) is a mirror image of the relic granitic landscape with high-altitude divides and alluvial-fluvial terraces. Its characteristic features are preserved in the uplifted hinterland of a peneplain which is tilted towards a lacustrine basin (or the sea). Stage II (U mineralization in the infiltration zone, regolith and saprock) includes planation and exhumation, resultant in the exposure of inselbergs and quartz reefs in front of the hinterland (stage I). Stages III and IV (U mineralization in percolation zone and saprock) are controlled by the base level lowering in the foreland. Rapid incision caused pinnacle-like tors and large first-order granitic land forms to form, whereas a slow-down of fluvial incision favors its destruction and the development of weathering pits of different kinds. A full blown cycle of planation and incision lasted for approx. 10 Ma, a stage which covers planation and exhumation, resulting in the formation of domal structures lasted for a period of time of as much as 2 Ma. Climate is an important factor but the most crucial factors for the geomorphological processes shaping the granitic landscape in the study area are uplift and erosion. The study area is located within the stress field of an ancient Variscan craton (Mesoeurope) and a highly mobile Alpine fold belt (Neoeurope).

The Na-rich phosphate minerals from Malpensata granitic pegmatite, Piona, Lecco province, Italy

Vignola, P.[1*], Hatert, F.[2], Fransolet, A.-M.[2] & Diella, V.[1]
[1]CNR-Institute for Dynamics of Environmental Processes, Milan, Italy ([*]pietro.vignola@idpa.cnr.it)
[2]Dept. of Geology, University of Liège, Belgium

The Malpensata pegmatitic dike occurs intruded into the high-grade metapelites of the Dervio-Olgiasca Zone (crystalline basement of the Southern Alps). In the field, the Malpensata dike displays an asymmetrical zoned structure composed of different units: 1) a wall zone; 2) an intermediate zone composed of medium-grained white albite and layers of medium grained black tourmaline + garnet + muscovite; 3) a main zone of blocky albite unit (megacryst plagioclase zone) with quartz + tourmaline + garnet graphic textures and many accessory phases as Li-Fe-Mn phosphates, oxides of Nb-Ta-Sn, zircon, uraninite, and many secondary uranium bearing minerals; 4) a roof zone composed of coarse white albite + quartz + muscovite. Masses of phosphates up to 25 cm in diameter were found in the intermediate zone and, mainly, in the blocky albite unit.

Careful investigations of thin sections, EMP chemical analysis and X-ray powder diffraction resulted in the identification of two different phosphates assemblages:

I) Graftonite + sarcopside + triphylite which characterizes the intermediate zone and the marginal part of the blocky albite unit; ferrisicklerite, heterosite, and vivianite are the main secondary phosphates.

II) Graftonite + triphylite + ferrowyllieite + arrojadite + a Na-rich iron phosphate (still under investigation) + sarcopside only observed in the central part of the blocky albite unit; ferrisicklerite, heterosite, Mn-rich vivianite, jahnsite-(CaMnFe), jahnsite-(CaMnMn), metaswitzerite, fairfieldite, rockbridgeite, and mitridatite(?) are the main secondary phosphates.

The usual assemblage I is very simple and Na-free: It is associated with poorly evolved accessory minerals like uraninite, zircon, ferrocolumbite and Th-rich monazite-(Ce). Assemblage II is more complex and particularly rich in Na-bearing phosphates as indicated by the presence of abundant ferrowyllieite, arrojadite, and of this interesting Na-rich iron phosphate. These phosphates are in very close association with highly evolved accessory phases like cassiterite, Sn-bearing zircon, ferrotantalite, ferrotapiolite and three different types of microlite, representing enrichment in Na and U. A Na-free microlite and one with a low Na-content form octahedrons showing an oscillatory zoning, whereas Na- and U-bearing microlite form fracture-fillings. These chemical features of microlite indicate a low temperature of crystallization [2]. We can infer that the primary phosphates belonging to association II crystallized together with the Sn-Ta-Nb-U mineral assemblage at a lower temperature in respect to phosphate association I formed from a fractionated melt strongly enriched in P. As proposed by London et al. [3], the high concentration of P allows the destabilization of albite that we can consider as the sources of Na and Al.

Paragenetic evolution of Be minerals (silicates and phosphates) from the Nanping No. 31 pegmatite dyke, SE China

Wang RuCheng[*], Rao Can, Zhang WenLan & Wu JinWei
School of Earth Sciences and Engineering, Nanjing University, Nanjing, China ([*]rcwang@nju.edu.cn)

The No. 31 dyke is the most evolved one in the Nanping pegmatite district in southeastern China. It is strongly mineralized in rare elements with crystallizations of cassiterite, columbite-tantalite, microlite, wodginite, spodumene, amblogonite, beryl, pollucite, etc. [1].

Beryllium minerals in the Nanping No. 31 pegmatite dyke exhibit complex parageneses of silicates and phosphates, including beryl, phenakite, herderite, hurlbutite and euclase. Moreover, they show distinct paragenetic features in different internal zones of the pegmatite dyke. In the quartz – albite – muscovite zone (zone I) are found small beryl crystals with fine inclusions of phenakite. These Be silicates are all included in quartz or garnet, or interstitial to albite. Occasionally, vein-like beryl occurs along muscovite cleavages. Be minerals are likely very complex in the saccharoidal albite ± muscovite zone (zone II). Although discrete beryl interstitial to saccharoidal albite can be observed, Be minerals are dominated by beryllosilicate + berryllophosphate + apatite assemblages as cavity-filling among rock-forming minerals, suggestive of a P-saturated environment of crystallization. Large crystals of beryl appear in the quartz – coarse albite – spodumene zone (zone III) and quartz – spodumene – amblygonite zone (zone IV), and chemically are rich in Cs. They exhibit considerably late-generation hydrothermal alteration. Secondary beryl is depleted in Cs, but Cs-dominated muscovite (nanpingite) is closely associated with it.

The study suggests that crystallization of beryllium minerals in the Nanping No. 31 pegmatite dyke followed changes in magma conditions, considerably controlled by P activities on one hand, and by hydrothermal fluids in the late stage on the other.

Alteration process of a graftonite + sarcopside + triphylite primary phosphate association from Luna pegmatitic dike, Lecco province, Italy

Vignola, P.[1*], Fransolet, A.-M.[2], Diella, V.[1] & Ferrari, E.S.[3]
[1]CNR-Istitute for Dynamics of Environmental Processes, Milan, Italy ([*]pietro.vignola@idpa.cnr.it)
[2]Dept. of Geology, University of Liège, Belgium
[3]Dept. of Earth Sciences, University of Milan, Italy

The mineral assemblage graftonite + sarcopside + triphylite is quite common in phosphate-bearing granitic pegmatites. In contrast to triphylite, graftonite and sarcopside are generally known to be resistant to alteration processes which characterize the crystallization/cooling history of pegmatitic dikes. Brian Mason [1] is the only author who described the alteration of graftonite as an oxidation of Fe^{2+} to Fe^{3+} accompanied by Ca leaching and progressive hydration with a constant Fe/Mn ratio. Nothing is reported in literature about alteration of sarcopside.

In the context of our investigation on phosphate associations of Piona granitic pegmatites, particularly in the Luna dike, phosphate masses consisting of sarcopside lamellae embedded in graftonite with minor triphylite, showing a well-developed alteration rims, have been found. Striking textures observed in thin sections indicate that graftonite + sarcopside underwent an alteration process similar to triphylite (Fig. 1).

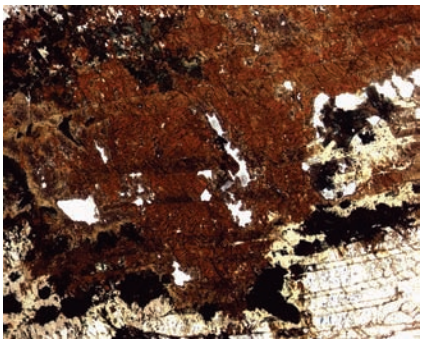

Fig. 1: Replacement of graftonite and sarcopside by brown kryzhanovskite, yellow jahnsite-(CaMnFe) and green-brown rockbridgeite; field of view 3 mm (plane polarized light).

Textural observations, electron microprobe chemical analyses and X-ray diffraction powder method enabled the identification of different alteration products exhibiting complex alteration mechanisms described herein in different steps. The first step, corresponding to the well-known hydrothermal alteration of triphylite, is marked by a progressive lithium leaching and Fe - Mn oxidation to form ferrisicklerite, and heterosite. The second step, involving sarcopside, graftonite, and the alteration products of triphylite, is characterized by a progressive hydration with Ca/Mg leaching in oxidizing conditions with the almost complete preservation of the lamellar texture. This transformation produced two distinct parageneses constituted by phosphoferrite + ferrostrunzite, and by jahnsite-(CaMnFe) + rockbridgeite + lipscombite. In a later alteration stage the auto-oxidation process transformed phosphoferrite-like mineral in kryzanovskite, ferrostrunzite in whitmoreite, and produced a totally oxidized rockbridgeite. It must be pointed out that kryzhanovskite displays two different chemical compositions reflecting those of the primary graftonite and sarcopside, and results as their alteration product.

Genesis, chemical composition and mineral speciation of tourmalines from the rare-element pegmatite vein with scapolite (Sangilen Highland, Tuva)

Kuznetsova, L.G.[1*], Zolotarev, A.A.[2], Frank-Kamenetskaya, O.V.[2], Rozhdestvenskaya, I.V.[2], Bronzova, Yu.M.[2], Spratt, J.[3] & Ertl, A.[4]
[1]Vinogradov Institute of Geochemistry SB RAS, Irkutsk, Russia ([*]lkuzn@igc.irk.ru)
[2]St. Petersburg State University, St. Petersburg, Russia
[3]Museum of Natural History, London, UK
[4]Institute of Mineralogy and Crystallography, University of Vienna, Austria

Chemical composition and substitution mechanisms of tourmalines with high contents of Ca, Li, Mg, Fe (Li-rich uvites), rarely occurring in granite pegmatites, were examined. They occur in the rare-element pegmatite vein with scapolite in the Solbelder river basin, Sangilen Highland [1]. Petrological study of tourmaline-bearing pegmatite rocks gave the evidence of their magmatic origin in specific P-T environments [2]. Refinement of the crystal structures of these tourmalines was done to determine which mineral species they belong to [3,4].

Most of rare-element granite pegmatites of Solbelder field belong to spodumene type and have typical mineral composition. Some of them are embedded in limestones but have no strong signs of *in situ* contamination. Only one pegmatite vein demonstrates contamination to a particularly high degree. Tourmalines, described in this paper, crystallized in this vein in association with K-feldspar, scapolite (with 73 mol.% Me), quartz, spodumene, pyrochlore, cassiterite and zircon.

Yellow tourmaline from the central zone of the vein has a constant composition, which can be described as a solid solution of 3 components:

(1) $Ca(Mg_2Li)Al_6(Si_6O_{18})(BO_3)_3(OH)_3F$,
(2) $CaMg_3Al_6(Si_6O_{18})(BO_3)_3(OH)_3O$,
(3) $NaMg_3Al_6(Si_6O_{18})(BO_3)_3(OH)_3F$.

Component (1) is dominant and exceeds 50 mol.%, thus yellow tourmaline may be considered as a new mineral species in the tourmaline group.

Zoned grains of tourmaline with a yellow core and green rims from the border zone of the vein reflect strong changes in the chemical regime of pegmatite crystallization. The main changes of their composition from the core to the rim - decrease of Mg and increase of Li, Al, and Fe. Substitution mechanisms are: $Mg^{2+} \leftarrow Fe^{2+}$; $2Mg^{2+} \leftarrow Li^{+} + Al^{3+}$; $Mg^{2+} + OH^{-} \leftarrow Al^{3+} + O^{2-}$. The composition of the yellow core is the same as in tourmaline grains from the centre of the vein. The composition of green rims can be described as a solid solution of 4 components:

(1) $\square(Al_2Li)Al_6(Si_6O_{18})(BO_3)_3(OH)_3(OH)$,
(2) $NaMg_3Al_6(Si_6O_{18})(BO_3)_3(OH)_3(OH)$,
(3) $NaFe_3Al_6(Si_6O_{18})(BO_3)_3(OH)_3(F)$,
(4) $Ca(Al_{1.5}Li_{1.5})Al_6(Si_6O_{18})(BO_3)_3(OH_2O)(F)$.

The dominant component (4) makes up 62 mol.%, thus, green tourmaline also can be represented as a new mineral species.

A unique composition of the studied tourmalines reflects specific environments in which this pegmatite vein was formed.

Genesis of spodumene pegmatites related to deep-seated faults in the East Sayan belt, Eastern Siberia, Russia

Makagon, V.M.
Institute of Geochemistry SB RAS, Irkutsk, Russia
(vmak@igc.irk.ru)

The East Sayan pegmatite belt, one of largest in the world, is situated in the south of Eastern Siberia (Russia), confined to the southern mobile marginal part of the Siberian craton. Rare-metal type pegmatite deposits are widely distributed in this belt. Formation of rare-metal pegmatites (LCT family) is divided into spodumene and petalite subformations, differing in the initial pressure of the mineral formation, which was 300-500 MPa, and 200-350 MPa, accordingly [1]. Spodumene rare-metal pegmatites are located in the south-eastern part of belt, occurring in the Urik-Iya graben, which is a rift structure of the southern mobile marginal part of the Siberian platform [2]. The age of the granitoids of the Sayan granitoid complex, with which spodumene pegmatites are connected, is determined by Rb-Sr method to be 1817 Ma and spodumene pegmatites were formed 1692 Ma ago. The Urik-Iya graben is limited by zones of deep fractures departing from a regional Main Sayan fault. The biggest Goltsovoye pegmatite field is controlled by zones of deep faults and is divided into western and eastern blocks. Lithium spodumene pegmatites are typical of the western part, while complex Ta-Cs-Li pegmatites occur in eastern block. On P-T diagram of quartz-saturated stability relations among lithium aluminosilicates in the system $LiAlSiO_4$-SiO_2-H_2O [3] lithium and complex pegmatites of Goltsovoye field crystallize in the field of spodumene stability. The initial pressure of crystallization was 450 MPa and then was lowering. Ta-Sn-Li pegmatites of the Belsk field originally crystallized in the field of spodumene stability, then petalite crystallization occurred, afterwards it was replaced by spodumene-2 and in the end by eucryptite.

Available geochemical data and the presence of large rare-metal pegmatite fields without any clear spatial connection with granitoid massifs do not prove the hypothesis of rare-metal pegmatite formation during differentiation of granite magma which formed these granitoid massifs. The relationship between granitoids and pegmatites is paragenetic. According to the data [2], granite magmatism in the Urik-Iya rift structure is caused by the presence of a deep (mantle) diapir, which was the source of both thermal energy, and fluids. They were transported in the zones of deep faults. Large rare-metal pegmatite fields formed due to a long process of pegmatite melt formation in the deep magmatic chambers under the influence of mantle fluids containing significant amount of SiO_2, alkalies and enriched in Rb, Li, Ta, Nb and other lithophile elements. The possibility of such fluid formation was shown in [4]. Small granodiorite and tonalite intrusions were found in the Urik-Iya graben, their geochemical feature is high Ba and Sr contents, on one hand, and increased Li, Cs and Sn contents, on the other hand. This indicates the possibility of enrichment in rare lithophile metals in the early undifferentiated granodiorite melt portions, which is possible due to the influence of such deep fluids.

The Sosedka gem tourmaline mine, Transbaikalia, Russia: the petrogenetic model of B-rich miarolitic pegmatites

Zagorsky, V.Ye.
Institute of Geochemistry, SB RAS, Irkutsk, Russia
(victzag@igc.irk.ru)

The Sosedka mine is the largest source of gem tourmaline in the Malkhan field of B-rich miarolitic pegmatites, which are confined to the roof pendant between the Bolsherechensk and the Oreshny massifs of porphyritic biotite granites and two-mica leucogranites. Both massifs and the pegmatite field adjoin closely the Chikoy deep-seated fault, along which the Chikoy rift depression was formed in the Lower Cretaceous. The age of the granites and pegmatites is Lower Cretaceous as well, so their formation is related to the rifting. A decrease in pressure, caused by crustal extension and uplift of the northern block of the rift, together with heat and fluid flows within the deep-seated fault zone, induced melting processes and formation of the Malkhan granite-pegmatite system [1]. When the granitic magma transformed into a pegmatitic melt the latter was strongly enriched in B, Cs, and to a lesser degree F, Li, Ta. Because of fluid flow-melt interaction pegmatite melts become heterogeneous, especially relative to alkalis and volatiles [2,3]; as a result, quartz-K-feldspar, quartz-oligoclase and quartz-two feldspar pegmatites are closely linked within the Malkhan field.

The Sosedka ovoid-shaped body (80 x 50 m) has a rather concentric zonal structure. The interrupted external zone, 0-20 m wide, is composed of schorl-rich quartz-oligoclase pegmatite of coarse graphic texture with enclaves of quartz-K-feldspar schorl-free pegmatite and rare lenses of petalite-rubellite-lepidolite-albite composition. The central zone consists of quartz-K-feldspar schorl-free pegmatite of graphic and blocky textures with “inclusions” of quartz-oligoclase pegmatite. Both zones contain abundant miaroles, their size reaching 40 m^3. Based on mineral composition, three types of pockets are recognized: 1) quartz-lepidolite-Li tourmaline (± pollucite, beryl, topaz, hambergite, danburite); 2) quartz-adularia-axinite (± laumontite); 3) quartz-laumontite. Type 1 occurs in the external zone only, mainly near contacts with country rocks. Pockets of types 2 and 3 are typical of the central zone; but sometimes they occur in the external zone, near the central one. Independent pockets of different types often lie 0.5-2 m apart. Pockets are filled with loose material to 80-95% of their volume. Such a quantity of silicate material can not be formed in pockets only due to the fluid released from the melt during crystallization of the pegmatite matrix. Boron-rich melt-like gels are considered to be the mineral-forming medium in pockets [4]. Alkalinity increases from type 1 to type 3 pockets. Adularia, axinite and laumontite indicate unfavourable conditions for gem Li-tourmaline formation.

Primary magmatic genesis of the Sosedka pegmatite is undoubted. All geochemical data and the pattern of distribution of pockets and B-Li-rich mineralization within the body can be explained only by a model of chemically heterogeneous pegmatite magma intrusion [2,3]. The Sosedka’s magma portion included three coexisting melts corresponding to quartz-oligoclase, quartz-K-feldspar and quartz-petalite-rubellite-lepidolite-albite pegmatite varieties with numerous bubbles of a B-rich fluid-gel substance (precursors of future pockets). The heterogeneous state of the pegmatite melts was attained at above-liquidus conditions within the magma chamber.

Possible mechanisms for the trace elements concentration during the evolution of volatile-saturated granitoid magmas

Badanina, E.V.[1*], Thomas, R.[2] & Syritso, L.F.[1]
[1]Dept. of Geochemistry, State University of St.-Petersburg, Russia ([*]elena_badanina@mail.ru)
[2]GeoResearchCentre of Potsdam, Germany

For the solution to this problem we have investigated the melt (MI) and fluid (FI) inclusions in quartz, topaz and beryl within the fully differentiated massive of the rare-metal granites of Orlovka, Spokojnoje, Etyka, Sherlovaya Gora (Transbaikalia), Voznesenka (Primorje) and the granite-pegmatite systems of Malkhany (Transbaikalia), Voronji Tundry (Kola Peninsula). These studies showed that the traditional process of fractionation is not the only mechanism of rare element concentration. The process of fractionation (ongonite trend) is recorded simultaneously in the rock and melts only to a certain stage of saturation of "typomorphic" elements - F, B, H2O, and Li, after which the melt system becomes heterogenic. Such a process was followed up by us an example of Orlovka massif of Li-F granites [1], where the melt achieved up to 9.9 wt% H2O, 1.8 wt% F, 2.09 wt% B and 2411 ppm Li. By contrast the residual melt concentration of certain associated elements - Al, Na, Li, F, Nb, Ta, REE are reduced which suggests the probable separation of hydrosaline Na-Al-F melt, which in experimental systems are linked the the concentration of rare elements. Liquid immiscibility in pegmatite systems is illustrated by the example of the Voronji Tundry pegmatites, where the separation of Cs-rich melt leads to the formation of unique quartz-pollucite lens [2]. Calculation of distribution coefficients in the systems of melt-mineral (mica, K-, Na-feldspar, quartz) shows a fundamentally different nature of the Li, Rb, Cs, Ta, Nb, REE, F, B behavior in the process of volatile-saturated magma evolution. Thus, at an early stage Li is greatly enriched in the melt, and then concentrated in the micas (equality content in rocks and melt), at later stages it is readily converted into a fluid phase with the formation of the polylithionite in FI [3]. The distribution coefficient for Rb in melt-mineral system is always in favor of the melt, passive during the processes of immiscibility and serves as ideal indicator of fractionation. Cesium is the most incompatible with the aluminosilicates rare alkali elements, which easy removed from the silicate melt. REE - probably moves with the Na-Al-F melt [4], as confirmed experimentally [5]. The absence of columbite-tantalite saturation of the melt and compositional variations of the zonal columbite-tantalite suggest different mechanism for the Ta and Nb concentration: accessory columbite-Fe at an early stage – from local saturation area; the main ore mineralization of the maximum Mn columbite-tantalite from hydrosaline (?) melts; tantalite-Fe in the FI - from saturated fluor-rich fluid. Distribution coefficients in the fluid-melt system are calculated to assess the role of magmatic-hydrothermal transition.

Origin of the Mn-enriched NYF-type pegmatites in the Searchlight granite-pegmatite-aplite District, Clark Co., Nevada, USA

Webber, K.L.[*], Simmons, W.B., Falster, A.U. & Masau, M.
Dept. of Earth and Environmental Sciences, University of New Orleans, Louisiana, USA ([*]kwebber@uno.edu)

Shallowly emplaced mid-Miocene (8-16 Ma) granites exposed near Searchlight in the Newberry Mountains, Clark Co., Nevada are located in the Colorado River extensional corridor in the Basin and Range Province of the western United States. The granites intrude older Proterozoic basement rocks of the Mohave terrane and subsequently, became exposed along several steeply bounded extensional faults. For this study, Newberry granites were divided into three major suites, the Searchlight, Bat Ears and South Ridge, on the basis of petrographic textures and mineralogy. Granites from all three suites host numerous miarolitic pegmatite bodies. Miarolitic cavities in the pegmatites range from microscopic to meter size and they host an assemblage of well-crystallized mineral species including smoky quartz, microcline, albite, annite (high Mg), spessartine, zircon, thorite, titanite, columbite group species, ilmenite-pyrophanite, magnetite, monazite-(Ce), bastnaesite-(Ce), polycrase-(Y) and fluorite.

Geochemically, the mineral assemblage found in the miarolitic cavities indicates enrichment in Mn, Ti, Zr, Nb>Ta, LREE>HREE, Th and F. The observed geochemical signature and mineralogical assemblage is characteristic of the NYF family of granitic pegmatites. Pronounced enrichment in Mn expressed in several mineral species is particularly striking. Annites show a progressive enrichment in both Mn and F from granites to pegmatites. The miarolitic cavities carry a primary assemblage of Ti-,Nb-,Ta-oxide minerals. Compositions of columbite group minerals correspond to manganocolumbite. Garnet in miarolitic cavities is spessartine rich with core and rims averaging $Alm_{13}Sps_{87}$ and $Alm_{17}Sps_{83}$, respectively. Ilmenite is also Mn enriched, with compositions close to pyrophanite. The extreme fractionation of Mn in the Newberry granites and pegmatites is inferred to be the result of high fluorine activity.

Even though the Newberry granites were clearly emplaced during an extensional tectonic event, a low Fe/(Fe+Mg) ratio in annites (compositionally very close to phlogopite), low HFSE and HREE abundances and high Al/Ga are geochemical characteristics that more typically characterize calc-alkaline magmatism or convergent margin tectonic settings. Similar geochemical signatures have been reported for other extension-related rocks in the region of the Colorado River extensional corridor. This suggests a petrogenetic history whereby extension-related, mantle-derived melts are modified by both fractionation and crustal assimilation processes in order to explain the observed geochemical trends in the Newberry granites and related pegmatites along the Colorado River extensional corridor. The differences in the geochemistry and mineralogy of the three Newberry mountain granitic suites and their related pegmatites appear to be the result of differences in magma ascent paths, localized assimilation of Proterozoic basement rocks and fractionation.

Nb-Ta oxide minerals: tracers of complex magmatic to hydrothermal evolution of the Jezuitské Lesy granitic pegmatite, Bratislava Massif, Slovakia

Chudík, P.[1] & Uher, P.[2*]
[1]Dept. of Mineral Deposits, Comenius University, Bratislava, Slovakia
[2]Dept. of Mineralogy and Petrology, Comenius University, Bratislava, Slovakia ([*]puher@fns.uniba.sk)

Nb-Ta phases, especially members of columbite, tapiolite and wodginite groups, represent characteristic accessory minerals of the LCT-family rare-element granitic pegmatites. Detailed BSE and electron-microprobe study of their textural and compositional variations reveal an evolution of parental granitic pegmatites. The Jezuitské Lesy pegmatite exhibits an example of moderately evolved and relatively narrow dike of the beryl-columbite subtype, where several generations of the Nb-Ta minerals portrayed their magmatic to post-magmatic (hydrothermal) evolution.

The pegmatite forms a 1-2 m thick dike in parental Hercynian S-type granodiorites to granites of the Bratislava Massif (SW Slovakia). The dike consists of a coarse-grained quartz-microcline-muscovite zone, locally with gradual transition into blocky microcline, and core quartz zone. Aplitic, fine-grained saccharoidal albite unit (albite >> quartz + muscovite + garnet), rarely platy albite (cleavelandite) extensively replaces the older zones. Accessory beryl, phenakite, bertrandite, almandine-spessartine, gahnite, zircon, fluorapatite, cheralite-huttonite-monazite-(Ce) s.s., uraninite, galena, pyrite, and the Nb-Ta oxide phases were identified.

The first generation of the Nb-Ta minerals comprises ferrotantalite (Ct1), ferrotapiolite (Ft1) and ferrowodginite (Fw1), in the quartz-microcline-muscovite zone. They show Ta,Fe-rich compositions with Ta# [Ta/(Ta+Nb)] = 0.52-0.70 (Ct1), 0.88-0.90 (Ft1) and 0.73-0.86 (Fw1); Mn# [Mn/(Mn+Fe)] = 0.32-0.49 (Ct1), 0.06-0.10 (Ft1) and 0.33-0.41 (Fw1).

The 2nd generation is represented by ferrocolumbite to ferrotantalite (Ct2) in saccharoidal albite, replacement zones of Ct2 in Ct1, and irregular overgrowths of ferrotapiolite (Ft2) and ferrowodginite (Fw2) on Ft1 grains. The minerals of the 2nd generation show decreasing of Ta# in comparison to the 1st group: 0.10-0.60 (Ct2), 0.85-0.87 (Ft2) and 0.73-0.77 (Fw2); Mn# attains 0.30-0.45 (Ct2), 0.06-0.09 (Ft2) and 0.26-0.37 (Fw2).

The 3rd generation includes fissure fillings, overgrowths and replacement zones of manganocolumbite to manganotantalite (Ct3), ferrotapiolite (Ft3) and ferrowodginite (Fw3) on the older Nb-Ta phases (Ct1, Ft1, Fw1, Fw2), in the coarse-grained unit. The 3rd population displays distinct Mn# increasing (Ct3: 0.51-0.69, Ft3: 0.11-0.24, Fw: 0.40-0.41), Ta# values reach 0.16-0.79 (Ct3), 0.88-0.92 (Ft3) and 0.80-0.81 (Fw3).

The latest, 4th generation of the Nb-Ta phases represent irregular veinlets and patches of microlite, replacing Ct1, Ft1, Fw1, Ct2 and Ft3. Microlite is distinctly Ta-rich, the Ta# values are evidently higher in microlite penetrating Ft1 (0.90-0.97) than it associate with Ct1 (0.82-0.85).

The compositional variations of the Nb-Ta phases show a complex evolution trend of the Jezuitské Lesy pegmatite, from initial (1) magmatic crystallization of Ta,Fe-rich assemblage, followed by (2) reversal Ta/Nb fractionation, (3) Mn-enrichment stage, and final (4) hydrothermal overprint.

Phosphates from the albite pegmatites of the Cap de Creus Granite pegmatite field, Eastern Pyrenees, Catalonia, Spain

Alfonso, P.[1], Fontan, F.[2] & Melgarejo, J.C.[3*]
[1]Dept. d'Enginyeria Minera i Recursos Minerale, Universitat Politècnica de Catalunya, Manresa, Spain
[2]Laboratoire de Minéralogie, CNRS-Université Paul Sabatier, Toulouse, France
[3]Dept. de Cristal·lografia, Mineralogia i Dipòsits Minerals, Universitat de Barcelona, Spain
([*]joan.carles.melgarejo.draper@eub.edu)

Albite pegmatites are the most evolved type in the Cap de Creus pegmatite field, and they are the most enriched in accessory phosphates. These pegmatites are internally complex, and the internal structure consists of a fine-grained border zone, two intermediate zones and a quartz core, all of them crosscut by quartz-muscovite lenses and late phosphate veins. The border and intermediate zones are made up by quartz and albite, with minor muscovite and tourmaline; other minor Al-rich silicates are andalusite and sillimanite. Chrysoberyl occurs at the border zones and in quartz-muscovite veins; beryl is common in the intermediate zones. Ta-rich members of the columbite group are found in all the zones, specially in the quart-muscovite veins, accompanied with cassiterite, gahnite, nigerite and Hf-rich zircon. In all the zones columbite minerals are replaced by tanteuxenite, microlite, rynersonite and tapiolite. Metasomatic processes at the exocontact of the pegmatites include replacement of the host biotite schists by apatite, muscovite, graphite and schorl.

Montebrasite is the dominant phosphate in the intermediate zones, with minor amounts of apatite in the border zone. It may be accompanied with Mn-rich members of the graftonite-beusite series, sarcopside and wyillieite. Some Al-rich phosphate nodules consist of intimate intergroths of wyllieite with scorzalite and diaspore, occassionally accompanied with montebrasite. Mn-rich members of the triphylite-lithiophylite are rare, and have been replaced by the typical sequence to sicklerite and purpurite; stanekite replaces the above minerals.

Phosphate veins have a complex mineralogy. The first mineral to be formed is berlinite, which is partly replaced by Al-rich phosphates as wyllieite, trolleite, secondary montebrasite and brazilianite.

Some late phosphates can be produced in supergene conditions and involve replacement of primary phosphates. Crandallite and apatite replace montebrasite.

The occurrence of phosphates in different pegmatite units allowed to analyze the pegmatite evolution in terms of the chemical composition of phosphates, and compare this composition with that of the rest of the field. F content in montebrasite decreases from the earlier stages of the pegmatite evolution, from 2.83% in the first intermediate zone to 0 in the secondary montebrasites. Ca-Fe-Mn-(Li) phosphates are enriched in Mn, and extremely empoverished in Mg. The members of the scorzalite-lazulite series are closer to the scorzalite end-member. The only phosphate rich in Mg from these pegmatites is quingeiite, which can reach up to 4.67 wt % MgO. A new phase similar to triplite, X-phase, was found in these pegmaties. Microprobe analyses reveal high Mn contents. The composition of this mineral is similar than triplite, $(Mn,Fe,Mg,Ca)_2$ $(PO_4)(OH,F)$, but with Cl instead of F.

A high P activity in the corresponding pegmatitic magma determinated not only the development of phosphates in all the pegmatite units, but also a high P content in the pegmatite silicates and an intense apatitization on the pegmatite exocontact. In contrast, a low F activity, as registered in the phosphates, prevented the development of Li silicates.

Evolution of the chemical composition of columbite-tantalite in Li-F granites and pegmatites – a comparative study

Badanina, E.V.[1*], Sitnikova, M.A.[2], Syritso, L.F.[1], Gordienko, V.V.[1] & Abushkevich, V.S.[3]
[1]Dept. of Geochemistry, State University of St.-Petersburg, Russia ([*]elena_badanina@mail.ru)
[2]Federal Institute for Geosciences and Natural Resources, Hannover, Germany
[3]Institute of Geology and Geochronology of Precambrian, St.-Petersburg, Russia

The mineral chemistry of columbite-tantalite from two famous Li-Ta deposits in Russia, the Orlovka and the Kholmozero deposits in Transbaikalia and the Kola Peninsula, respectively, was studied. In the Orlovka massif of Li-F-granites, columbite-tantalite occurs in all five zones of a complex differentiated vertical sequence ranging from protolithionite granites to amazonite granites with lepidolite [1]. In spodumene pegmatites of the Kholmozero deposit, columbite-tantalite is found in four zones of a differentiated pegmatite body. In both deposits, columbite-tantalite is characterised by a zoned internal structure. This zoning mainly reflects Nb/Ta ratios and changes from progressive to oscillatory, overgrowing the old core of the crystals. In late varieties of tantalite from pegmatite, the oscillatory zoning is replaced by irregular spot zoning. Columbite in the pegmatite system develops from Fe-columbite towards pure Mn-tantalite. A columbite group mineral develop only towards Mn-enriched varieties in rare metal granites.

Columbite-tantalite from these two complexes is very different in its trace element contents, especially rare elements and REE. Firstly, columbite-tantalite from Orlovka is characterised by the highest concentrations of REE (up to 12335 ppm) compared to columbite-tantalite in all known pegmatites worldwide. Secondly, columbite-tantalite from Orlovka has high concentrations of Li (up to 106 ppm), Rb (up to 20 ppm), W (up to 1.6 wt%), and Sn (13.8 wt%). Thirdly, no pure Ta-end members of columbite-tantalite are present in the rare metal granites of Orlovka, probably because of the presence of other Ta-oxides like microlite with up to 75 wt% Ta_2O_5.

Columbite-tantalite from the Kholmozero pegmatite is characterised by consistent contents of Rb. The contents of Rb increase from 3.4 to 70.4 ppm from early to late generations. This trend was not observed in columbite-tantalite from the Orlovka Li-F granites.

In general, the behaviour of rare and rare earth elements in columbite-tantalite in Li-F granites indicates a more complex fractionating process compared to pegmatites. The process of fractional crystallisation in small chambers of pegmatite bodies is probably more evolved compared to granites. As a result, "space isolated" parageneses are formed, fixing the time sequence. In rare metal granites, such parageneses are not observed probably because of slower evolution of the granitic melt which leads to an incomplete fractionation process.

Epidote populations in contaminated granitic pegmatites from Northern Portugal

Dias, P.A.* & Leal Gomes, C.
CIG-R – DCT, Universidade do Minho, Braga, Portugal
(*patriciasdias@gmail.com)

In Domo de Covas mega-anticline (Serra de Arga, N Portugal) the digestion of metacarbonate host-rocks during pegmatitic intrusion produced Ca saturation and high silica impoverishment, resulting desilicated pegmatite veins with plagioclase, scapolite, and local concentrations of phosphate and epidote.

The following vein-fillings are distinguished:

1. *Hybrid pegmatoids* (π1): include plagioclase (mainly anorthite) ± quartz ± triphylite – lithiophilite. Fluorapatite occurs in border units and mark the transition to π2 veins. Vesuvianite is discordant in exo-contact metasomatic hosts.

2. *Hybrid and fractionated pegmatoids* (π2): occur laterally and are the products of fractionation of π1 pegmatites. They consist mainly of prehnite + pink clinozoisite. The clinozoisite is larger where it has crystallized first and these crystals manifest progressive zoning (Fig. 1). Textures also indicate simultaneous crystallization of zoisite and prehnite. Some latest veins only have prehnite (π2-2).

Oligoclase neosome, with scapolite and epidote, bearing sulphide cavities (chalcopyrite and sphalerite) fall into a more typical primary tendency, directed towards the albite pole in the haplogranite system.

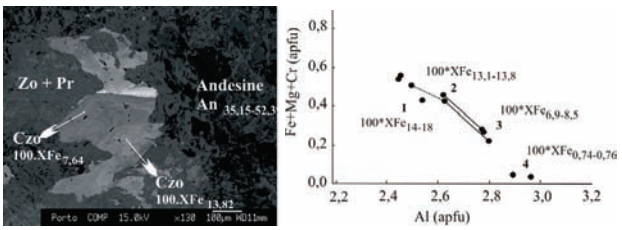

Fig. 1: Mineral intergrowth from veins (π2) – subhedral corroded crystal of clinoizoisite (Czo) in transition to sympletitic zoisite (Zo) and prehnite (Pr) - and compositional fields of epidote from π2 veins.

Epidote and prehnite would come from the earlier crystallization of melts, which composition was modified by desilication. Low Fe content of zoisite (maximum XFe calculated content, 0.76) indicates low P, T conditions. The minimum temperature of crystallization is 440-500ºC (P <5Kbar), deduced from zoisite and clinozoisite compositions, in coexisting crystals, according to [1].

The lowest temperature is accompanied by a zoisite – plagioclase transition, consistent with the final reaction: 3 anorthite + 2 calcite ⇔ 2 zoisite + CO_2. Plagioclase may result from the reaction CO_2 + 2 clinozoisite ⇔ 3 anorthite + calcite + H_2O.

The contamination of Li-rich residual magma by Fe and Mn transfer, gives rise to the emergence of triphylite-lithiophilite concentrations that under normal conditions would not occur. Contamination is also expressed by high Zn concentrations in zircon (maximum content observed, 1.52%) and the deposition of sulphides in oligoclase pegmatoids. The protolith contains exhalite with high contents of Zn and Mn that were remobilized by the intrusion of pegmatite magmas.

Compositional evolution of grossularite from leucotonalitic pegmatite Ruda nad Moravou, Czech Republic; EMPA and LA-ICP-MS study

Gadas, P.* & Novák, M.
Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic (*pgadas@centrum.cz)

The zoned leucotonalitic pegmatite Ruda nad Moravou is characterized by high Ca-contents manifested by an abundance of plagioclase (An_{98-19}), epidote-group minerals including allanite-dissakissite, diopside and grossularite [1]. The latter is present in most textural-paragenetic units from the contact inwards: *G1* is almost monomineral, fine-grained, white zoned grossularite (core - Grs_{97-99} Adr_{1-3}, rim - Grs_{89-90} Adr_{8-9} Sps_{0-1} Prp_{0-1}) from the grossularite subunit, developed along the contact with host serpentinite; *G2* is microscopic, interstitial grossularite (Grs_{77-85} Adr_{11-16} Sps_{0-1} Prp_{0-1} Sch_{0-4}) from leucocratic subunit; *G3* is graphic intergrowths of pale brown grossularite + quartz (Grs_{73-86} Adr_{11-24} Sps_{1-2} Prp_{0-1} Sch_{0-4}) from coarse-grained granitic unit; *G4* is large crystals of colorless grossularite (Grs_{98-100} Adr_{0-1} Prp_{0-1}) at the contact of the blocky unit and quartz core. Grossularite is associated with plagioclase, quartz and epidote-group minerals (*G1*, *G2*). EMPA show compositional evolution from almost pure grossularite (*G1)* through Fe^{3+}-enriched (*G2* and *G3)* to pure grossularite *(G4)*. LA-ICP-MS study of the individual types of grossularite revealed distinct patterns of REE (Fig. 1), which exhibit similar patterns for Fe^{3+}-poor grossularite (*G1+G4*) and Fe^{3+}-enriched grossularite (*G2+G3*), respectively. Similar behavior was obtained also for V, Ni, Cr and Sn. Only concentrations of Ga, Zn and Hf increase during crystallization as well as Zr/Hf ratio.

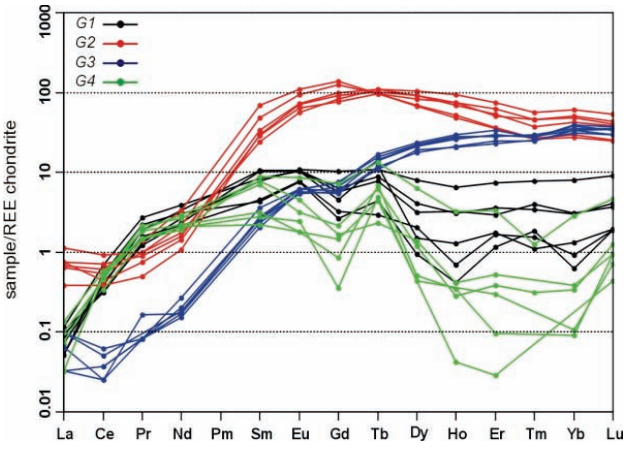

Fig. 1: REE contents of the individual grossularite types compared with chondrite [2].

Incorporation of most trace elements into the grossularite structure is controlled chiefly by crystal structural constraints – entering of Fe^{3+} into the B-site. The role of allanite-dissakissite seems low because *G1*, *G2* show lower La but Ce and LREE are similar or higher relative to *G3* and *G4*. Also the degree of fractionation manifested by evolution of plagioclase from anorthite to oligoclase has only minor importance on concentrations of trace elements except for Ga, Zn, and Ta.

Evolution of phosphates from the pegmatitic field of Giraúl, Namibe (Angola)

Gonçalves, A.O.[1], Fontan, F.[2], Alfonso, P.[3], Melgarejo, J.C.[4*] & Paniagua, A.[5]
[1]Dept. de Geologia, Univ. Agostinho Neto, Luanda, Angola
[2]Laboratoire de Minéralogie, CNRS-Université Paul Sabatier, Toulouse, France

([*]joan.carles.melgarejo.draper@ub.edu)
[5]Depto. Ciencias de la Tierra, Universidad de Zaragoza, Spain

The pegmatitic field of Giraúl (Namibe, Angola) is distributed around a leucogranite intrusion. It comprises 5 types of pegmatites that, from less to more evolved, are: type I (barren, intrabatholitic and grading to the leucogranite host), type II (barren, peribatholitic); type III (beryl-columbite); type IV (beryl-columbite-phosphate); type V (spodumene). With the exception of apatite, phosphates are found only in the 2 last types.

Phosphates in type IV pegmatites occur in all the internal zones. In border and wall zones blue apatite and rare triphylite are found, nearly completely replaced by secondary phosphates. The first intermediate zone contains skelethal triphylite crystals, up to 50 cm in lenght, completely replaced by ferrisicklerite, heterosite and alluaudite, in association with reddish microcline, quartz, albite, muscovite, yellow beryl and minor ferrocolumbite and zircon. However, these phosphates become an important volumetric component in the second intermediate zone, associated with reddish microcline, albite, quartz, muscovite, yellow beryl and ferrocolumbite. Phosphates have nodulous shape and blocky sizes, up to 3 m in diameter. The third intermediate zone is made up by white microcline, quartz, albite, muscovite and white beryl; montebrasite is the only phosphate found therein. Quartz-muscovite-elbaite veins crosscut and replace all the above units, and some montebrasite is formed during this stage.

Phosphates in type V pegmatites have a different mineral association. Blue apatite is found in the earlier zones, and amblygonite is widespread in the third intermediate zone, in asociation with spodumene, petalite, elbaite, beryl, pollucite, manganotantalite and members of the microlite group.

Supergene phosphates are poorly developed, owing to the dry climate from the Giraúl desert. The most common are jahnsite, rockbridgeite, lipscombite and mitridatite. Todorokite and cryptomelane are also produced during the late stages of weathering.

The ratio Fe/Mn is preserved during the triphylite-ferrisicklerite-heterosite replacement. On the other hand, there are no changes in the chemical composition of minerals of the heterosite-purpurite series among the different units in type IV pegmatites. This can suggest that the crystallisation of these phosphates buffers the ratio Fe/Mn during the crystallisation of these zones.

The F content in members of the montebrasite-amblygonite series increases from type IV pegmatites to type V ones. This F increase in phosphates is consistent with the F enrichment in other minerals, especially in members of the tourmaline group, and with the development of spodumene and petalite in the third intermediate zone in type V pegmatites.

On the other hand, a slight enrichment in F is observed from the early to the late units of both type IV and V pegmatites. This enrichment is congruent with the development of elbaite only in the late stages of crystallisation.

Sn-rich thortveitite intergrowth with xenotime-(Y): Y versus Sc fractionation in NYF miarolitic pegmatites at Baveno (Southern Alps, Italy)

Guastoni, A.[*] & Nestola, F.
Dept of Geoscience, University of Padova, Italy
([*]alessandro.guastoni@unipd.it)

The crystal-chemistry of both Sn-rich thortveitite $(Sc,Y)_2Si_2O_7$, and xenotime-(Y) $(Y,HREE)PO_4$ have been investigated by single crystal X-ray diffraction and WDS electron microprobe analysis to assess the activity of scandium and yttrium in NYF miarolitic pockets at Baveno. At this locality the crystallization processes in the pockets are controlled by alkaline supercritical fluids characterized by high contents of H_2O and volatiles elements (B, F, P). Fluoride complexes of scandium, phosphate complexes of yttrium and rare earths are interpreted to be responsible for the transportation and deposition of these incompatible elements once the crystallization of K-feldspar and albite occurred in the cavities. Xenotime-(Y), which forms intergrowth crystals with Sn-rich thortveitite, has crystal faces corroded; Sn-rich thortveitite shows no corrosion, but the core of the crystal is enriched with yttrium and depleted with scandium (Y_2O_3 up to 6.00 wt%, Sc_2O_3 up to 40.50 wt%), the rim depleted with yttrium and enriched with scandium (Y_2O_3 up to 1.6 wt%, Sc_2O_3 up to 44.70 wt%). An early crystallization of xenotime-(Y) is followed by corrosion due to circulation of F-rich fluids. A late crystallization of Sn-rich thortveitite occurs and at the early processes the yttrium enrichment at the core can be related to free Y ions activities liberated by surface corrosion of xenotime-(Y) [1-4].

Columbite-group minerals in the Cruz del Rayo pegmatite dikes, SW Salamanca, Spain

Llorens, T.* & Moro, Mª.C.
Dept. of Geology, Faculty of Sciences, Salamanca University, Spain (*tllg@usal.es)

The Sn-W Navasfrías district is located in the southwestern part of Salamanca (Spain) and belongs to the Sn and W Variscan Belt of Western Europe. It was mined during the last century for cassiterite and wolframite from a group of intragranitic quartz veins and pegmatite dikes related to the Jálama batholith, a zoned, allochtonous and peraluminous granitic body [1].

There are abundant barren pegmatite dikes hosted by the border leucogranitic and aplitic facies of the Jálama batholith. They contain a scarce tin mineralization but a wide variability of Fe-Mn phosphate minerals depending on the host rock [2,3]. The most evolved granitic pegmatites of the Navasfrías district are hosted by pre-ordovician metamorphic rocks and belong to the Cruz del Rayo pegmatite field. These pegmatites strike N170°E, dip subvertically and have been grouped in two types of pegmatite bodies: on one hand, the pegmatite dikes of granitic composition are essentially constituted of quartz, microcline, albite and muscovite, with accessory apatite, alluaudite and mitridatite; and on the other hand, the greisen-like pegmatite dikes are formed of quartz, muscovite and albite, with abundant beryl and phosphates of the amblygonite-montebrasite series which are especially abundant at the inner zones of the bodies. Both pegmatite types show a more or less complex internal zoning and are affected by a Na-metasomatism which lead to the crystallization of a late albite-rich unit.

Cassiterite and minerals of the columbite group appear disseminated through the dikes, although there are some differences depending on the type of pegmatite bodies. The dikes with granitic-like composition are poorly mineralized, consisting mainly of cassiterite, which commonly includes strongly zoned columbite-(Fe) crystals, and locally tantalite-(Fe). However, the greisen-like pegmatite dikes display a strong mineralization with abundant cassiterite hosting columbite-(Mn) crystals, which display an oscillatory zoning and a Ta- and Mn-rich rim, although sometimes a reverse zoning pattern is present.

The primary minerals of the columbite group evolve from columbite-(Fe) in the granitic-like pegmatite dikes to Mn-rich compositions in the greisen-like bodies, as a consequence of the magmatic differentiation of the pegmatite-forming melts, which increases the F content of the melt. Nevertheless, the secondary assemblage shows a Ta enrichment in both types of dikes, with intermediate amounts of Fe and Mn, which is caused by the late Na-metasomatic replacement processes of the pegmatite dikes.

These fractionation trends and the slight degree of evolution of the columbite-group minerals of the pegmatite dikes, which is shown by a strong Fe enrichment and variable Fe and Mn contents, suggest that they belong to the rare-element class, beryl-columbite-phosphate subtype, in the classification of Černý [4].

Nb-Ta-oxide minerals in the LCT granitic pegmatites of La Canalita, SW Salamanca, Spain

Llorens, T.* & Moro, Mª.C.
Dept. of Geology, Faculty of Sciences, Salamanca University, Salamanca, Spain (*tllg@usal.es)

The La Canalita pegmatites in the Navasfrías Sn-W district, in Spain, are a group of Li-rich LCT rare-element pegmatites of the complex type, lepidolite-subtype in the classification of Černý [1], with high phosphorus contents, hosted by low-grade metamorphic rocks of the contact aureole caused by the intrusion of the Cadalso-Casillas de Flores batholith [2]. It consists of several dikes with a constant N130°E to N145°E direction and subvertical dipping of up to 1 m thick, 16 m in length and unknown depth that were mined during the forties and fifties for tin.

The pegmatite dikes of La Canalita show a regular pattern of symmetrical zoning from the outer to the inner parts of the dikes and are mostly composed of quartz, white mica, lepidolite and albite, the latter commonly of the "cleavelandite" habit, and subordinate microcline [3]. Topaz and montebrasite are accessory minerals, although occasionally they can be considered major phases, especially in the outer and intermediate zones of the pegmatite dikes. A fine-grained late unit shows a distinct layering formed of alternating purple bands with dominant lepidolite and quartz and of white albite bands.

The main ore mineral is cassiterite, which is abundant in almost all the zones of the pegmatite dikes but specially hosted by albite aggregates and the late unit. Abundant Nb- and Ta-oxide minerals are found related or not to the cassiterite crystals. A primary assemblage is formed of extremely Mn-rich columbite and tantalite, and microlite, the latter forming the host of columbite-(Mn) exsolution lamellae in the intermediate parts of the dikes.

The influence of metasomatic processes led to the formation of the lepidolite-albite late unit and the crystallization of a secondary assemblage consisting of tantalite-(Fe), tantalite-(Mn) and tapiolite-(Fe). U-rich microlite (up to 6 % wt. UO_2) is present in this assemblage, replacing tantalite.

Subsequently, the possible interaction of residual hydrothermal fluids with metamorphic fluids caused a partial greisen-like alteration of the pegmatite bodies and formed a second generation of microlite replacing tapiolite, with high Ca and Ta and low F contents.

The lack of a chemically suitable protolith in the surrounding metamorphic rocks, combined with the mineralogical paragenesis containing U-rich microlite and the composition of the Sn, Nb and Ta oxide minerals of the pegmatite dikes, suggest that the residual melts of the Cadalso-Casillas de Flores batholith, which migrated through fractures and were probably little influenced by host metamorphic hydrothermal fluids, are the most probable source of the melts forming the La Canalita pegmatite dikes.

Trace elements behaviour in tourmaline and mica from the Pinilla de Fermoselle rare-element pegmatite (Zamora, Spain)

Roda-Robles, E.[1*], Gil-Crespo, P.[1], Pesquera, A.[1] & Torres-Ruiz, J.[2]
[1]Dpt. De Mineralogía & Petrología, Universidad del País Vasco (UPV/EHU), Bilbao, Spain ([*]encar.roda@ehu.es)
[2]Dpt. de Mineralogía & Petrología, Univ. de Granada, Spain

The rare-element Pinilla de Fermoselle, (PF) pegmatite, crops out in the apical part of a leucogranite body. It shows a clear non-symmetrical vertical zoning from the contact with the leucogranite to the contact with the metamorphic country-rocks. The pegmatitic facies evolve upwards from (1) the undifferentiated lower border zone (LBZ), with quartz, feldspars, muscovite, biotite and black tourmaline, through (2) the intermediate zone (IZ), with quartz, muscovite, zinnwaldite, black tourmaline and Fe-Mn phosphates, to (3) the highly evolved upper border zone (UBZ), with quartz, albite, lepidolite, Fe-lepidolite, elbaite and beryl.

Trace element analyses of representative samples of mica and tourmaline from the three zones of the pegmatite have been performed by Laser Ablation. In addition, micas from greisenization bodies inside the UBZ and from the associated leucogranites, plus tourmaline associated to hydrothermal veins occurring inside this granite, have been also analyzed for trace elements. Li, Be, Sc and Sr show a similar behaviour for the white and ferro-magnesian micas and tourmaline. Li and Be contents increase from the leucogranite to the most evolved pegmatitic facies (UBZ), whereas Sc and Sr contents decrease upwards. The rest of the trace elements have different behaviour depending on the mineral phase. In the case of the tourmaline, Nb and Ta contents increase upwards, with the increasing evolution degree of the pegmatite facies, whereas Zn contents decrease in this sense and Mn contents increase till intermediate degrees of evolution (IZ), to decrease again in the pinkish elbaite. Rb and Cs show the same trends for white and ferro-magnesian micas, with a gradual increase upwards. Ta and Tl increase from the leucogranite to the UBZ in the white micas, whereas Ga increases till the IZ and later decreases in the UBZ. In the case of the ferro-magnesian micas, Zn, Ga, Nb, Sn, Ta and W show a similar trend, with a gradual increase from the leucogranite to the IZ, and a final decrease in the UBZ. In general, the three mineral phases are depleted in REE. A slight decreasing trend is observed for the HREE in the pegmatitic white micas, whereas for the ferro-magnesian micas the LREE contents decrease with the pegmatitic evolution. White micas are also present in small greisenization bodies occurring in the UBZ. This late mica shows the highest contents in Li, Rb, Cs, Nb, Ta and Tl; and the lowest in Mn, Ga and Sr.

Regarding the distribution of these trace elements among the three mineral phases in the different facies where they occur together (leucogranite, LBZ, IZ and UBZ), Li, Rb, Cs, Mn, Nb, Ta and Tl are mainly partitioned into ferro-magnesian micas. Be, Sc, and W are partitioned into white micas, whereas REE are partitioned into tourmaline. In general, tourmaline is the poorest phase in Li, Rb, Cs, Be, Sc, Sr, Nb, Ta, W, and Tl contents; whereas white mica is the poorest in Mn, Zn and LREE contents. Ferro-magnesian micas are the poorest in Ga and HREE contents.

Chemical variation in micas and tourmaline is consistent with an internal evolution by crystal fractionation processes. Li, Be, Sr and Sc in micas and tourmaline may be indicative of the degree of evolution in the PF pegmatite. Other elements that may be used to establish the degree of evolution in this body are the Rb, and Cs for the micas; and the Nb and Ta for the white-micas and tourmaline. The transition metals Mn and W seem to be a good indicative of fractionation just in the ferro-magnesian micas.

Graftonite-triphylite-sarcopside intergrowths from the Palermo No. 1 pegmatite (New Hampshire, USA): textures and chemistry

Roda-Robles, E.[1*], Nizamoff, J.W.[2], Simmons, W.B.[2], Falster, A.U.[2] & Hatert, F.[3]
[1]Dept. De Mineralogía y Petrología, Universidad del País Vasco (UPV/EHU), Bilbao, Spain ([*]encar.roda@ehu.es)
[2]Dept. of Earth & Environmental Sciences, University of New Orleans, USA
[3]Laboratoire de Minéralogie, Université de Liège, Belgium

The Palermo No. 1 (P1) rare-element pegmatite (North Groton, New Hampshire, USA) belongs to the Grafton pegmatite field, where beryl-columbite-phosphate and beryl-phosphate pegmatites are the most evolved [1]. The P1 pegmatite is hosted by sillimanite-muscovite grade schists of the Devonian Littleton formation. The pegmatite is pod-shaped and mainly concordant with the host rocks. Major minerals in this body are quartz, feldspars, muscovite, phosphates and beryl, with minor schorl.

The core margin and core zones of the P1 pegmatite contain locally abundant phosphate pods (up to 5 m long and 2.5 m across). In these pods, close to 90 different phosphate phases (primary and secondary) have been identified. Triphylite is the most abundant primary phosphate in the pods. Periodically triphylite occurs intergrown with graftonite ± sarcopside. The most common intergrowth is an assemblage of graftonite containing coarse lamellae of triphylite (or ferrisicklerite and/or heterosite). Most lamellae are platy and form a single set that shows a quite uniform optical orientation, enclosed in monocrystalline graftonite, giving rise to a laminated parallel intergrowth. Less commonly graftonite and triphylite show a granular texture, probably as a result of deformation, where the triphylite lamellae are not as regular, and the single crystallographic orientation is lost. In both cases, the triphylite lamellae may in turn host lamellae of sarcopside.

All the phosphates analyzed belong to the Fe-rich end-members, with values for the Fe/(Fe+Mn) ratio in the range 0.57 to 0.73 for graftonite, 0.74 to 0.89 for triphylite, and 0.81 to 0.88 for sarcopside, with a clear correlation among the ratios of the different phases belonging to the same sample. The Ca content in graftonite varies considerably, from 8.64 to 13.23 wt.% CaO. Graftonite intergrown with triphylite + sarcopside is the richest in Ca, whereas no correlation has been found between the Ca contents of graftonite and its Fe/(Fe+Mn) ratio.

In relation to the distribution of Fe, Mn and Mg among coexisting phases, in all the cases, graftonite shows a strong preference for Mn, whereas both triphylite and sarcopside are Fe-rich, with a slight preference of sarcopside over triphylite for this element. Mg is clearly partitioned preferentially into triphylite, with graftonite being the Mg-poorest of the three phases.

Taking into account the textural and chemical features of the graftonite, triphylite and sarcopside from the P1 pegmatite, they all may be considered as primary phases. Exsolution processes from a disordered homogenous precursor most likely could have been responsible for the development of the intergrowths present. In the case of the graftonite-triphylite intergrowths, graftonite exsolved triphylite. In the case of the graftonite-triphylite-sarcopside intergrowths, a Ca-richer graftonite exsolved triphylite, which in turn broke down to triphylite with sarcopside lamellae.

Tourmaline from the rare-element Berry-Havey pegmatite (Oxford County, Maine, USA): paragenesis and petrography

Roda-Robles, E.[1*], Simmons, W.B.[2], Nizamoff, J.W.[2], Pesquera, A.[1], Gil-Crespo, P.[1] & Torres-Ruiz, J.[3]
[1]Dept. de Mineralogía y Petrología, Universidad del País Vasco (UPV/EHU), Bilbao, Spain ([*]encar.roda@ehu.es)
[2]Dept. of Earth & Environmental Sciences, University of New Orleans, USA
[3]Dept. De Mineralogía y Petrología, Univ. of Granada, Spain

The Berry-Havey pegmatite (Poland, Androscoggin County, Maine, USA), belongs to the Oxford pegmatite field, which is proximal to the Sebago granitic batholith. The Berry-Havey is a highly evolved rare-element pegmatite, is enriched in Li, F, B, Be and P, and contains gem-bearing cavities. The pegmatite has a complex internal structure, with five different zones identified: border zone, two intermediate zones, core margin and core zone. Tourmaline is present in all of them, with textural and compositional differences among the different zones.

In the border zone tourmaline is scarce, occurring as very fine-grained prismatic black crystals, together with quartz, feldspars, muscovite, garnet and biotite. The mineralogy of the first intermediate zone is quite similar whereas the average grain size is larger. Graphic intergrowths of quartz and K-feldspar are very common in this zone. Locally, schorl may also be very abundant, appearing as black prismatic crystals up to 6 X 40 cm. In the second intermediate zone the quartz-K-feldspar graphic intergrowths are not so common. In this zone tourmaline is abundant and displays a characteristic texture. Many crystals exhibit a tapered black prism growing perpendicular to the pegmatite contacts, that increases in width in the direction of the core of the pegmatite. The thick end of the crystal is often "crowned" by black ± green tourmaline + quartz ± K-feldspar. The crystals, that show a sharp boundary between the black schorl and the greenish elbaite, are frequently broken, giving rise to a pull-apart structure. The next zone is the core margin, which is the most complex zone, not only because of its mineralogy, but also because of its textures. The main minerals of this zone are quartz, feldspars, micas from the muscovite-lepidolite series and tourmaline. The core margin also contains rounded Fe-Mn phosphate pods, montebrasite, beryl and greenish, fine–to–medium–grained elbaite crystals associated with medium–to–coarse book muscovite crystals. Lepidolite occurs as fine–grained irregular to rounded purple masses, close to the muscovite + green elbaite-containing areas. Small pinkish elbaite crystals have been observed inside the lepidolite masses. Prismatic crystals of watermelon tourmaline have also been observed in this zone, but most are replaced by clay minerals. Moreover, radial prisms of multicoloured tourmaline (elbaite) embedded in feldspars and quartz are also abundant. Finally, the quartz-K-Feldspar core represents the innermost zone of the pegmatite. Along the boundary between the core margin and core, pockets are common and may contain multicoloured gem–quality tourmaline, quartz, hydroxylherderite, cassiterite, cookeite, lepidolite, and beryl, among others.

The textural and chemical variations observed in tourmaline from the pegmatite, from the border zone to the core suggest an inward crystal fractionation model. The development of the quartz-K-feldspar and quartz-tourmaline graphic intergrowths could indicate undercooling of the pegmatite melt. The development of quartz-tourmaline crowns around elongated tourmaline crystals frequently showing pull-apart structures could be related to a sudden change in P conditions. Finally, the pockets located along the core margin and core zone of the pegmatite suggest elevated fluid activity during the last stages of crystallization of this pegmatite.

Hydrothermal synthesis, crystal chemistry, and stability of fillowite-type phosphates in the Na – Mn – Fe^{2+} - Mg – PO_4 system

Rondeux, M.[*] & Hatert, F.
Laboratory of Mineralogy, University of Liège, Belgium
([*]M.Rondeux@ulg.ac.be)

Fillowite [$Na_2CaMn_7(PO_4)_6$], johnsomervilleite [$Na_2Ca(Fe^{2+})_7(PO_4)_6$], and chladniite [$Na_2CaMg_7(PO_4)_6$] are Na-, Mn-, Fe- and Mg-bearing phosphate minerals which occur as primary phases in granitic pegmatites, in metamorphic rocks and in meteorites. Their crystal structure (space group *R*-3, a = 15.28 Å, c = 43.51 Å, Z = 18) is characterized by a hexagonal packing of three types of rods parallel to the c axis [1]. The rods are constituted by an alternation of five- to seven-coordinated sites containing Fe, Mn, and Mg, of six- to nine-coordintaed sites containing Na and Ca, of PO_4 tetrahedra, and of cation vacancies.

In order to understand the stability of fillowite-type phosphates, the $Na(Mn_{1-x}Fe^{2+}{}_x)_4(PO_4)_3$ system (x = 0, 0.25, 0.5, 0.75, 1.0)[2], as well as compounds with the $Na(Mn_{0.33}Fe^{2+}{}_{0.33}Mg_{0.33})_4(PO_4)_3$, $Na(Mn_{0.6}Fe^{2+}{}_{0.2}Mg_{0.2})_4(PO_4)_3$, $Na(Mn_{0.2}Fe^{2+}{}_{0.6}Mg_{0.2})_4(PO_4)_3$, $Na(Mn_{0.2}Fe^{2+}{}_{0.2}Mg_{0.6})_4(PO_4)_3$ starting compositions, were synthesized under hydrothermal conditions, between 400 and 700°C, at 1 kbar. Single-phase fillowite is obtained only for the $NaMn_4(PO_4)_3$ starting composition, between 400 and 700°C. The incorporation of iron and magnesium immediately provokes the crystallization of alluaudite [$Na_2(Mn,Fe^{2+},Mg)_2Fe^{3+}(PO_4)_3$] and of sarcopside [$(Fe^{2+},Mn,Mg)_3(PO_4)_2$], in association with fillowite in the Mn-rich part of the Mn-Mg-Fe diagram. In the Mg-rich part of the system, an assemblage alluaudite + hydrated alluaudite [$\square Na(Fe,Mn)Mg_2(PO_4)(HPO_4)_2$] + $(Mg,Mn,Fe)_2P_2O_7$ occurs at 400 and 500°C, and an assemblage alluaudite + $(Mg,Mn,Fe)_2P_2O_7$ occurs at 600 and 700°C. Finally, in the Fe-rich and central parts of this diagram occurs the alluaudite stability field.

The electron-microprobe analyses of fillowite-type phosphates show an decrease of the $Mg/(Fe_{tot.}+Mn+Mg)$ ratio, from 0.25 at 400°C, to 0.20 at 600°C, followed by an increase to 0.28 at 700°C. At 800°C, the Mg-richest fillowite-type phosphate has been observed, with a composition $Na_{2.14}(Mn_{4.90}Mg_{2.15}Fe^{2+}{}_{0.33}Fe^{3+}{}_{0.37})(PO_4)_6$.

The $Mg/(Fe_{tot.}+Mn+Mg)$ ratio of sarcopside increases from 0.25 at 400°C, to 0.39 at 500°C, and then decreases to 0.14 at 700°C. The composition of the Mg-richest sarcopside is $(Mg_{1.17}Fe^{2+}{}_{1.62}Mn_{0.21})(PO_4)_2$.

At high temperatures, the proportions of alluaudite-type phosphates significantly increase compared to experiments at lower temperatures. This feature probably results in an oxidation of iron, favoured by the increase of hydrogen diffusion through the gold capsule at high temperatures.

Hydrothermal alteration of Y,REE,Nb,Ta,Ti-oxide minerals from the Písek pegmatites, Czech Republic: a low-temperature As enrichment

Škoda, R.[1*], Novák, M.[1], Gadas, P.[1], Cicha, J.[2] & Heroldová, N.[1]
[1]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic ([*]rskoda@sci.muni.cz)
[2]Prácheň Museum, Písek, Czech Republic

Primary Y,REE,Nb,Ta,Ti-oxide minerals commonly underwent intensive hydrothermal alteration enhanced by their tendency to be metamict [1]. At the Písek pegmatites (beryl-columbite subtype with abundant tourmaline and accessory arsenopyrite and niobian rutile) primary "písekite" (an inadequately described Y,REE,Nb,Ta,Ti-oxide phase [2]) was found as relics, ~ 10-500 μm in size (Fig. 1) of several primary phases compositionally related to polycrase-(Y), samarskite-(Y) and fergusonite-(Y), respectively. These are typically hydrated and altered to a fine-grained mixture of numerous phases with complicated textural relations (Fig. 1). Newly formed monazite-(Ce), xenotime-(Y), zircon, ferrocolumbite, pyrochlore-group minerals, scheelite, uraninite, and pharmacosiderite were tentatively identified by EMP as well as several unidentified phases with unclear stoichiometry, some of them Sc-enriched.

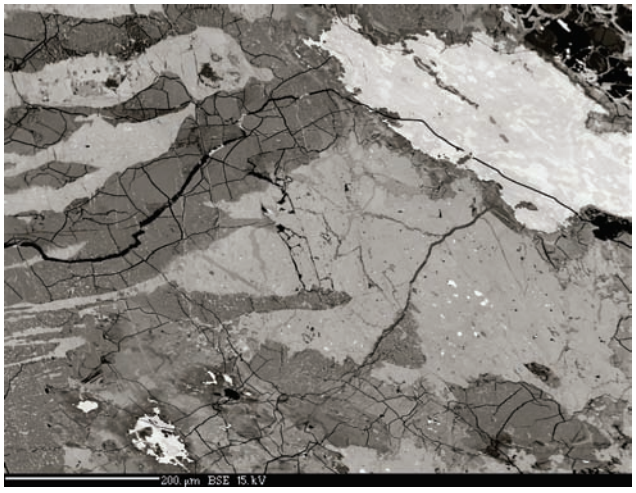

Fig. 1: "Písekite" relic (bright, right upper part) replaced by a mixture of several breakdown products (various shades of grey to bright).

Arsenic was determined as a minor constituent in "písekite" [2]; however, all our examined relics yielded As below the detection limit of EMPA. Elevated contents of As (up to 6.22 wt.% As_2O_5) were found exclusively in highly hydrated outermost portions of "písekite" grains locally associated with other secondary As-rich minerals e.g., metamict zircon and pharmacosiderite. Absence of As in relics of primary Y,REE,Nb,Ta,Ti oxides and its enrichment solely in the outer rims suggest that As was preferentially partitioned to arsenopyrite during the primary (late magmatic to early hydrothermal) stage of pegmatite crystallization. Exclusively during low-temperature hydrothermal alterations of arsenopyrite As appeared to be mobile and entered various metamict Y,REE,Nb,Ta,Ti oxides. Elevated As contents in the outermost parts of "písekite" grains are accompanied by strong depletion of REE and Y and enrichment of Si (up to 7.12 wt.% SiO_2) as well as P (up to 3.72 wt.% P_2O_5**)**.

Relationship between clay mineralogy, fluid inclusions and K/Ar ages in the Triassic and Palaeogene hydrothermal alteration zones within the Variscan granite of the Velence Mts. (W-Hungary)

Benkó, Zs.[1*], Molnár, F.[1], Németh, T.[1], Pécskay, Z.[2] & Lespinasse, M.[3]
[1]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]benko.zsolt@ttmk.nyme.hu)
[2]Institute of Nuclear Research, Hungarian Academy of Sciences (ATOMKI), Debrecen, Hungary
[3]UMR CNRS, Université HP-Nancy 1, Nancy, France

The Variscan (Carboniferous) granite intrusion of the Velence Mountains (W-Hungary) has suffered intense argillic alteration in several zones. To determine the structural, temporal and spatial relationship, as well as the p-T conditions of the hydrothermal systems responsible for alterations, a detailed study of the hydrothermal clay mineral assemblages and mineralogical properties of clay minerals has been completed. The idea was that clay mineral assemblages as well as clay mineral properties (e.g. illite structure, kandite minerals) in hydrothermal alteration zones are useful for temperature estimation. Temperatures were compared with the results of fluid inclusion studies and were used as independent thermometers for pressure estimation. K/Ar radiometric age dating was performed on the illite phase to determine the temporal relationship of the alterations. Comparison of clay mineral assemblages, clay mineralogy, fluid inclusion data and K/Ar radiometric dates suggests that the superimposing hydrothermal alterations can be distributed in three groups:

1) Argillic alteration around the quartz-fluorite-base metal veins is composed of illite-kaolinite and smectite clay mineral assemblage and is regionally characteristic for the granite. Intensity of alteration increases towards to the mineralized NE-SW trending structural zones and towards the quartz-fluorite-base metal veins. Age of this type of alteration and thus of the syngenetic base metal veins is middle-late Triassic according to the results of K/Ar age measurements. Field evidence and mineralogical analysis prove that the clay mineral suites did not form simultaneously. Comparing the fluid inclusion data with the clay mineral thermometer the fluids started to cool down from 220°C at relatively low pressure (1 kbar). Cooling was accompanied by dilution of the hydrothermal fluids.

2) Alteration zones of Palaeogene age in the granite evolved in structurally controlled narrow zones in the eastern part of the granite, in the vicinity of Palaeogene subvolcanic andesite dikes cutting the granite. Alteration can be characterized by well-crystallized illite, thin quartz-stringers and silicification. Structural characteristics of illite indicates temperature of at least 220°C in accordance with the fluid inclusion data, measured on fluid inclusions trapped from a shallow level boiling hydrothermal system. K/Ar ages for illite scatter in a narrow time range between 29 and 32 Ma, indicating early-Oligocene age for the hydrothermal system, as well as for the andesitic magmatism.

3) In the broader vicinity of the illitic alteration zones, but also structurally related Palaeogene andesite dykes, illite and dickite were found. Their assemblage indicates 200-220°C temperature but a characteristic fluid inclusion assemblage cannot be connected to this alteration type. Radiometric ages vary in a very broad range between 200 and 50 Ma, depending on the location and the measured sample. Therefore it is assumed that this assemblage does not represent a third, individual hydrothermal event but can be interpreted as a transitional zone between the Triassic and the Palaeogene alteration zones.

Alpine (Cretaceous) very low- to low-grade metamorphism recorded on illite fraction from South Tisia (eastern Mt. Papuk, Croatia)

Biševac, V.[1*], Balogh, K.[2], Balen, D.[1] & Tibljaš, D.[1]
[1]Institute of Mineralogy and Petrology, Department of Geology, Faculty of Science, University of Zagreb, Croatia ([*]vabisevac@geol.pmf.hr)
[2]Institute of Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary

Alpine very low- to low-grade metamorphism related to Cretaceous orogenesis has been investigated in the Slavonian Mts., Croatia. Samples belonging to the Psunj metamorphic complex (PMC), Radlovac metamorphic complex (RMC) and clastic-carbonate succession of the Late Permian to Early Triassic age i.e. Permian-Triassic sedimentary sequences (PTSS) were studied.

Kübler and Árkai indices of all analysed samples indicate high temperature anchizonal to epizonal conditions of thermal alteration (~300°C). The degree of thermal alteration tends to be constant in all measured samples implying that different complexes passed through and recorded the same event. Measurements of b_0-parametar of samples belonging to the RMC imply transitional low-medium pressure metamorphism. K-Ar ages measured on <2 μm fraction indicate Late Cretaceous very low-grade metamorphism of PTSS as well as Late Cretaceous overprint of older Paleozoic metamorphic rocks (PMC and RMC). No considerable systematic or gradual variation between the K-Ar age of <2 μm fraction and metamorphic indicators of analysed samples, regardless to the stratigraphy, was observed (Fig. 1).

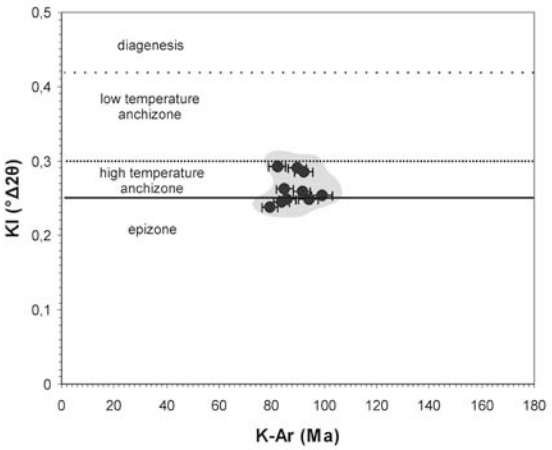

Fig. 1: Plot of KI values vs. K-Ar ages of <2 μm fraction.

All these data together with K-Ar ages measured on <2 μm fraction point to Late Cretaceous very low- to low-grade regional metamorphism related to the Austrian and/or Subhercynian phase of Alpine orogeny that were responsible for the main nappe-forming compressional events in the Pannonian Basin area and the Carpathians [1].

Metamorphic and geochronological evolution of the studied area is in good agreement with similar scenario for the surrounding area of Tisia, but also from ALCAPA (e.g. [2]).

The Arosa zone in Eastern Switzerland, the diagenetic to metamorphic pattern of a tectono-metamorphic mélange

Ferreiro Mählmann, R.[1,3,4*] & Giger, M.[2,3]
[1]Inst. für Angewandte Geowissenschaften, Technische Universität Darmstadt, Germany
([*]ferreiro@geo.tu-darmstadt.de)
[2]Dammweg 27, Thun, Switzerland
[3]Abteilung für Isotopengeologie, University of Bern, Switzerland
[4]Lehrstuhl für Geologie, Geochemie und Lagerstätten der Kohle und des Erdöls, RWTH Aachen, Germany

In the area of Arosa-Davos-Klosters (Eastern Switzerland) the different tectonic elements of the Arosa zone mélange e.g. the Austroalpine fragments, the mafic and ultramafic basement rocks as well as the matrix (oceanic sediments and flysch rocks) show a distinctively different metamorphic history and also a different climax („peak“) of alpine metamorphism. This is proved by a wealth of Kübler Index (KI) - vitrinite reflectance (VR) measurements and kinetic numerical modelling, bituminite reflectance, illitization indices (related to the smectite-illite reaction progress), K-white mica b-cell dimension determinations, index minerals, microprobe data as well as geo-chronological results.

Whereas the matrix sediments of the Arosa zone mélange are overprinted by a low anchizonal to high anchizonal metamorphism Lower Austroalpine fragments in the mélange and the adjacent Lower Austroalpine units (e.g. Tschirpen-Dorfberg nappe) were overprinted by a widespread syn-sedimentary burial and orogenic epizonal metamorphism. High anchizonal rocks are found in the Lower Austroalpine locally. Flysches at the hanging wall of a disconformity in the mélange zone show lower diagenetic thermal conditions.

At least six main metamorphic events can be recognized in the area of Arosa-Davos-Klosters:

i) A pre-orogenic event is recognized in the sediments at the base of the Silvretta nappe, typical for the Upper Austroalpine.

ii) The epizonal oceanic metamorphism observed in the close vicinity of oceanic basement rocks (e.g. pillow-basalts, peridotites of the South Penninic units) of the Arosa zone is another pre-orogenic process.

iii) Based on stratigraphic, tectonic and geo-chronologic considerations the overprint of lower structural Austroalpine fragments in the Arosa zone and the adjacent Lower Austroalpine nappes is attributed to the orogenic metamorphic processes during the Late Cretaceous.

iv) The thermal climax observed in the sediments of the Arosa zone can be bracketed into the time span between the Austroalpine Late Cretaceous (iii) event and the middle Tertiary event in the Middle Penninic (v) as well as the Oligocene "Turba phase". North of Klosters, in the northern part of our study area, the entire tectonic pile from the North Penninic flysches to the Upper Austroalpine is strongly influenced by a late Tertiary event (vi).

In the Arosa zone mélange an individual orogenic metamorphic event is evidenced and gives a new chance to resolve still not understood diagenetic-metamorphic versus deformation relations. By different KI-VR correlations we can distinguish 6 heating episodes in sedimentary rocks and 7 deformation cycles. This is well explained by the propagation of the Alpine deformation front onto the foreland units.

Origin and timing of brittle shear zones in the Mórágy Granite (Hungary): mineralogy and K-Ar geochronology of illite-rich fault gouges

Koroknai, B.[1*], Maros, Gy.[1], Kovács-Pálffy, P.[1], Kónya, P.[1], Viczián, I.[1], Balogh, K.[2] & Pécskay, Z.[2]
[1]Geological Inst. of Hungary, Budapest, Hungary
([*]koroknai@mafi.hu)
[2]Inst. of Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary

The Mórágy Granite — exposed in the south-eastern hilly foreland (Mórágy Hills) of the Mecsek Mts. — represents an Early Carboniferous pluton (~340 Ma) in the Variscan crystalline basement (Tisza unit) of the Pannonian Basin. It is mainly composed of microcline megacryst-bearing biotite-monzogranites with mafic enclaves of predominantly monzonitic composition, hybride rocks and leucocratic dykes crosscutting all of these rocks. Following a Variscan regional metamorphism, during cooling associated with the formation of a regional, generally NW-dipping foliation and localized ductile shear zones, the pluton suffered intense brittle deformation in several phases. During these events — beside micro- and macro-scale individual fractures — numerous, map-scale brittle shear zones were also formed which display a remarkably large variety in orientation, width, internal structure as well as in mineralogical composition.

In this study we focus on the so-called core zone(s) of mature shear zones containing well-developed, partly foliated, brittle fault rocks as fault breccias, cataclasites and clay gouges concentrating the deformation into relatively narrow zone(s). Among them, (foliated) clay fault gouges are of special interest, since these represent not only the most intensively deformed brittle fault rocks, but also the products of syntectonic fluid/rock interaction. The analyzed gouge samples contain illite/smectite + chlorite + palygorskite + kaolinite + quartz + K-feldpar + plagioclase + calcite + dolomite + hematite + goethite assemblage with highly various ratios of the individual minerals. Clay minerals and chlorite are clearly new phases, formed at the expense of feldspars and mafic minerals of the original granitoid protolith. According to detailed XRD analyses, the polytypic variety of illite in clay gouges containing illite in considerable amount is almost exclusively 1M, suggesting hydrothermal origin of illite. In some samples minor amounts (<10 wt%) of $1M_d$ and/or $2M_1$ polytypes also occur. The $1M_d$ polytype may represent the low-T alteration product of the 1M hydrothermal illite, whereas the $2M_1$ polytype presumably display inherited component from primary magmatic biotite and/or metamorphic muscovite. The FWHM (full-width-at-half-maximum) values of 1M illite are mostly higher than 0.73 Δº2θ), but another group with significantly lower values (0.51–0.61 Δº2θ) is also present. The higher values of the first group probably reflect the mixed-layer structure (illite/smectite) of the analyzed phases and occasionally additional smectite as well, whereas the second group represents a discrete illite structure. K/Ar dating of illite-rich fine fractions (<10, <2, <1 μm) resulted in strongly scattered Mesozoic ages (Middle/Late Triassic–Late Cretaceous). Considering various mineralogical/structural criteria (amount of I/S, smectite, other, „disturbing” phases, as well as the FWHM values), we conclude that the oldest (Triassic–Early Jurassic) and presumably the youngest (Late Cretaceous) ages seem to represent indeed the time of important brittle tectonic activities accompanied with syntectonic fluid flow. The Middle Jurassic and Early Cretaceous ages might also indicate real tectonic events, if one regards the considerable amounts of illite/smectite and smectite in these samples as cogenetic phases with hydrothermal illite (and not as alteration products of it). However, further detailed investigation is needed to verify this hypothesis.

Two types of illite with different chemical composition in Upper Riphean shale, the Zil'merdak Formation (South Urals)

Zaitseva, T.S.*, Gorokhov, I.M., Kuznetsov, A.B., Melnikov, N.N., Konstantinova, G.V, Turchenko, T.L. & Kutyavin, E.P.
Institute of Precambian Geology and Geochronology, RAS, St.Petersburg, Russia (*tatiana.s.zaitseva@gmail.com)

Precambrian argillaceous rocks often contain mixtures of non-cogenetic illite minerals with different crystallochemical and isotope characteristics. The end-members of these mixtures could be formed at different stages of lithogenesis.

Shale samples were collected from the two sections of the Upper Riphean Zil'merdak Formation (Bakeevo village and Minyar) spaced by 200 km. The <2-μm fractions of these samples were separated into 1-2, 0.6-1, 0.3-0.6, 0.2-0.3 and 0.1-0.2 μm subfractions (SF). SFs were leached with NH_4OAc to remove mobile Sr adsorbed on the surface and located in interlayer positions of clay particles, or incorporated into the soluble accessory minerals such as carbonates and phosphates. SFs were studied by the XRD technique, and concentrations of K, Rb, Sr and the Sr isotope composition were determined in the residues after leaching. All the SFs in both samples are dominated by illite, an admixture of chlorite is no more than 5-10 per cent.

The 0.1-0.2 and 0.2-0.3 μm SFs of the sample from the Bakeevo section contain $1M_d$ illite, the 0.3-0.6 and 0.6-1 μm SFs contain 1M-$1M_d$ illite. A small admixture of $2M_1$ illite occurs only in coarser SFs (0.6-1 and 1-2 μm). The SFs of the sample from Minyar section also consist of illite. $1M_d$ illite is abundant in finer SFs (0.1-0.2 and 0.2-0.3 μm), whereas 1M illite with some amount of $2M_1$ dominates in coarser SFs (0.3-0.6 and 0.6-1 μm). Illites in all the SFs of both samples have high CIS values (Crystallinity Index Standard) and comply with the zone of diagenesis.

Table 1: XRD and chemical data for fine subfractions of the Zil'merdak shale

SF, μm	CIS	I_{002}/I_{001}	K, %	K/Rb	$^{87}Sr/^{86}Sr$	$^{87}Rb/^{86}Sr$
# Bakeevo						
0.1-0.2	1.63	0.46	6.13	254	1.2039	62.26
0.2-0.3	1.57	0.39	6.20	254	1.1491	52.98
0.3-0.6	1.38	0.36	6.11	243	0.9223	21.54
0.6-1	1.17	0.25	5.50	235	0.8506	11.71
1-2	0.95	0.25	5.15	228	0.8282	8.915
# Minyar						
0.1-0.2	0.92	0.40	5.81	225	1.4653	80.29
0.2-0.3	0.80	0.28	5.93	235	1.3615	67.43
0.3-0.6	0.80	0.36	5.56	234	0.8999	17.73
0.6-1	0.74	0.38	4.65	215	0.8397	9.898
1-2	0.60	0.40	4.21	212	0.7854	5.358

These relationships together with the XRD data suggest that the silicate component in SFs includes a mixture of two possibly non-cogenetic illite end-members with different chemical composition. In addition, the linear alignment of the residue data points for the SFs of different size in both the $^{87}Rb/^{86}Sr$ - $^{87}Sr/^{86}Sr$ and the 1/Sr - $^{87}Sr/^{86}Sr$ diagrams provides a convincing proof of the two-component mixing systematics.

Clay minerals as climatic proxies, possibilities and limitations

Deconinck, J.-F.
Laboratoire Biogéosciences UMR/CNRS 5561, University of Burgundy, Dijon, France
(jean-francois.deconinck@u-bourgogne.fr)

In sedimentary geology, clay minerals have been widely used to reconstruct palaeoclimates as it has been shown that their latitudinal distribution in modern soils depends on climatic conditions. Latitudinal distribution also occurs in marine sediments deposited in oceans, thus allowing clays from old marine sediments to be used for palaeoclimate studies. These include many techniques, the most widely used being the determination of stable isotope ratios measured on carbonates and/or phosphates that give an idea of oceanic temperatures, but few proxies except clay minerals can be used to estimate moisture which is the other main parameter of climate. The combination of stable isotopes and clay mineral studies in very fruitful, as the two main climatic parameters can be associated for the same period.

The interpretation of clay mineral assemblages in terms of climate is possible only if burial diagenesis is negligible, generally when the total burial depth is estimated to be less than 1500m. The occurrence of smectite and/or I/S R0 in the sedimentary successions indicates weak diagenetic influences but additional data on T_{max} measured on organic matter can be very useful to evaluate the diagenetic influences. Practically, in most sedimentary basins it is difficult to identify a reliable climatic signal in sediments older than the Jurassic.

In porous sedimentary rocks (sandstones or dolomites), the occurrence of authigenic clay minerals (kaolinite and chlorite) is common and should be taken into account in the interpretation of clay assemblages. Generally, strong relationships between lithology and clay assemblages reveal the occurrence of authigenic clays.

Palaeoclimatic studies should also be based on many sections originating from different sedimentary basins, because strong differences in clay mineral assemblages are often encountered from one section to another either because of differential settling processes or because of different provenances for clay minerals. Therefore a compilation of clay mineral data originating from coeval sediments is necessary.

Clay minerals must originate from the erosion of weathering profiles contemporaneous to sedimentation. This condition is rarely obtained as clays are often reworked from old sedimentary rocks cropping out on continental areas. Despite all these limitations, we present several examples from Meso-Cenozoic successions showing the possibility of using clay minerals as a palaeoclimatic tool in association with other proxies, but also some examples showing misinterpretations of clay mineral assemblages either because of diagenesis, authigenic processes or reworking from old rocks.

Cretaceous-Paleocene-Eocene sedimentation in Arctic Ocean: results from the clay minerals investigation (IODP-ACEX, 302 data)

Krupskaya, V.[1,2*], Krylov, A.[3], Garshev, A.[2] & Sokolov, V.[2]
[1]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM RAS), Moscow, Russia ([*]vi.krupskaya@gmail.com)
[2]M.V.Lomonosov Moscow State University, Moscow, Russia
[3]I.S.Gramberg All-Russian Research Institute for Geology and Mineral Resources of the World Ocean (VNIIOkeangeologia), St. Petersburg, Russia

Arctic Ocean's influence on the Earth climate is difficult to underestimate. Evolution of climatic periods of the planet is encrypted in the sedimentary section of the Ocean and can be reconstructed through a detailed study of the sediments composition. Present work is based on the materials obtained from the ACEX-IODP Leg 302 drilling on the Lomonosov Ridge, Central Arctic Ocean. Clay fraction of the Campanian, Paleocene and Eocene sediments sampled from the depths of 200-400 m below sea floor was studied with the following methods: X-ray diffraction of bulk and clay samples, scanning electron microscopy, infrared spectroscopy in the near and medium field, and thermal analysis. Based on these data, as well as published data on paleontology and stratigraphy [1,2], it is possible to study the history of the basin development in the Cretaceous-Paleocene-Eocene time including the Paleocene-Eocene Thermal Maximum (PETM), Early Eocene Climate Optimum (EOCO) and Eocene Thermal Maximum (ETM2). Each of these events, as well as the intervals between them are characterized by various associations of clay minerals and the amount of amorphous silica of different origins and different characteristics of clay minerals structure and morphology, which are interpreted as results of different conditions of weathering and transport. Based on experimental data and published materials [2,3], 7 major stages of sedimentary basin evolution in Cretaceous-Paleocene-Eocene time were distinguished:

1. Around 80 Ma (Campanian) – illite-kaolinite association, transport and deposition of material from the water flow of high density – neritic warm humid conditions. 2. ~55 Ma – PETM – smectite association, traces of transportation of sedimentary material, shallow warm basin. 3. ~ 53 Ma – ETM2 – kaolinite-chlorite-illite association, kaolinitization. 4. ~ 52 Ma – EOCO – illite-smectite association, the content of clay minerals not more than 5-10%, large-scale processes desilication, amorphous silica dominant in sediments – continental (probably soil) conditions in a warm climate. 5. ~ 49 Ma – Azola phase – smectite formation in shallow fresh water channels – continental conditions. 6. ~ 46.5 Ma – Early-Mid Eocene Cooling – smectite-illite association, the content of clay minerals 10-30%, the biogenic silica dominant. 7. ~ 44.5 Ma – high variation of clay minerals, due to drastic changes in the supply of terrigenous clay material under the seasonal ice conditions.

After that surface of Lomonosov Ridge was raised and information about sediments period from 44.5 till 22 Ma was lost.

Clays and authigenic minerals composition on the glacigenic and bedrock contact zone

Lūse, I.[1*], Karpovičs, A.[2], Segliņš, V.[2], Stunda, A.[3] & Randers, M.[2]
[1]Institute of Soil and Plant Sciences, Latvia University of Agriculture, Jelgava, Latvia ([*]Ilze.luse@llu.lv)
[2]Faculty of Geography and Earth Sciences, University of Latvia, Riga, Latvia
[3]Riga Biomaterials Innovation and Development Centre, Riga Technical University, Riga, Latvia

Origin of authigenic minerals in the Pleistocene and modern glacigenic and underlying sediments over the world is known and studied long time. Many scientists (e.g. Lavrushin & Golubiev [1], van der Meer et al. [2]) relate formation of the authigenic minerals in the glacial environment to glacial dynamics, bed material deformations and water implication on the sediments. New formed minerals in these conditions on the sediments contact zones are considered as sensitive paleo-environmental indicators.

Aim of this study was clarify possible authigenic minerals in tills from Latvia for future paleoenvironmental reconstructions. Four geological sections in Latvia were analyzed in details. The study sites are situated on the different last glaciation implication zones – the eastern, western and central parts of Latvia and all selected sites has real and visible recognizable contact zone.

Glacigenic (Weichselian) and underlying illitic clayey (Upper Devonian and Upper Pleistocene glaciolacustrine) sediments were analyzed with x-ray powder diffraction (XRD) method. Clay mineral diagnostic was performed on textured samples with chemical treatment, but untextured samples were used for quantitative analysis applied by Quanto software. Scanning electron microscopy (SEM) was used to verify identified minerals and their morphological studies.

Besides several authigenic minerals like calcite and gypsum in the clay sized fractions were recognised also primary minerals – quartz, hematite, feldspars, and secondary minerals – calcite, dolomite and clay minerals illite, kaolinite, smectite. The authigenic minerals mostly are found in the < 0.4 μm fraction, because the differences in the mineral composition do~~es~~ not indicate only mechanical material mixing as in the fractions < 2 and < 1 μm. Calcite was recognized in all clay fractions in all samples from the contact zones of studied sediments. Amount of calcite increase in the fractions < 1 μm and < 0.4 μm, but in the fraction < 2 μm variety was insignificant. The calcite amount increases until 16% in samples which were taken 15 cm above the sediments contact zone. Gypsum amount increase on the sediments contact zone was recognized in fraction < 0.4 μm in the geological section from the western part of Latvia. Clay mineral composition is different between studied geological sections and those variations at the section are not systematically, just illite quantity decrease with authigenic minerals increase in the < 0.4 μm fraction.

Observed calcite and gypsum amount increase in the clayey bedrocks and till contact zone can be explained with settling in the subglacial conditions or with groundwater activity in the postsedimentation time.

The influence of allophane and palagonite appearance on the unfrozen water content in the frozen volcanic ashes

Motenko, R.G., Kuznetsova, E.P.*, Vigasina, M.F. & Melchakova, L.V.
Lomonosov Moscow State University, Moscow, Russia
(*geotap@gmail.com)

Kamchatka and Iceland are the subject areas of very few geocryological studies. All the physical and mechanical properties of the frozen grounds and most of geocryological processes in the cryolithozone are predetermined by the unfrozen water content.

Volcanic ashes of different ages and compositions have been collected from the Kluchevskaya volcano group in Kamchatka (№1-8) and in the south of Iceland (№9). Ash samples had different ages (Table 1).

Unfrozen water content (W_w, %) in the Kamchatka ashes (at -5°C) is change from 0 to 11%; and in the Iceland ash it is 3.5 % [1]. Hygroscopic water (W_g, %) is different for all samples too (table 1).

The unfrozen water content in the studied ashes is connected with the transformation of volcanic glass and the appearance of clay minerals that is presumably controlled by the duration of alteration.

The samples were analyzed by IR-spectroscopy (IR-Fourier spectrometer FSM-1201) in order to determine their mineralogical composition [2]. As results, it was found that the sample № 1 was the waterless allophone, the samples № 2, 5, 6, 7 – were opal, № 3, 4, 8 – were allophanes with the various water contents and the sample № 5 – palagonite [3].

The thermal behavior of the allophanes and the palagonite was studied by DTA and TGA techniques on a Q-1500 D derivatograph (Hungary). The thermal study showed that the mass (W_{term}, %) loss depends directly on the ages of the investigated samples (Table 1).

Table 1: The results of water studies in the volcanic ashes

№	W_{term}* %	Age, years	Glass composition	W_g* %	W_w* %
1	0	35	waterless	0	0
3	3.8	1500	allophane	1.24	2
4	6.2	2000	allophane	4.3	10
8	16.8	8500 –9000	allophane	7.3	10
2	0.6	35	opal	0	0
5	3.1	2500	opal	1	1.1
6	4.4	7000	opal	1.32	2
7	6.7	7000	opal	2.52	3
9	11.6	15000-150000	palagonite	4.71	3.5

*Comment: W_{term} – the water amount, mass. %; W_g, W_w – accordingly the gyroscopic humidity and humidity that conform to unfrozen water content (with respect to dry ground mass), %

Geochemistry of the hydrothermal dickite from Jedlina Zdroj (Lower Silesia, Poland): Fe^{3+}

Krstić, N.S., Đorđević, D.M.* & Premović, P.I.
Laboratory for Geochemistry, Cosmochemistry & Astrochemistry, University of Niš, Niš, Serbia
(*dragance73@yahoo.com)

Geochemical analysis for Fe has been made on a representative sample of the dickite-rich hydrothermal clay from Jedlina Zdroj. The mineralogy of the sample is comparatively simple, dickite being the principal component (>90 wt% of total sample), with lesser amounts of goethite and barite. Inductively coupled plasma-optical emission spectrometry (ICP-OES) measurements of the products of subsequent chemical treatments indicate that most of Fe (ca. 97 wt% of total metal) reside in the dickite (Table 1). Electron spin resonance shows that a part of Fe in the dickite structure is in the form of Fe^{3+} ions. A substantial part of these ions (as well as of Fe in the dickite matrix) was probably contained in the original hydrothermal dickite-forming solution.

Table 1: Geochemical concentrations of Fe [ppm][a] in Jedlina Zdroj dickite sample from selective leaching experiments

Fraction	Sediment (±5 wt%)	Fe (ppm)
Acetate buffer	2.0	≤1[b]
Cold-HCl	5.0	3750
Boiling-HCl	2.0	5200
Dickite	91.5	1900
Insoluble residue	0.0	-
Total sample	100.5	2030[c]

[a]Determined by ICP-OES. [b]Detection limit of ICP-OES employed. [c]Obtained by summation of fractional Fe concentrations.

From geochemistry of Fe^{3+}, it is deduced that the oxidation potential (Eh) and H^+ concentration (pH) of the solution during the formation of dickite from the Jedlina Zdroj were approximately >0.45 V (highly oxygenated) and 0-4 (highly acidic), respectively (Fig. 1).

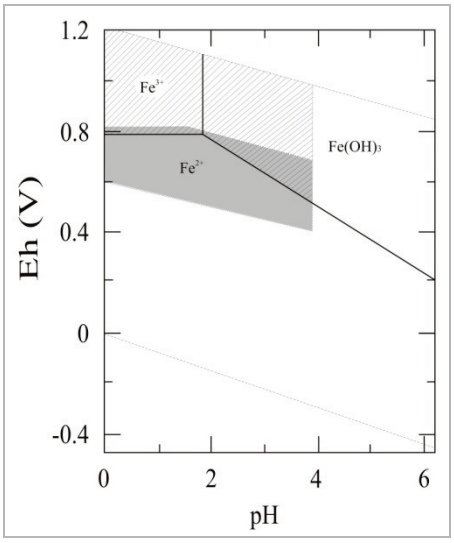

Fig. 1: Eh-pH diagram for iron species in solution at 300 K/l atm. The assumed total Fe concentration is 200 ppm. The shaded area represents Eh/pH region of the hydrothermal waters [1]. Probable physicochemical conditions of the crystallization of dickite from Jedlina Zdroj are represented by the hatched area.

Hydrothermal kaolin minerals and smectite occurrences in the Gedikler area (Uşak, western Anatolia, Turkey)

Erkoyun, H.* & Kadir, S.
Dept. of Geological Engineering, Eskişehir Osmangazi University, Eskişehir, Turkey (*herkoyun@ogu.edu.tr)

The Gedikler kaolins and coexisting alteration minerals developed within two Pliocene units: the Ahmetler Formation and Beydağı volcanites. The Ahmetler Formation is made up of the Gedikler member, comprising siltstone, claystone and tuffite that formed in a lacustrine enviroment. The Beydağı volcanites, laid down by volcanic activity in the Pliocene, comprise andesitic lava, tuff and agglomerate, which periodically fed the Ahmetler Formation.

These units have been studied via petrography, reflected-light polished-section microscopy, X-ray diffractometry (XRD), differential thermal analysis-thermal gravimetry (DTA-TG), scanning electron microscopy (SEM-EDX), IR spectroscopy (FT-IR) and geochemical analysis. Plagioclase and K-feldspar are argillized, feldspar is sericitized, biotite and hornblende are opacitized, groundmass is argillized and Fe-oxide/hydroxide phases also developed in the volcanic units.

In Gedikler area, kaolin minerals coexist with illite, smectite, gypsum, barite, quartz, calcite, feldspar, hornblende, dolomite, pyrite and traces of alunite (jarosite locally). Infrared spectral analysis exhibits two peaks at 789 (FeFe-OH) and 430 cm^{-1} (Si-O-Mg), confirming partial substitution of octahedral Al by Fe and by Mg. SEM studies reveal that kaolin occurs as rod-like halloysite and platy kaolinite, and that smectite flakes cover degraded volcanic material. Geochemically, the volcanic rocks plot within the trachyandesite and rhyodacite/dacite fields. SiO_2 contents vary from 43.55 to 66.02%, and Al_2O_3 contents are in the range of 13.12-20.86%. SiO_2/Al_2O_3 ratios decrease from fresh rock samples to pure kaolin samples. High Fe_2O_3 (0.74-14.56%) values indicate alteration and the presence of iron-oxide/hydroxide phases. High K_2O (1.03-5.26%) and lower MgO (0.10-2.28%) values reflect the presence of illite, feldspar and smectite. Na_2O and K_2O, which are highly mobile, are extensively removed from all alteration zones, reflecting plagioclase breakdown. Depletion of Mg suggests the degradation of biotite and hornblende during hydrothermal alteration. All of the samples are enriched in large-ion lithophile elements (LILE) and light rare-earth elements (LREE), and depleted in high-field-strength elements (HFSE) and heavy rare-earth elements (HREE) with respect to primitive mantle and chondrite, and are characterized by distinct negative Eu anomalies. These geochemical signatures reflect fractional crystallization and alteration of feldspar.

Clay mineralogy of the hydrothermal alteration around Sındırgı, Balıkesir, Turkey

Kocabaş, C.[1*], Papoulis, D.[2] & Çolak, M.[1]
[1]Dept. of Geological Engineering, Dokuz Eylül University, İzmir, Turkey (*cumhur.kocabas@deu.edu.tr)
[2]Dept. of Geology, University of Patras, Greece

Hydrothermal alteration hosted by Miocene calc-alkaline volcanism related to extensional tectonic activity is widespread in Western Anatolia. Simav Graben is the latest product of this tectonic regime and includes a wide range of ore deposits and hydrothermal mineralizations.

One hundred samples collected from the surface and cores in the alteration zones of Simav Graben were investigated by XRD, SEM and FTIR. Two types of hydrothermal alteration zones were identified: 1) hydrothermal alteration related to quartz porphyry intrusions and 2) hydrothermal alteration related to epithermal quartz veins. Close to the quartz porphyry intrusion the dominant clay mineral is mixed layer illite/smectite while at a distance of about 20 m dickite is dominant and the mixed layer clay minerals are absent. Secondary quartz and alunite are the non-clay minerals in each zone. The clay mineral sequence from inner to the outer parts of the quartz veins is as follows: kaolinite + illite→ mixed layer illite/smectite + kaolinite→ smectite. Quartz and feldspars of volcanic origin accompany the clay mineral paragenesis.

The presence of quartz-dickite indicates the formation temperature of about 160-200°C, while the transformation of illite/smectite to illite occurs at ~230°C [1,2]. The assemblage kaolinite + illite indicates a temperature of around 200-250°C. It is therefore concluded that the temperature of the hydrothermal fluids was ~200°C in the region.

Hydrothermal alteration is controlled by a fault system, which allows intrusion of quartz porphyry dikes and quartz veins. The presence of alunite and dickite is indicative of an acidic sulfate alteration [3]. On the other hand, alteration around the quartz veins indicates acid to intermediate type of alteration [1].

Mysterious silver microparticles of the Cretaceous-Paleogene boundary Fish Clay (Stevns Klint, Denmark)

Ilić, B.S.*, Đorđević, N.R. & Premović, P.I.
Laboratory for Geochemistry, Cosmochemistry and Astrochemistry, University of Niš, Serbia
(*bucabule@yahoo.com)

Instrumental neutron activation analysis (INAA) showed the Ag concentration in the Fish Clay is about 1.0 ppm and that its carbonate-free fraction contains about 2 ppm. Alvarez et al. [1] determined the Ag concentrations in the whole Fish Clay (1.2 ppm) and in its carbonate-free fraction (3.5 ppm). In order to evaluate the overall (terrestrial or extraterrestrial) source of Ag in the smectite of the Fish Clay, we compared these data with Ag contents in normal seawater, sediments, soils, igneous rocks (basalts having the highest content), upper continental crust, mantle and chondrites (Table 1). The Ag content of the Fish Clay is much higher than in seawater, sediments, soils, igneous (basaltic) rocks, crust or mantle. Thus, it is likely that none of these sources were capable to supply Ag to the Fish Clay. The concentration of Ag in the Fish Clay is approximately twenty times higher than its average content of chondrites. Consequently, it is likely that most of Ag in the Fish Clay is of the terrestrial origin.

Table 1: Ag content of the Fish Clay and potential suppliers of Ag

Rock	Ag [ppb]
Fish Clay	2×10^{3} (this work)
Seawater	2×10^{-3}
Sediments	120
Soils	700
Igneous (basaltic) rocks	37-110
Upper continental crust	530
Mantle	2.92-19
Chondrites	97-107

We also report here a new find of the occurrence of micrometer-sized silver (Ag) particles in the red layer of the Fish Clay that appear to have been embedded into the biogenic calcite matrix. 100 of these microparticles (AgMPs) were hand-picked under a binocular stereomicroscope. Energy dispersive X-ray analysis (EDS) analysis (Fig. 1A) indicates that these microparticles are composed of pure silver (>99 % of the total weight).

Stereomicroscopy shows that the AgMPs are shiny black or light brown. SEM images show that their shapes are irregular and predominantly rounded with rugged surfaces that often contain a few pits and voids (Fig. 1B). Aggregates of numerous AgMPs are spherical (Fig. 1C), and some of them exhibit dendritic textures (Fig. 1D).

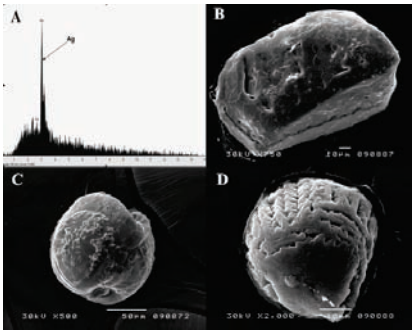

Fig. 1: Ag microparticles from the red layer of the Fish Clay: (A) EDS spectrum; and SEM micrographs of samples: (B) rounded; (C) common spherical; (D) spherical with dendritic surface texture.

Geochemistry of the Cretaceous-Paleogene boundary (Fish Clay) at Stevns Klint, Denmark: Au in the basal black marl

Krsmanović, M.M.*, Stanković, M.N. & Premović, P.I.
Laboratory for Geochemistry, Cosmochemistry and Astrochemistry, University of Niš, Serbia
(*milena.krsmanovic@yahoo.com)

The Fish Clay (of earliest Danian age) at Højerup belongs to one of the classic Cretaceous-Paleogene boundary deposits at Stevns Klint. This boundary clay constitutes four distinctive layers: the latest Maastrichtian bryozoans-rich chalk, a 2-5 cm thick basal black marl, brown-to-grey marl and grey marl overlain by the lower Danian Cerithium limestone Member. Black and brown-to-grey marls represent the main part of the Fish Clay. The mineralogy of the black marl is comparatively simple, smectite and authigenic (mainly biogenic) calcite being the principal components.

We report here the study of Au in the black marl and in its inorganic (carbonate, smectite, silicate) and kerogen fractions. The selective leaching procedures were used to establish geochemical associations and specific mineralogical residences for Au. The sample was analyzed by instrumental neutron activation analysis (INAA).

Table 1: Geochemical data for Au of basal black marl

Metal		Fraction*				
		Total	Carbonate	Smectite	Silicate	Kerogen
Geochemical concentration						
Au	[ppb]	25	0	35	10	475
Geochemical distribution						
Au	[ppb]	25	0	15	<5	10
	%	100	0	60	6	34

*The percentage of the whole sample: carbonate [52.0 %], smectite [21 %], silicate [25.2 %], kerogen [1.8 %]

The analytical results (Table 1) indicate that most of Au resides in the smectite (60 %) and kerogen (34 %). We suggest that a substantial amount of this metal was probably contained in the detrital smectite (and kerogen) arriving at the site of deposition. Preliminary considerations implied that Au in the black marl could have been both of terrestrial and of meteoritic origin.

Cation exchange capacity (CEC) – a tool for determination of secondary alteration of chlorite from Fore Sudetic Monocline (western Poland)

Sokalska, E.T.[*] & Aagaard, P.
Dept. of Geosciences, University of Oslo, Norway
([*]e.t.sokalska@geo.uio.no)

Chlorites are very common metamorphic and hydrothermal minerals composed of Mg, Fe, Al and Si. They are phases, which can be unstable during retrogressive metamorphism or late stage hydrothermal alteration.

Chlorites from Bolewice-1 borehole (western Poland) were studied using XRD and EMPA methods. Diffraction data indicate that the chlorites are usually altered. The aim of this study was to find a tool suitable for the analysis of spatial differences in the degree of alteration. CEC was applied to determine changes in degree of chlorite alteration in thin section scale. There procedure proposed by [1] using in situ Cs saturation on thin sections and electron microprobe analysis was applied.

There are two factors controlling CEC of partly altered chlorites. First of them is late fluid migration producing vermiculitization of chlorite and the second one is K-metasomatism and celadonite formation which can close the crystal structure to Cs.

The main factor controlling chlorite alteration under retrograde conditions is the contact with migrating fluid. EMPA data collected from samples saturated with Cs indicate that there is strong decrease in CEC in the case of amygdules with good sealing, where secondary fluids couldn't migrate. In these cases CEC can have values less than 3 meq/100 g even if there was no K-metasomatism, whereas clays, which fill pseudomorphs after pyroxene indicate highly differentiated values, usually from 8 to 11 meq/100 g, sometimes even higher than 12 meq/100 g. These values are lower than reported before for mixed layer phases [1], but evidently higher than values proposed for pure chlorite, which should not have any CEC. Moreover, CEC varies between samples from different depths and sometimes indicate values in range 4 – 6 meq/100 g. This is in agreement with XRD data showing different degrees of chlorite alteration.

Celadonitization affected both clays from the amygdules and pseudomorphs and was probably a relatively early process, forming celadonite layers in amygdule fillings. It is connected with the decrease of CEC to values smaller than 5 meq/100 g because K stabilizes crystal structure and does not allow for Cs incorporation into it.

Results of this study indicate that CEC is extremely useful for some type of investigations in clay mineralogy. It allows for discrimination of spatial changes in clay mineral distribution connected with their partial decomposition and alteration, giving us insight into late fluid migration development during hydrothermal metamorphism.

Bentonite; its resources and geological settings in Iran

Ghorbani, M.[1,2*] & Tajbakhsh, P.[2]
[1]Dept. of Geology, Faculty of Earth Sciences, Shahid Beheshti University, Tehran, Iran
[2]Pars Geological Research Center – Arian Zamin, Tehran, Iran
([*]arianzamin@arianzamin.com)

Bentonite is a swelling clay rock known to Iranians for ages. Old famous scientists like Avicenna and Ebne Bitare mentioned this material, which was named clay soap (1173), taylorite (1888) and bentonite (1897). Its name is derived from the shaly Benton Formation in the U.S.A. Smectite minerals are the main components of bentonite.

Bentonite often forms in warm and humid environments such as lagoons and shallow coastal areas, which are oxidation zones with basic pH of 8-9. The source rocks of bentonites are acid volcanic rocks ranging from dacite to rhyolite. When these volcanics enter into aforementioned environments they undergo bentonitization process, which may be followed by the burial diagenesis alteration.

So far more than 70 bentonite deposits have been identified in Iran. Most of these deposits formed in the Eocene and Oligocene, i.e. during the time period with intense acid volcanic activities. No bentonite deposit has yet been found in the vicinity of plutonic bodies in Iran. In most cases, the bentonite deposits occur along the contact with acid volcanic rocks. Comparing the distribution map of bentonite deposits with the geological map of Iran, one finds the genetic relationship between these deposits and the volcanic rocks.

The age of the world's bentonite deposits ranges from Jurassic to Pleistocene. There are large reserves of the Cretaceous bentonite in the U.S.A., Europe and Asia. But most of the world's bentonite deposits belong to the Tertiary.

All bentonite deposits in Iran formed after Cretaceous. The absence of large-scale acid volcanism and presence of an exceptional marine environment dominating Iran during the Cretaceous period could explain the formation of bentonite deposits in Iran after Cretaceous. Near 40% of bentonite deposits of Iran formed in the Eocene, and there is almost equal number of the deposits of the Oligocene-Miocene age.

Lower Paleozoic K-bentonites and their application for tectono-stratigraphic correlation in Europe and North America

Huff, W.D.
Dept. of Geology, University of Cincinnati, Ohio, USA
(huffwd@ucmail.uc.edu)

Continuing studies of Ordovician and Silurian K-bentonites in Europe and North America show that many of them are distributed regionally and thus can serve as important marker horizons for stratigraphic correlation. Two examples of projects underway are from the Carnic Alps in Austria and the North American midcontinent. Lower Paleozoic K-bentonites occur in a region of the Carnic Alps that is characterized by a metamorphic overprint ranging from anchizone to epizone. As a consequence of this thermal history, the illite/smectite clay mineralogy that commonly characterizes such beds has been altered to illite and chlorite, similar to the clay minerals found in associated mudrocks. The volcanogenic origin of these beds is confirmed, however, by the presence of primary magmatic phenocrysts of biotite, apatite and zircon. In some samples the zircons show evidence of magmatic resorption. Four horizons fall approximately within the *amorphognathoides* zone at the Oberbuchach section and eight in the Lower Wenlock, which appear to be traceable across the Cellon, Oberbuchach and Nölbling sections. The K-bentonite sampled from the Uggwa section may be of a similar age to those from the Llandovery of Nölbling Graben. Sixteen levels have been recorded from the *vesiculosus* zone and upwards within the Rhuddanian and eleven from the *triangulatus* zone (Aeronian). The abundant presence of these horizons in the Llandovery sequences of the Carnic Alps is similar to those in the British Isles, Sweden, Canada and North America and documents widespread volcanism related to the closing of the Iapetus Ocean and northward drifting of microplates derived from the northern margin of Gondwana. The Osmundsberg K-Bentonite has been recognized throughout NW Europe in the late Llandovery (Telychian) and it is probable that this level may also be identified from the samples taken at this stratigraphic level from the Cellon, Seewarte and Oberbuchach sections (*celloni* zone).

Although Gondwana was tectonically quiescent during the Silurian, Laurentia experienced at least two separate phases of collision. Evidence can be found in the basal Silurian strata of the Appalachian Basin in the form of widespread sheet sands and shale successions, K-bentonites, and zones of soft-sediment deformation. K-bentonites have been positively identified at multiple levels in the Llandovery-Wenlock interval in eastern North America.

For the Silurian rocks of the Cincinnati Arch in Ohio, Kentucky, and Indiana seven depositional sequences are assigned on the basis of through-going unconformities that mirror those already recognized in the early Llandovery to early Ludlow of the northern Appalachian Basin. Revision of the conodont biostratigraphy for the Cincinnati Arch by previous authors has produced results that both agree and disagree with the other lines of data implemented in the sequence stratigraphic depositional model. Biostratigraphic correlations between southern Ohio and the Niagara Falls area are largely in agreement with correlations based on other lines of data, such as K-bentonite evidence, as are correlations between west-central and western Ohio, southeastern Indiana, and northern Kentucky. The integrated analysis suggests a relatively simple history of high-frequency relative sea level fluctuations superimposed on a tectonic signature of long-term basin subsidence and very slow forebulge migration.

Comparative investigation of Sarmatian bentonites in the region of Miskolc (North Hungary)

Papp, I.[1*], Kozák, M.[1], Kovács-Pálffy, P.[2], Püspöki, Z.[1], Vámos M.[1] & McIntosh, R.W.[1]
[1]Dept. of Mineralogy and Geology, University of Debrecen, Hungary ([*]asvanypista@citromail.hu)
[2]Geological Institute of Hungary, Budapest, Hungary

During the complex mapping and investigation of the north-eastern foreland of the Bükk Mountains, our research team noticed an extensive Sarmatian (Upper Miocene) volcanic-sediment series. The Lower and Upper Sarmatian succession showing similar lithological characteristics is subdivided by a widespread extraclastic andesite tuff. The incomplete, eroded sections of these formations occur in numerous locations in the region of Miskolc and Putnok. The thickest and most uniform sediment series is located in Sajóbábony, 5 km to the north of the city of Miskolc. This area was explored at the turn of the millenium with the support of the Széchenyi Program [1,2].

The age of the Sarmatian series was determined on the basis of bivalve fauna and by K/Ar radiometric analyses. Complex analyses were carried out on the material of the bentonitic sequence, including major and trace element analyses and several hundred X-ray diffraction and thermal analyses in order to give a horizontal and vertical, qualitative and quantitative characterisation of the bentonite deposit [3].

Another significant bentonitic sequence is located in the Avas Hill, in the city centre of Miskolc. The underlying extraclastic andesite tuff of the Sajóbábony bentonitic sediment series appears to be the overlying bed of the Avas Hill. The Sarmatian sediment sequence is found under the andesite tuff with a vertical extent of about 80 m. This sequence is composed of alternating bentonite and sandstone layers. On the basis of observations and geodetical measurements of more than a hundred outcrops, the thickness of the bentonite layers varies between 0.5 – 3 m, despite the frequent alternation of layers of different lithology. The characteristics of the bentonite layers in the Avas Hill are very similar to the sediment sequence of the Sajóbábony bentonite deposit. Weathering products of acid tuff in shallow-sea environment were identified in both locations. Both bentonitic sediment deposits contain 30 – 70 % poorly crystalline montmorillonite.

The aim of this presentation is to give a comparative mineralogical and geochemical insight regarding the two sediment sequences, and is to give an overview on the Sarmatian sequence and the processes of the shallow-marine environment from an economic geological and paleoenvironmental point of view.

Hydrothermal kaolinite occurrences of the Gediz area (Kütahya, western Anatolia, Turkey)

Kadir, S.*, Erman, H. & Erkoyun, H.
Dept. of Geological Engineering, Eskişehir Osmangazi University, Eskişehir, Turkey (*skadir_esogu@yahoo.com)

The kaolinite occurrences at Akçaalan and Sazak (Gediz area, Kütahya, western Anatolia) formed by hydrothermal alteration of the Civanadağ tuffs and Akdağ volcanites in relation to Miocene volcanism, resulting in the development of a silica cap and iron-oxide/-oxyhydroxide veins, with local precipitation of pyrite. These units were studied via petrography, reflected-light polished-section microscopy, X-ray diffractometry, differential thermal analysis-thermal gravimetry (DTA-TG), scanning electron microscopy (SEM-EDX) and geochemical methods. Petrographically, the volcanites comprise andesite, rhyolite and tuff. Plagioclase and K-feldspar are argillized, biotite and hornblende are opacitized, groundmass is argillized, and Fe-oxide/-hydroxides are widespread in these volcanic units. Mineralogical zonation, such as kaolinite+opal-CT in the inner zone and smectite+illite outward, is observed. Kaolinite, quartz, smectite, illite, opal-CT, feldspar, calcite and dolomite were all determined in these rocks. Micromorphologically, kaolinite is well-crystallized and of vermiform character. SiO_2 of the bulk rocks vary from 52.06 to 70.91%, and Al_2O_3 from 14.71 to 20.77%. Despite increasing SiO_2, Al_2O_3 and Fe_2O_3+TiO_2 decrease laterally, and Fe_2O_3 increases upward. Decreasing Sr values suggest degradation of feldspar at low temperatures. Albitization is compatible with decreasing Rb and K contents. Al was enriched during hydrothermal alteration, in contrast to other elements, which were depleted. All samples are enriched in large-ion lithophile elements (LILE) and light rare-earth elements (LREE), and depleted in high-field-strength elements (HFSE) and heavy rare-earth elements (HREE) with respect to primitive mantle and chondrite. Negative Eu anomalies, relative to chondrite, reflect alteration of feldspar. Field observations along with mineralogical and geochemical determinations reveal that kaolinites of the Gediz area developed by hydrothermal alteration of feldspar, hornblende and volcanic glass within the volcanites.

Mineralogy and environment of the Qarain clay deposits, Riyadh region, Saudi Arabia

Almohandis, A.A.
Dept. of Geology and Geophysics, College of Science, King Saud University, Riyadh, Saudi Arabia (mohandis@ksu.edu.sa)

The Qarain area is about 220 km west of Riyadh city, capital of Saudi Arabia. The Qarain clay deposits lie within the Marrat Formation (Lower Jurassic). They are characterized by the dominance of kaolinite clay mineral. Illite occurs in a lesser amount in the clay fraction. The dominant non-clay mineral is quartz. X ray diffraction analyses were obtained using Ni-filtered K_α radiation from a Philips (PW1050).

It is suggested that the clay deposits were the result of partial laterization of the source rocks, mainly acid igneous rocks of the Arabian shield. Partial laterization occurred under humid tropical conditions. The weathered rocks were transported to the present area and deposited in a shallow and near shore environment of the Toarcian Sea.

The concentration of boron in the 20-2 micron grain size fraction is higher than 50 ppm with an average value of 73 ppm, while the average value of boron is 41 ppm in the finest fraction of 2 micron. It is suggested that the high B contents in the 20-2 micron size fraction largely derived from the source rocks, may indicate a non-marine origin for the Qarain clay deposits.

Stable isotopes in clay minerals from the Northern Alpine Molasse basin as archives for alpine climate and elevation change

Bauer, K.K.[1,2*], Vennemann, T.W.[1], Mulch, A.[2] & Adatte, T.[3]
[1]Institut de Minéralogie et Géochimie, Université de Lausanne, Switzerland ([*]kerstin.bauer@unil.ch)
[2]Institut für Geologie, Leibniz Universität Hannover, Germany
[3]Institut de Géologie et de Paléontologie, Université de Lausanne, Switzerland

The stable isotope composition of oxygen and hydrogen in rain water correlates with the air temperature and with the altitude of precipitation. If meteoric water is taken up into the structure of minerals with a known water-mineral fractionation factor, it is possible to reconstruct its original $\delta^{18}O$ and δD values from the isotopic composition of the host mineral.

Our study aims on reconstructing the oxygen and hydrogen isotopic composition of Miocene water via the analyses of clay minerals from different origins across the European Alps and the north Alpine foreland basin, the so-called Molasse basin. As clay minerals are hydrous, they contain both hydrogen as well as oxygen, allowing the use of both isotope systems to reconstruct the paleoprecipitation. Measurements were carried out on clay mineral separates from Molasse sediments from the northern foreland, covering the deposits from western Switzerland, via southern Germany, the Vienna Basin to the Pannonian Basin, with a sedimentation age from 8.5 to 19.2 Ma. Fossils from the same samples (ostracods, foraminifera, shark teeth, mammal remains) have already been analysed in previous studies for their O and Sr isotope composition [1, 2]. It is the aim of this study to compare the results from both the marine as well as the detrital record in order to address climatic as well as elevation changes in the Alpine region during orogenesis.

Prior to analyses, the material was treated with HCl to remove carbonates and separated to grain size fractions of <2µm, <0.5µm, and <0.2µm by centrifugation based on Stokes' law. XRD measurements were made to determine the mineralogical composition. Smectite and mixed layer minerals, determined with glycol treatment, dominate the clay fractions. SEM analyses of the clays support a detrital origin.

Oxygen isotopes were measured using CO_2 laser fluorination and hydrogen isotopes using high temperature reduction (TC/EA) on dried separates. The values of the <2µm fraction have a range of 14.1‰ to 21.2‰ for $\delta^{18}O$ and –143 to –102 for δD, relative to VSMOW. For hydrogen, a clear grain size dependence was observed, smaller particles have lower δD values down to –164‰, with a non-linear trend. The $\delta^{18}O$ values have no clear relation with grain size. It also appears that there is no overall correlation between the δD and $\delta^{18}O$ values, which indicates that both tectonic and climatic variations may have influenced their isotopic compositions.

An application of the relations proposed by [3] to calculate the $\delta^{18}O$ values of water in equilibrium with the clays and the temperature of clay formation suggests $\delta^{18}O$ values that may be as low as –8 to –9 for the water in the <2µm fraction and temperatures of 10-20°C, both of which are typical for modern precipitation in the circum-alpine region today.

Ongoing research will include sampling more material from the Molasse basin for a better spatial and temporal coverage.

The distribution of late diagenetic illite and kaolinite in Rotliegend aeolian sandstones from the Fore-Sudetic Monocline, SW Poland

Biernacka, J.
Inst. of Geology, University of Poznan, Poland
(julbier@amu.edu.pl)

In terms of hydrocarbon prospecting, Rotliegend aeolian dune sandstones from the Fore-Sudetic Monocline constitute a good target. Their reservoir properties depend primarily on diagenetic clay minerals, which not only are the most abundant among authigenic phases but also dominate the grain surface area. Whereas illite is by far the most ubiquitous diagenetic phase, other clay minerals occur locally. The mutual relationship between late diagenetic illite and kaolinite was studied for the south-eastern part of the Fore-Sudetic Monocline, where these two minerals are common, by a combination of methods (polarising microscopy, XRD, SEM, XRF).

The Rotliegend sandstones are buried at a depth of ca. 2000 m in the area studied, which is the minimal burial after a two-stage Mesozoic inversion. Three distinct sandstone types were observed: (a) kaolinite-rich arenites devoid of detrital feldspars, (b) illite-rich arenites with scarce detrital feldspars, and (c) feldspar-bearing arenites (av. 10 vol% Fsp) containing fibrous illite. Individual types occur in adjacent wells, distant from several hundred meters to 1-2 kilometres. The illite and kaolinite exhibit features of late diagenetic minerals that crystallized after significant compaction and post-dated other diagenetic phases (hematite, dolomite, quartz). The fibrous illite co-occurs with the kaolinite in some wells. Also, the remnants of kaolinite dissolved flakes with illite growing on them were observed under SEM.

A relatively small area studied and one sedimentary facies (aeolian dune) allow assuming similar initial parameters, such as framework grain composition and porosity. Therefore, the crystallization of late diagenetic kaolinite (a) and illite (b) must have been associated with a pore-fluid flow and the alteration of detrital feldspars whereas the fibrous illite (c) crystallized independently at a later stage without feldspar dissolution. A model proposed by Gaupp et al. [1] of acid pore-fluids originated from Carboniferous coal-bearing rocks juxtaposed Permian sandstones along faults is in accord with the case studied. The pore-fluid flow resulted in kaolinite crystallization in the vicinity of faults and illite formation in more distant zones from more neutralized fluids.

K-Ar ages versus grain size and illite Kübler index: a case study of parametamorphic rocks from eastern Mt. Papuk, Croatia

Biševac, V.[1*], Balogh, K.[2], Tibljaš, D.[1] & Balen, D.[1]
[1]Inst. of Mineralogy and Petrology, Dept. of Geology, Faculty of Science, University of Zagreb, Croatia
([*]vabisevac@geol.pmf.hr)
[2]Inst. of Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary

One of the frequent and most important problems in K-Ar dating is the contamination with detrital materials which can results in hard to interpret mixed ages. The coarse fraction isolated from samples is most often heterogeneous i.e. composed partially of detrital minerals and of more recent authigenic minerals which grew as a result of post-depositional thermal processes. Variable age mostly depends on the proportions of detrital and authigenic phases, both of which are considered to have a fixed K-Ar age. On the contrary, it is generally assumed that small grain-size fractions (e.g. <2 μm fraction) are mostly devoid of the detrital mica, while their K-Ar age represents the "mix age" of different generations of illitic minerals present within it.

A special attention here was paid to the evaluation of the influence of detrital minerals by observation of variation in K-Ar ages and illite Kübler index (KI) obtained on different grain-size fractions. Samples of high temperature anchizonal to epizonal altered parametamorphic rocks, representing various lithologies with different petrographic characteristics and stratigraphic age were used for this purpose.

Some trends can be observed. The decrease of K-Ar ages with decreasing grain-size (Fig. 1) can be attributed to an increase of diffusion of radiogenic ^{40}Ar resulting in increasing reset of the K-Ar system with decreasing grain size and to a reduction of detrital minerals contamination effect which becomes less and less pronounced as grain size decreases. Furthermore, KI of the finer fractions increases with decreasing grain size showing negative correlation with decreasing K-Ar ages. This effect is closely connected with the prolonged formation of illitic minerals and their wide temperature stability.

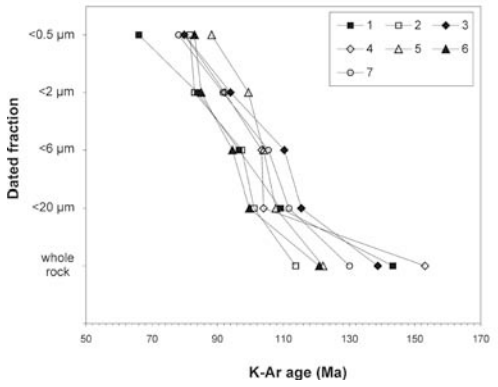

Fig. 1: K-Ar ages determined for different grain size fraction of analysed samples (1- chlorite schist; 2 - chloritoid schist; 3 - metasandstone; 4 - quartzite; 5 - phyllite; 6 - phyllitic metaconglomerate; 7 - quartz metasandstone).

Clay mineralogic evidences for a Mid Paleozoic tectono-thermal event in Zonguldak Terrane, NW Turkey

Bozkaya, O.[1*], Yalcin, H.[1] & Goncuoglu, M.C.[2]
[1]Dept. of Geological Engineering, Cumhuriyet University, Sivas, Turkey ([*]bozkaya@cumhuriyet.edu.tr)
[2]Dept. of Geological Engineering, Middle East Technical University, Ankara, Turkey

The Zonguldak Terrane (ZT), a Gondwana-derived continental microplate [1] along the Black Sea coast in NW Anatolia, was believed to comprise more or less continuous Paleozoic successions. It was considered to be rifted off the northwestern Gondwana-margin in the Early Paleozoic and drifted across the Rheic Ocean during the Mid Paleozoic and successively accreted to Laurasia along the Eastern European Suture during the Variscan Orogeny [2]. Along several cross-sections in ZT, the siliciclastic rocks of Ordovician to Middle Silurian age overlay unconformably a Cadomian basement with orthogneisses, oceanic and island-arc sequences. Late Lower Devonian quartzites unconformably overlay Middle Silurian (Wenlock) graptolitic shales, indicating an important event.

This study aims to investigate whether this unconformity is accompanied by a thermal event, and hence to trace the fingerprints of an orogenic overprint. For this, the diagenetic characteristics of the Paleozoic sedimentary rocks in ZT are investigated by means of petrographic and X-ray diffraction methods. Clay mineralogic associations, Kübler Index value (KI), *b* cell dimension (Å) and polytype of illites are determined throughout Ordovician-Carboniferous units. Siliciclastic and calcareous rocks mainly contain phyllosilicates, quartz, feldspar, calcite, dolomite, hematite and goethite minerals. Phyllosilicates are represented by illite, chlorite, kaolinite, mixed-layered chlorite-vermiculite (C-V), chlorite-smectite (C-S) and illite-chlorite (I-C). Quartz and clay/phyllosilicate minerals are common in all formations, whereas the amounts of feldspar, calcite and dolomite increase in some levels. The main phyllosilicate assemblages of Ordovician-Silurian units are illite + chlorite + I-C ± C-V ± C-S, whereas Devonian-Carboniferous units have illite + kaolinite + chlorite. The appearance of kaolinite and the absence of chloritic mixed-layers in the Devonian units is the main difference in terms of the clay mineral association. KI values of Ordovician-Silurian and Devonian-Carboniferous units (0.58 ± 0.18 and 1.13 ± 0.24 Δ°2θ) reflect late diagenetic and early diagenetic grades, respectively, and show sudden jump from Silurian to Devonian. The *b* cell dimension values of illites of Ordovician-Silurian units (9.011 ± 0.013 Å) are somewhat higher than those of Devonian-Carboniferous units (8.998 ± 0.012 Å). Illites are composed of a mixture of the $2M_1$, $1M$ and $1M_d$ polytypes. Ordovician-Silurian units have $2M_1$ and $1M_d$, whereas Devonian-Carboniferous units include $1M$ polytype in addition to $2M_1$ and $1M_d$ polytypes.

In brief, the new mineralogic data indicate that the pre-Middle Devonian rocks in ZT experienced a tectono-thermal event, prior to the Middle Devonian transgression. This Caledonian-time event is also reported in some Balkan-Moesian terranes but not noticed in the neighboring Istanbul Terrane, supporting a complex terrane distribution [3] at the S margin of Laurasia, prior to the Variscan closure of the Rheic Ocean.

Clay minerals composition: a significant tool for glacial till studies and paleo reconstruction, with a reference to the glacial history in Drenthe - the Netherlands, North West Germany and the Baltic

Bregman, E.P.H.[1*], Lūse, I.[2], Stunda, A.[3], Karpovičs, A.[4] & Randers, M.[4]
[1]Province of Drenthe & Faculty of Geosciences, Utrecht University, Utrecht, the Netherlands ([*]E.Bregman@drenthe.nl)
[2]Inst. of Soil and Plant Sciences, Latvia University of Agriculture, Jelgava, Latvia
[3]Riga Biomaterials Innovation and Development Centre, Riga Technical University, Riga, Latvia
[4]Faculty of Geography and Earth Sciences, University of Latvia, Riga, Latvia

Till deposits reflect glacial history of landscapes. That is the main reason to have good knowledge about tills for paleo-reconstruction of glaciations and a better understanding of the impact of glacial processes on actual eco(-hydro)logical relationships. For sustainable protection and development of nature- and landscape-values more insights in till deposits are therefore necessary. That is the main conclusion of a recent study in Drenthe, the Netherlands [1].

The aim of our study is to verify a new glacial model. To differentiate glacial tills and sedimentation conditions for (i) glaciations (Saale, Weichsel) in the Netherlands, Germany and the Baltic; (ii) stages within glaciations in Drenthe and (iii) supposed phases within one stage with attention to local conditions.

XRD analyses of clay minerals confirm conclusions of formerly used analyzing techniques (e.g. shear stress-measurements). Clay minerals and their structures are tools to differentiate tills from different stages and phases of surging at a lower level. Contrary to other methods quarries are not needed for sampling. So the method opens more possibilities for sampling and studying tills at more places in areas with a lack of quarries like in Drenthe province.

Our study shows that clay mineral composition in glacigenic sediments indicates significant influence of glacial sedimentation conditions such as sediment transport and postsedimentation changes. Vermiculite is a clay mineral that indicates postsedimentation changes – weathering and soil forming processes. Various mineral compositions may indicate sediment mixing due to surging processes. It was possible to separate different till forming stages.

Our final conclusion is that clay minerals are a useful tool for paleo environmental reconstruction of glacial landscapes of different ages, which give more information about positional, local conditions of formed tills. We showed that in Drenthe, the Netherlands, tills are formed under saltwater conditions whereat indicate authigenic minerals (basanite, halite, syngenite) in fraction < 0.2 µm. The influence of pro- and subglacial processes to surface pressed up deep groundwater changed till composition and weathering products does have also an ecological impact.

TEM-AEM study of hydrothermal smectite formation in Fe-Mn-metalliferous sediments: samples from the HMS Challenger expedition (1872-1876)

Cuadros, J.[1], Dekov, V.[2], Arroyo, X.[3*] & Nieto, F.[4]
[1]Dept. of Mineralogy, Natural History Museum, London, UK
[2]Dept. of Geology and Paleontology, University of Sofia, Bulgaria
[3]Depto. de Mineralogía y Petrología, Universidad del País Vasco, Bilbao, Spain ([*]xarroyo001@ikasle.ehu.es)
[4]Depto. de Mineralogía y Petrología and IACT, Universidad de Granada-CSIC, Granada, Spain

The aim of this study is to investigate the formation of smectite in three samples of submarine Fe-Mn-metalliferous sediments of hydrothermal origin, collected by the British HMS Challenger during the first oceanographic expedition (1872-1876). They were collected from the seafloor in the vicinity of the Pacific-Antarctic Ridge and the Chile Ridge. Firstly, the samples were analyzed by means of XRD, chemical analysis, SEM-EDX and IR. After removal of biogenic calcite, the results from the above techniques indicated that they consist mainly of two amorphous or semiamorphous phases intimately mixed: Fe-Mn oxyhydroxides and a Si-Al-Mg-Fe phase of chemical characteristics similar to smectite and with variable proportions of the above elements.

The TEM-AEM study was carried out to complete the previous data. The analysis, obtained from powders dispersed on holey C-coated formvar Au grids, showed the morphological and chemical characteristics of the several components of the sediment. To clearly identify mineral phases, SAED patterns, High-Resolution images and microanalyses were correlated. The appearance of Fe-rich oxyhydroxides, as round-shape particles, is clearly different from that of the other phases. Mn-rich oxides, previously identified by XRD as the δ-MnO_2 phase, related to birnessite, aggregate to form high-contrast clusters with an apparently layered structure. Smectite particles have the typical flaky and wavy morphology of smectite with the particular presence of relative large basal plates. These smectite particles always appear associated to Fe-Mn oxyhydroxides. Smectite composition corresponds in most cases to nontronite, frequently containing a trioctahedral (Mg-rich) component, although there are compositions corresponding to Fe-montmorillonite and Al-montmorillonite. No Mn-rich smectite was detected but Mn abundance is significantly greater than in typical smectites of other geological environments. Electron diffraction patterns confirm the poor crystallinity of both Fe-Mn oxyhydroxides and most smectite particles. These results are interpreted as representing hydrothermal smectite formation from Fe-Mn-rich metalliferous sediments as the Fe-rich gels react with solid particles and dissolved species. Possible sources of Si, Al and Mg are detrital silicate minerals, glass of basaltic origin, silica gel precipitated from hydrothermal fluids and seawater as the main source of Mg.

Climate recorded by clay minerals from surface sediments of Lake Kusai, the Hoh xil Area, China

Gao Xiang[*], Fang Qinfang, Ma Hongwen & Peng Qiang
National Lab of Mineral Materials, China University of Geosciences, Beijing, China ([*]xiang.gao@sohu.com)

Lake Kusai is selected as research area because it is located in natural safeguard area of the Hoh xil, northern Tibetan Plateau, having too bad natural environment and only weakly influenced by human activity. Present work is aimed at studying the relationship between clay minerals in surface sediments of a lake from high cold region and its climate in recent years.

23 surface sediment samples and their corresponding three oriented aggregates (natural air-dried, glycolated, and heat-treated) of clay minerals were studied by X-ray powder diffraction. The bulk rock results show that major detrital minerals are quartz, feldspar, and calcite, the content of summation is 65%-80%; minor phases are aragonite, gypsum, dolomite, and amphibole. The clay mineral content of the bulk rock samples is 15%-33%. Based on the analysis of oriented specimens, and according to the distribution of illite/smectite mixed-layer (I/S), we plot four districts (Fig. 1).

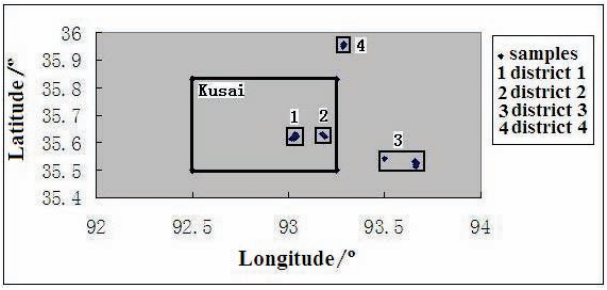

Fig. 1: Samples distributions in Lake Kusai and its nearby.

Clay minerals mainly comprise of illite (65%-82%), chlorite (12%-23%) and kaolinite (5%-7%). 4-15% ordered I/S mixed-layer appears in district 1 and 3 rather than district 2 and 4 (Table 1). Illite and chlorite as major clay minerals indicate that the whole lake area has been dominated by arid and cold climate conditions in recent years. I/S mixed-layer appearing at local areas may indicate the climate had ever undergone alternately arid-humid environment within a short period of time.

Table 1: Qualitative and semi-quantitative clay mineralogical composition, CI and IC values of illite of studied samples

Distribution	Illite	Chlorite	Kaolinite	I/S	CI	ICr	ICa
district 1	66-78%	12-24%	5-7%	5-15%	0.21-0.33	0.41-0.58	0.51
district 2	65-82%	12-25%	5-6%	0	0.27-0.35	0.30-0.46	0.39
district 3	65-77%	12-21%	5-6%	4-12%	0.24-0.33	0.43-0.58	0.48
district 4	70-74%	20-23%	5-6%	0	0.32-0.36	0.34-0.39	0.37

CI-Chemical Index of illite, ICr- IC value range, ICa –IC average value

Five international standard illite samples (provided by Prof. L.N.Warr, Germany) were tested to correct for the experimental conditions, making the data directly comparable to the international standards. The corrected illite crystallinity values (IC) of the samples from district 1and 3 are higher than those from district 2 and 4. Chemical Index (CI) values of illite are less than 0.5 indicating that it is the result of physical weathering, and possesses of Fe-Mg. Therefore, we assume that a weak hydrolysis occurs in our research area, and its intensity in district 1 and 3 is stronger than in district 2 and 4.

In conclusion, we have obtained initial results between clay minerals and the climate, and the formation mechanism of clay minerals in Lake Kusai will be studied later in details.

On spatial-temporal variations of secondary phases formed during mud diagenesis

Hellevang, H.*, Jahren, J., Aagaard, P. & Thyberg, B.
Dept. of Geosciences, University of Oslo, Oslo, Norway
(*helghe@geo.uio.no)

Chemical compaction of soft muds to shales during burial leads to large changes in rock-physical properties like stiffness porosity and permeability. The smectite to illite dissolution presippitation reaction releases surplus silica that is precipitated as fine-grained (1-3µm) pore-filling quartz crystals [1-3]. Surplus magnesium and iron is precipitated in chlorites, or if calcium carbonate is present may be precipitated as ferroan dolomites.

In this study the spatial distribution of secondary phases by varying the effective diffusion coefficient and initial spatial distribution of mineral phases have been explored using the PHAST 3D-reactive transport code. The initial system consisted of a 1 mm cube divided into smectite-rich and smectite-poor domains discretized into 720 cells.

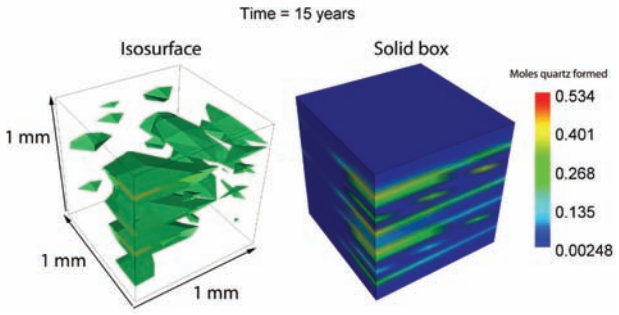

Fig. 1: Spatial distribution of quartz formed at 80ºC. Local quartz formation is dominated in the gradients between the smectite-rich low-diffusivity domains and local K-feldspar. The blue colors denote low/no formation of quartz in smectite-rich domains.

Preliminary simulations suggest that quartz and illite formation is dominated in chemical gradients forming locally between K-feldspar and smectite. As magnesium builds up the transformation slows down and may be locally constrained by the precipitation of the magnesium and iron sink (chlorite or ferroan dolomite, in addition some iron and magnesium is incorporated into illite). Low effective diffusion rates leads to strongly localized illite and quartz precipitation, whereas increasing the effective diffusion coefficient results in more dispersed precipitation. Strongly localized microquartz formation observed in cemented mudstones [1-3] support that low diffusivity and the initial spatial distribution of mineral phases controls the spatial distibution of the secondary phases.

Chemical weathering intensity and clay minerals in Plio-Pleistocene red clays (Hungary)

Kovács, J.[1*], Fábián, S.Á.[2] & Varga, G.[2]
[1]Dept. of Geology, University of Pécs, Hungary
(*jones@gamma.ttk.pte.hu)
[2]Dept. of Physical Geography, University of Pécs, Hungary

The Tertiary red clays in the Carpathian Basin of Hungary (Tengelic Red Clay Formation: TRCF; Kerecsend Red Clay Formation: KRCF) are overlain by loess paleosol sequences named Paks Loess Formation (PLF) in S Transdanubia. The thickness of the red clay ranges from 4 to 90 m. The red clay sediments are known from both exposures and boreholes. The age of these formations is ~3.5–1.0 Ma.

Elemental oxide analyses of the red clays were performed by X-ray fluorescence (XRF), and the X-ray powder diffraction (XRD) was used for mineral identification. In this study, we aim to determine the changes of clay minerals due to chemical weathering and age.

As shown in the A–CN–K diagram (Fig. 1), the samples are distributed along the joint A–CN and tend to approach the A-pole, reflecting a process in which K_2O, CaO, and Na_2O are leached out and Al_2O_3 is enriched in the samples, i.e. mineralogically, the dissolution of feldspar minerals and the production of clay minerals (smectite, illite, and kaolinite).

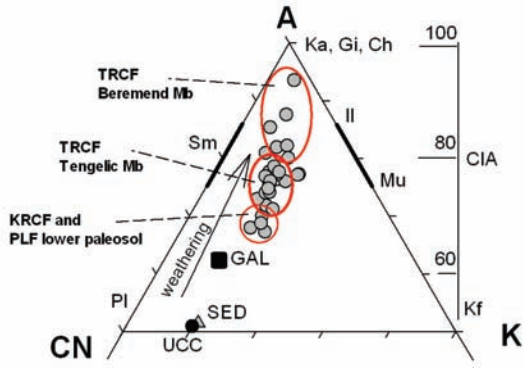

Fig. 1: Basic A–CN–K (Al_2O_3–CaO + Na_2O–K_2O) ternary diagram with CIA values showing the weathering trend of red clays. Note positions of selected mineral compositions (Pl: plagioclase, Kf: K-feldspars, Mu: muscovite, Il: illite, Ka: kaolinite, Gi: gibbsite, Ch: chlorite, Sm: smectite).GAL: global average loess [1]; SED: average sedimentary rock [2]; UCC: upper continental crust [3].

The older type (Beremend Mb) of the TRCF is a red kaolinitic clay containing typically disordered kaolinite, mixed-layer smectite/kaolinite, smectite and little gibbsite. It was formed in a local subaerial weathering crust in warm, humid, subtropical or monsoon climate. The younger member (Tengelic Mb) of the TRCF contains red (or "reddish") clay beds. It contains relatively unaltered material (rich in illite, chlorite), the weathering products are predominantly smectite and goethite formed under warm and temporarily dry climatic conditions of savannah and steppe or forest steppe. The basal red clay layers of the PLF and KRCF contain similar minerals as the underlying red clays belonging to the younger member of the TRCF. The phyllosilicate assemblage (more illite and chlorite, less smectite) indicates a decreased rate of hydrolysis triggered by cooling and/or drying of the climate.

Illite crystallinity and intensity ratio in the marine surface sediments around the Korean Peninsula

Moon Dong-Hyeok[1], Cho Hyen Goo[1*] & Yi Hi-Il[2]
[1]Dept. of Earth and Environment Sciences and Research Inst. of Natural Science, Gyeongsang National University, Jinju, Korea ([*]hgcho@gsnu.ac.kr)
[2]Marine Geoenvironment Research Division, Korea Ocean Research and Development Institute (KORDI), Ansan, Korea

Illite is the most abundant clay mineral in the marine surface sediments around the Korean Peninsula. We studied the mineralogical characteristics of illite such as Kübler index (KI) and intensity ratio (IR), using 33 surface sediments which were collected at Northwest Mudbelt deposit (NWMD, 17 samples), South Sea of Korea Mudbelt deposit (SSKMD, 3 samples), Hucksan Mudbelt deposit (HSMD, 2 samples) and Jeju Mudbelt deposit (JJMD, 11 samples).

Illite has very low KI (0.14-0.16) and wide range of IR (1.15-1.90) in the JJMD, medium to high KI (0.32-0.44) and IR (1.46-1.95) in the SSKMD and HSMD, and wide range of KI (0.28-0.58) and IR (1.08-1.70) in the NWMD (Fig. 1).

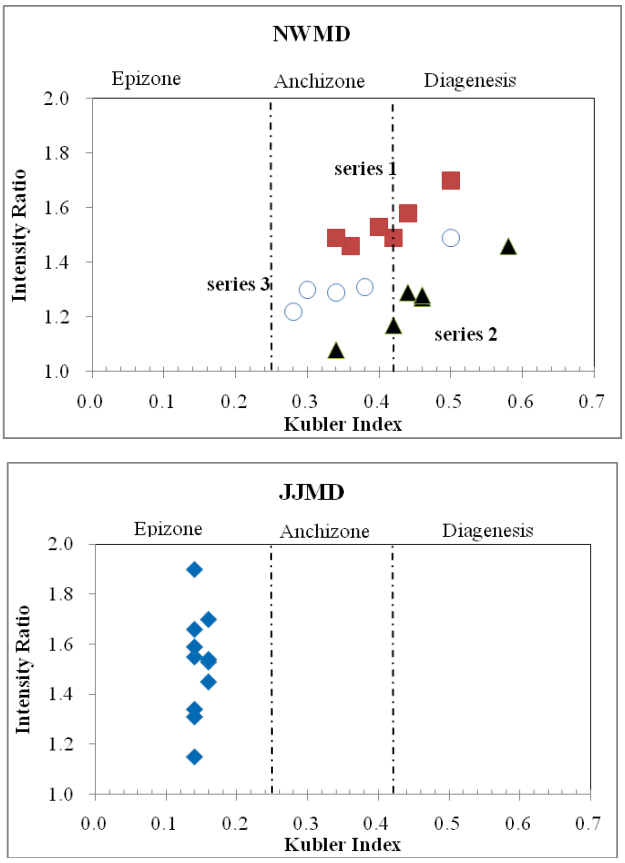

Fig. 1: Relationship between Kubler Index and Intensity Ratio at Northwest Mudbelt deposit (NWMD) and Jeju Mudbelt deposit (JJMD). Dashed lines are boundaries between each metamorphic zone after Kübler [1].

In the NWMD, KI and IR have positive relationship in the NWMD. Generally series 1 is distributed in eastern part, series 2 is in western part, and series 3 is in central part of NWMD. Each series might stand for different sediment provenance.

Cretaceous-Paleogene boundary clay (Fish Clay) at Højerup (Stevns Klint, Denmark): Cu and Cr in the smectite concentrate

Stanković, M.N.[1*], Djordjević, M.G.[1], Nikolić, N.D.[1], Todorović, B.Ž.[2] & Premović, P.I.[1]
[1]Laboratory for Geochemistry, Cosmochemistry and Astrochemistry, University of Niš, Niš, Serbia ([*]mpetaric@yahoo.com)
[2]Laboratory for General Chemistry, Faculty of Technology, University of Niš, Leskovac, Serbia

The Fish Clay (of earliest Danian age) at Højerup belongs to one of the classic Cretaceous-Paleogene deposits at Stevns Klint. The main part of this sediment constitutes basal black marl. The mineralogy of the marl is comparatively simple, authigenic (mainly biogenic) calcite and detrital (Cheto-type) Mg-smectite being the principle components.

We report here a geochemical study of trace Cu and Cr in the inorganic (carbonate, smectite, silicate) fractions and in kerogen of the basal black marl. These metals were determined by inductively coupled plasma-optical emission spectroscopy in the whole rock sample, in the inorganic fractions and in kerogen.

Table 1: Geochemical data for Cu and Cr in the basal black marl

	Fraction*				
	Total	**Carbonate**	**Smectite**	**Silicate**	**Kerogen**
Concentration [ppm]					
Cu	80	10	160	15	715
Cr	150	20	350	15	160
Distribution [%]					
Cu	100	6	74	6	13
Cr	100	7	89	<3	<3

* Composition of the whole sample: carbonate [52.0 %], smectite [21 %], silicate [25.2 %], kerogen [1.8 %].

The analytical results show that geochemical concentrations of the Cu and Cr in the smectite concentrate is 160 and 350 ppm, respectively, and most of Cu and Cr reside in this fraction (Table 1). Substantial proportion of Cu is terrestrial and was probably contained in the detrital smectite arriving at the site of deposition. The predominant source of Cr was probably ejecta fallout deposited on the top of nearby coastal soil which was leached by impact-induced, possibly, acid surface waters. Most of Cr was derived from the chondritic component of the fallout. The incorporation of Cr into the smectite took place at the Cretaceous-Paleogene boundary, before the smectite redeposition to the Fish Clay site.

Composition and origin of the Barremian clay-rich sediments from the Mljet Island, Croatia

Tibljaš, D.[1*], Balogh, K.[2], Oros Sršen, A.[3], Molnar, T.[1], Biševac, V.[1], Cvetko Tešović, B.[1] & Gušić, I.[1]
[1]Dept. of Geology, Faculty of Science, University of Zagreb, Croatia ([*]dtibljas@geol.pmf.hr)
[2]Inst. of Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary
[3]Inst. for Quaternary Paleontology and Geology, Croatian Academy of Sciences and Arts, Zagreb, Croatia

Grayish-green clay and marl can be found in several localities on the island of Mljet (Dalmatia, Croatia) within the Lower Cretaceous shallow-water carbonate platform rocks. The clays and marls are usually present as thin irregular layers, couple of centimetres thick, but in some localities they build layers having thickness up to 2 metres. They were analyzed by X-ray diffraction, IR-spectroscopic, chemical and K-Ar dating methods in order to determine their composition and origin. Samples of limestones taken immediately below and above the clay layers were analysed by micropalaeontological and microfacies methods while their insoluble residues were analysed by X-ray diffraction method. This study focuses on major mineralogical observations.

The age of underlying limestones is Barremian, as indicated by their microfossil content (mainly dasycladacean algae). Microfacies analysis of some layers, classified as algal or peloidal-bioclastic wackestone-packstones, indicate shallow sea environment with low to medium energy. Some of them show possible remains of paleosol and mm to cm-sized cracks that could be produced by plant roots (rhizoliths). Limestones above clay layer, deposited in interdital/supratidal environment, classified as mudstone-wackestones, are micritic with cracks and fenestrae showing geopetal infilling and sometimes with stromatolites. The succession of deposits is composed of shallowing-upward cycles and the clays indicate emersion.

Minerals that were determined in the clay are illite, chlorite, kaolinite and calcite. Limestones sampled above the clay layer had 0.4-2.5wt.% of insoluble residue composed of illite, chlorite and kaolinite, which is very similar in composition to the clay samples. In addition some of them contain authigenic potassium feldspar. The mineral composition of insoluble residue, which accounts for 1.6 wt.% of the brecciated limestone underlying the clay layer, is dominated by muscovite, quartz and kaolinite, which is significantly different from that of clay.

The origin of clay cannot be determined unambiguously. Different mineral composition of clay and of the insoluble residue from the underlying limestone indicates that most likely clay is not derived from these limestones. It can be presumed that volcanic dust, possibly transported by wind from very distant areas, can be the source of the clay material, which is a result of volcanic dust weathering and subsequent diagenetic processes.

Interstratified chlorite/smectite minerals from some epithermal Au-Ag vein deposits in Japan, occurrence characteristics and chemical composition

Yoneda, T.[1*], Mokko, T.[2] & Sato, T.[1]
[1]Laboratory of Environmental Geology, Faculty of Engineering, Hokkaido University, Sapporo, Japan
([*]yonet@eng.hokudai.ac.jp)
[2]Graduate School of Engineering, Hokkaido University Sapporo, Japan

Interstratified chlorite/smectite minerals including corrensite occur widely in hydrothermal ore deposits [1]. The occurrence characteristics and mineralogical properties of chlorite/ smectite minerals are important in understanding the formation in hydrothermal environments and the usefulness of hydrothermal indicators in exploration for ores. The occurrence characteristics and chemical composition of the minerals from some Neogene epithermal Au-Ag vein deposits in Japan were investigated by XRD, optical microscopy, SEM, ATEM and EPMA.

The chlorite/smectite minerals are frequently observable as a vein mineral occurring in the ore veins and as an alteration mineral in the host rocks. In the former case it is characteristic that the minerals show microscopically banded or spotted shapes of aggregates in vein quartz, closely assembled with Au-Ag minerals and/or base metal sulphide minerals, and occasionally with manganese minerals. The chlorite/smectite minerals contain Mn in addition to the major octahedral cations (Mg, Fe). The Mn content of the minerals reflects the mineral assemblage, and the minerals assembled with rhodochrosite ($MnCO_3$) show higher Mn content than those without rhodochrosite. It is characteristic that grain by grain ATEM-analysis of the minerals shows a negative correlation of (Mn + Fe) vs. Mg. In addition, Mn/Fe ratios of the chlorite/smectite minerals vary in a wide range and positively correlate with the Mn/Fe ratios of coexisting sphalerite [(Zn, Fe, Mn)S]. As alteration mineral in the host rocks, spatial distribution of the chlorite/smectite minerals exhibits a close relationship with that of the Au-Ag ore veins [2].

These observations suggest that the interstratified chlorite/smectite minerals closely associated with the epithermal Au-Ag vein deposits have formed in and around the ore veins during the Au-Ag ore formation, and that the mineralogical properties of the minerals have been constrained by the hydrothermal conditions of the vein formation.

Geological, mineralogical and chemical characterization of kaolinite from Micaya, La Paz- Bolivia

Zeballos, A.[1*], Weihed, P.[1] & Blanco, M.[2]
[1]Dept. of Chemical Engineering and Geosciences, Technological University of Luleå, Sweden (*arizeb@ltu.se)
[2]Institute of Geology and the Environment, Universidad Mayor de San Andrés, La Paz, Bolivia

The aim of this study is to characterize clay deposits in the Micaya area located between the towns of Totorani and Colquencha, in the North Altiplano, Aroma Province, La Paz in Bolivia. This area was studied in order to enhance the knowledge of the local geology and to characterize kaolinite clay deposits identified within the Vila Vila formation. Geological mapping and chemical and mineralogical analytical techniques such as x-Ray Diffraction (XRD), Differential thermal analysis (DTA), Thermo-gravimetric Analysis (TG) and Induced Couple Plasma (ICP) have been used in this study.

In the Bolivian Altiplano, three main deposits of clays have been discovered, all of them used as construction materials [1]. The clay deposits are widely distributed in the country, and are derived from alteration and weathering of igneous and sedimentary rocks, transported and eventually deposited in the Tertiary and Quaternary sedimentary basins. The geologic mapping was performed in order to identify lithological and geological features, and clay samples from the Vila Vila Formation were collected for analysis and igneous samples for petrographic studies.

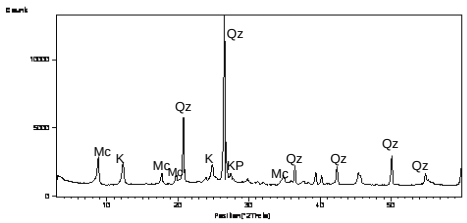

Fig. 1: Representative X-ray powder diffraction pattern of a sample from the Vila Vila Fm., showing the mineral assemblage.

In Figure 1, the XRD pattern of a representative sample from the Vila Vila formation is shown. Quartz is the major constituent showing a strong peak at 26,8° very characteristic of this phase, and is estimated semi-quantitatively as 56 wt.%. Muscovite is represented by a peak at 8,81° and estimated as 21 wt.%, kaolinite shows a peak at 12,3°, characteristic of this mineral phase [2] and corresponding to 18 wt.% and finally potassium feldspar, semi-quantitatively corresponds to 5 wt.%.

ICP analysis result confirms the XRD results with an SiO_2 content of 71wt.% and an Al_2O_3 content of 16,7wt.% for the same samples. DTA and TG analysis show an endothermic peak at 573°C related to the transformation of α-quartz to β-quartz and also an exotherm peak at 989, 1°C due to the phase change of kaolinite, when the hydroxyl (OH) groups are lost during heating.

This initial study shows that kaolinite is a major constituent of the Vila Vila Formation and could constitute a new important source of commercial kaolinite clay in Bolivia.

Character of chlorite composition in Palaeo-Uplifts of Tarim Basin, China

Zhao, M.[1*], Ji, J.F.[1], Chen, X.M.[1], Wu, C.Z.[1], Chen, Y.Q.[2], Pan, Y.G.[1] & Wu, B.[1]
[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, China (*zming412@nju.edu.cn)
[2]Survey and Design Institute of Xinjiang Tarim Oilfield, Korla, China

Chlorites are common in mudstones of the Mesozoic Formations in Palaeo-Uplifts of Tarim Basin, China. In order to study the chemical composition of chlorites, the authors collected samples systematically from different depths of bored wells. The rock samples were prepared as probe flakes. The chemical composition of was analyzed by EPMA. The analytical results are listed in Table 1.

Table 1: Results of EPMA measurements on chlorites

depth (m)	2777.4	3586.5	4405.3	5261.2
n	19	13	18	25
Al^{IV}	0.8839	1.0106	0.9880	0.9396
Al^{VI}	1.6384	1.7311	1.5581	1.6376
Si/Al	1.2462	1.0986	1.1906	1.1958
Fe/Fe+Mg	0.4551	0.5049	0.5340	0.5940
Ave.Temp (℃)	249.72	249.73	195.73	144.46

n: number of samples

The results show that in all cases the content of octahedral Al is greater than that of tetrahedral Al (Table 1), which suggests an authigenic origin and typical of what is found in other diagenetic chlorites [1,2]. The excess Al in the octahedral sites is due to the relatively high Si/Al ratio found in these authigenic chlorites (Table 1). The burial depth is strongly correlated with the Fe/Fe+Mg ratio of the chlorite. Using standard methods of geothermometry, for chlorite from the depth of 5261.2 m, a significantly lower crystallization temperature is estimated than for those from the shallower depths (Table 1). Using SEM, chlorite crystals appear together with NaCl grains except of the sample from the depth of 5261.2 m. Considering that other parameters (fO_2 and pH of the solution, coexisting mineral assemblages, and the bulk mineral composition of the host rock etc.) influence chlorite composition [3], an increased salinity indicated by the NaCl grains would be a major parameter influencing the composition of the chlorites in the area. The chemical analysis and the trace element data of rocks also show that the content of Na_2O is only 0.77 wt% in the rocks that does not contain NaCl grains , and the ratio of Sr/Ba is only 0.2; while the content of Na_2O is 1.14-2.29 wt% in the NaCl-rich rocks where the ratio of Sr/Ba is 0.4-5.7. These data can reflect the relative paleosalinity of the rocks. Because the salinities from the depths of 2777.4m and 3586.5m are higher than that of 4405.3m, thus it can be estimated the paleotemperatures are also higher. Furthermore, the paleotemperature from 5261.2m is the lowest since no NaCl grains can be observed at this depth. Therefore, chlorite geothermometry should be used with caution.

Influence of extrinsic factors on granite weathering in a glacier forefield

Wongfun, N.[1*], Brandl, H.[2], Furrer, G.[1] & Plötze, M.[3]
[1]Inst. of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland ([*]nuttakan.wongfun@env.ethz.ch)

[3]Inst. for Geotechnical Engineering, ETH Zurich, Switzerland

Initial weathering processes and soil formation are of particular interest in alpine postglacial area due to their crucial role on life under harsh conditions [1]. At near-neutral pH under aerobic conditions, the availability of nutrients in fine-grained rock material and soil is usually very low. To overcome this limitation, microorganisms and plants modify their local environment by various exudates including organic ligands, siderophores and also cyanide, which is a very important agent during the initial period of colonization and soil formation.

We study mechanisms of weathering of primary rock-forming minerals in terms of intrinsic (e.g. mineralogy, surface area) and extrinsic weathering factors (e.g. pH, Eh, concentrations of ligands). Rocks and weathered stream sediments were obtained from the Damma glacier area (Central Alps, Switzerland) at approximately 2200 m.a.s.l.

Mineralogical composition determined by X-ray diffraction spectroscopy and Rietveld analysis shows homogeneity throughout the glacier forefield. Grain-size distribution is influenced by hydrological factors such as temporal availability and flow velocity of water. In the grain-size fraction <250 µm, the effect of weathering processes was observed from the loss of feldspar and biotite.

In addition to field observations, weathering of crushed granite is investigated in controlled lab experiments. At 25 °C, the influence of cyanide is studied in batch reactors as function of pH and ligand concentrations. The concentration of cyanide is maintained by a constant partial pressure of hydrogen cyanide through gas bubbling. Thus, the concentration of cyanide anion strictly depends on pH. Preliminary results show that the presence of cyanide leads to an increase in the mobilization of phosphorus and nutrient cations (e.g. calcium and magnesium).

Initial pedogenesis in a recently exposed Alpine proglacial area

Mavris, C.[1*], Egli, M.[1], Plötze, M.[2] & Haeberli, W.[1]
[1]Dept. of Geography, University of Zurich, Switzerland ([*]christian.mavris@geo.uzh.ch)
[2]Institute for Geotechnical Engineering, ETH Zurich, Switzerland

Climate change and glacier melting feed the need for understanding the processes related to weathering of recently exposed areas. Past studies in high Alpine environments show that clay mineral formation rates are higher in younger soils (<1000 yr) than in older soils (>10000 yr). However, investigations of processes that occur in the first decades of soil formation are rare.

In the present study we investigated the clay mineral formation in a recently exposed high Alpine chronosequence. The study was undertaken in the Morteratsch glacier forefield, located in SE Switzerland. The progressively exposed proglacial area offers a full time sequence from 0 to 150 yr old surfaces. The rock basement is the Bernina crystalline unit, a lithostratigraphic formation that is mostly constituted of Variscan granitoid rocks. Previous mineralogical studies carried out in the soils of the proglacial forefield [1] show a decrease of biotite and epidote as a function of time in the fine earth fraction (<2 mm). Mineralogical measurements of the clay fraction (<2 µm) were now carried out using XRD and DRIFT. The X-ray investigations included treatments of the clay fraction (Mg- and K-saturation, ethylene glycol solvation, heating at 335 and 550°C), a hot Na-citrate treatment to determine low-charged 2:1 clay minerals, whose expansion was hindered in the untreated state by interlayered polymers, and a layer charge estimation using alkylammonium (C18). Furthermore, analyses in the d(060) range were carried out. Decreasing content of trioctahedral phases with time in the clay fraction confirm active chemical weathering processes and formation and transformation mechanisms of parent rock mineralogy.

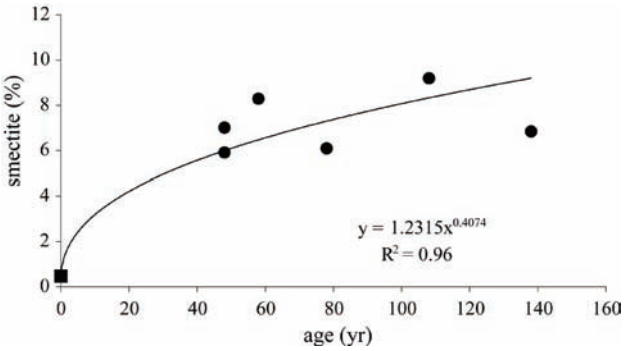

Fig. 1: Smectite formation as a function of time.

Smectite, having a charge of about 0.3 per half formula unit, was detected in a small amount already in the parent material. Along the selected chronosequence, smectite content increased steadily (Fig. 1). Hydroxy-interlayered smectites (HIS) were also present in the very early stages of soil formation and showed a weak increasing tendency with time. The clay mineral formation and transformation processes that are detectable already within a time span of 150 yr, confirm the high reaction rates of young areas in the glacier forefield.

Weathering and pedogenesis from ultrabasic rocks (dunite-harzburgite complex) in bioclimatic conditions of mountainous tundra, the Polar Urals, Russia

Lesovaya, S.[1*], Krupskaya, V.[2,3], Vigasina, M.[3] & Melchakova, L.[3]
[1]Dept. of Physical Geography and Landscape Planning, St. Petersburg State University, St. Petersburg, Russia ([*]lessovaia@yahoo.com)
[2]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM RAS), Moscow, Russia
[3]Geological Faculty Moscow State University, Moscow, Russia

Ultrabasic rocks of the Rai-Iz massif, the Polar Urals (Russia) are represented by a dunite - harzburgite complex. Shallow Haplic Cryosols (Reductaquic) [1] are located in mountainous tundra where the permafrost is at a depth of ~ 30cm. Crushed stones and gravels of serpentinous dunites (olivine) are made up by ~ 70% of the total volume in sola. Olivine grains were broken into fragments; in veins, olivine may be replaced by serpentines, talc, and chlorites. Serpentine is also may be replaced by chlorite. Fragments of olivine, amphiboles, chlorites, serpentine, and pyroxenes are frequent in thin sections of soil horizons. Source of pyroxenes are harzburgite.

Mineral identification and swelling properties of minerals were studied in fine size fractions (<1μm and 1-5μm) by a complex of methods: thermal analysis, infrared spectroscopy, scanning electron microscopy, and X-Ray diffraction (XRD) in natural disordered state and oriented mono-cationic forms (Mg, Li, K) - air-dried, ethylene glycol solvated and heated at 550°C during 2 hours.

The studied solum (loamy - clayey loamy) is pH- neutral in the upper and alkaline in the basal horizons keeping by high amounts of exchangeable Mg. In fine size fractions of sola inherited serpentine (chrysotile), talc, and chlorite are identified as well as pedogenic minerals [2]. Pedogenic minerals that are appeared in solum and are absent in rock, are represented by smectite and vermiculite. These minerals are characterised by different distribution in solum. Smectite is present in the bottom (Bgf) horizon as well as in the upper (Ah) where its content decreases. Vermiculite is identified only in the upper horizons of solum. This distribution could be a result of the acidic effect of moss and lichens despite the pH value of bulk samples. The acidic effect is the cause of: (i) selective decomposition of smectite as the most unstable minerals in acid conditions; and (ii) vermiculite appearance as a result of chlorite transformation. The intensity of processes (smectite decomposition and chlorite transformation) increases probably due to permafrost influence leading to pronounced rock disintegration and rise of their dispersion as a consequence of stability of inherited silicates.

Clay mineralogy and organo-mineral associations of Carboniferous paleosols (Moscow region, Russia)

Alekseeva, T.V.[*], Zolotareva, B.N., Kabanov, P.B. & Alekseev, A.O.
Institute of Physical, Chemical and Biological Problems of Soil Science, Russian Academy of Sciences, Pushchino, Russia ([*]alekseeva@issp.serpukhov.su)

Lower Carboniferous (Missisipian) and Upper Carboniferous (Pennsylvanian) cyclothems and subaerial unconformities of the Moscow Basin contain abundant paleosols [1]. Here we report the properties of two Lower Carboniferous (334-326 My) and Late Carboniferous (308±2 My) paleosols which were obtained by means of the following methods: XRD, XRF, HCNS, FTIR and solid-state CP/MAS ^{13}C – NMR. Additionally chemical OM fractionation has been done [2].

For Holocene paleosols organic matter (OM) mineralization results in the organic carbon (OC) loss which reaches 50-70% after several hundred years after burial. More ancient paleosols as a rule contain only traces of OC (<1%), which is predominantly concentrated in their clay fraction [3]. OM transformation in paleosols includes not only quantitative but also the compositional changes and the increasing of humic acids and aromatic component is documented

Both Missisipian paleosols were formed under (semi) humid climate. They are smectitic, where beidellite (Profile 1) and saponite (Profile 2) predominate. OC content in their clay fraction is 1.2% and 0.5% respectively. Humic acids dominate in both profiles (C_{HA}/C_{FA} = 1.23-1.53). Humin content is 45% in Profile 1 and 18% in Profile 2. ^{13}C – NMR spectra are very similar and simple with the absolute predominance of aromatic component (60-64%).

Pennsylvanian (semi)arid paleosol is palygorskitic. Its clay fraction contains 1.1 - 1.5% of OC where fulvic acids visibly predominate (C_{HA}/C_{FA} = 0.55). ^{13}C – NMR spectra show the presence of well resolved peaks of alkyl-, aromatic carbon and polysaccharides (30 : 30 : 30%).

Basing on data obtained we suppose that OC content and composition of paleosols depends not only on pedogenesis, age and conditions after burial but also on the mechanisms of OM protection. These mechanisms are determined by the mineralogical composition and interactions between mineral matrix and organic molecules. In case of Pennsylvanian (semi)arid paleosol the labile organic compounds (polysaccharides) were stabilized by palygorskite matrices to a similar extent as humic compounds and both showed the resistance against mineralization for a period more than 300 My. The remarkable preservation of fulvic type of humus is related to formation of organo-mineral derivate where organic molecules are chemically bound to palygorskite lattice [3].

Holocene climate dynamic and biogeochemistry of palaeosols

Alekseev, A.O.*, Alekseeva, T.V., Kalinin, P.I. & Tatianchenko, T.V.
Institute of Physicochemical and Biological Problem in Soil Science, RAS, Pushchino, Russia
(*alekseev@issp.serpukhov.su)

Palaeosols can act as integrative records of past climatic, lithological, geochemical, biological, and hydrological conditions. Kurgans in Russian steppe were constructed at different times from the mid-Holocene onwards; they preserve a range of palaeosols recording past environmental changes through this whole interval. Applying a soil magnetism climofunction, calculated from a modern day soil training set, to each set of buried soils enables quantitative estimation of precipitation at each time step when soil burial occurred [1].

The present study was related to the soil biogeochemical processes in connection with climate variation and duration of weathering. XRF analysis for bulk, clay and course fractions of palaeosols samples were done. Mass balance was used to differentiate between pedogenic processes and sources of elemental additions and losses. Considerable changes in the clay and iron oxide mineralogy, molar chemical ratios of the soils permit us to assess the rates of the mineralogical transformations caused by the climate dynamics in the interval of the last 5000 years. A change in soil mineralogy and as a consequence of the transformation of the chemical composition of the buried soils testifies the primary importance of climate factors in comparison with the total duration of the weathering process.

The relationship of ratio of Rb in humus horizon to the background concentration with climatic changes was observed. In soil, the behavior of Rb is controlled mainly by adsorption on clay minerals and organic matter.

The median Rb content is 60 mg kg^{-1} in subsoil and 80.0 mg kg^{-1} in topsoil; with increase in clay fraction up to 150 mg kg^{-1} in topsoil .The average ratio topsoil/subsoil is 1.45 for bulk samples, and 1.27 for clay fraction. The decrease of the K:Rb in the progressive development of soil observed. Plants use K, whereas Rb is not a biologically important cation, so the difference between the two represents pedogenesis development in our case with variability of climate.

Clay minerals and humic acids in European paleosoils

Wriessnig, K.* & Ottner, F.
Institute of Applied Geology, University of Natural Resources and Applied Life Sciences, Vienna, Austria
(*karin.wriessnig@boku.ac.at)

Soil characteristics of loess-paleosoil sequences reflect the changes of climate and vegetation during past glacial/interglacial cycles. Clay minerals, soil organic matter and carbonate content are indicators of weathering intensity and pedogenesis [1-3]. In warm periods kaolinite and poorly crystallized expandable minerals like smectite and vermiculite were formed, in cold periods enrichment in better crystallized illites, chlorites and feldspars occurred. The composition and structure of humus substances also reflect the climatic and ecological conditions during the time of their formation [4].

Different loess-paleosoil sequences from Wolkersdorf, Krems and Niederabsdorf (Lower Austria) and Dolni Vestonice (Czech Republic) were studied.

The mineralogical composition (bulk sample and clay fraction <2µm) was determined using X-ray diffraction. Dominating clay minerals in samples from all sites are chlorite, illite, and smectite, in some of the samples considerable amounts of vermiculite were found.

Soil analyses included chemical parameters like pH-value, electrical conductivity, total carbon and nitrogen, C/N-ratio, carbonate content and cation exchange capacity of the fine soil fractions. The CEC of the clay fraction was also determined. Grain size analyses were made by a combination of wet sieving and sedimentation.

Humic acids of the paleosoil samples were extracted using 1M NaOH and characterized using thermogravimetry, differential scanning calorimetry, Fourier transform infrared (FT-IR) spectroscopy and mass spectroscopy.

Sorption of copper on the eluviaton and accumulation horizons of a brown forest soil

Balázs, R.[1,2], Németh, T.[2*] & Sipos, P.[2]
[1]Eötvös Lorand University, Budapest, Hungary
[2]Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary (*ntibi@geochem.hu)

In this study copper immobilization ability in high ionic strength NaCl solution and at acidic pH is examined by comparing the sorption properties of two distinct soil horizons within one profile. The adsorption experiments were carried out on the well distinguishable eluviation and accumulation horizons of a brown forest soil, one of the dominating soil types in Hungary.

The eluviation (E) and accumulation (B_1) horizons of the studied soil profile differ from each other in their mineral composition and clay mineral characteristics. The clay mineral content of B_1 horizon is 30% larger than that of E horizon. According to the XRD studies two major clay mineral phases were distinguishable in the samples: a swelling interstratified chlorite/vermiculite in the B_1 horizon, and a non-swelling, probably hydroxy-interlayered vermiculite in the E horizon.

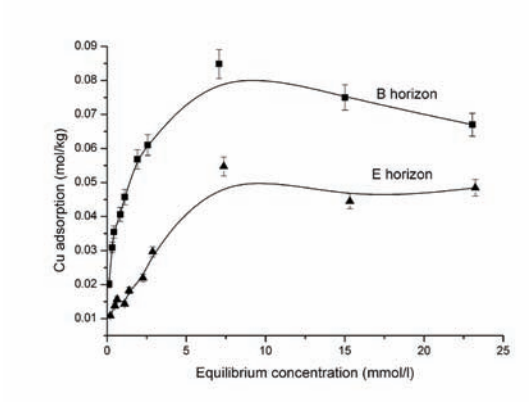

Fig. 1: Cu adsorption isotherms for B and E horizons.

The maximum copper adsorption calculated by Langmuir equation was 0.052 mol/kg Cu (3 304 mg/kg Cu) for the E horizon, and 0.071 mol/kg (4 512 mg/kg) Cu for the B horizon (Fig. 1). The differences arise from the different mineral composition of the distinct horizons. Hydrous iron oxides and swelling chlorite/vermiculite in the accumulation layer increase Cu adsorption capacity, while hydroxy-interlayering in vermiculite, and absence of iron oxides decrease Cu uptake of the eluviated horizon. Based on XRD studies, measurable fraction of Cu was sorbed in the interlayer space of vermiculite by ion exchange mechanism. This sorbed Cu caused the loss of expansion capacity of the vermiculite.

Our study of Cu adsorption on the eluviation and accumulation horizon of a brown forest soil confirmed that the different genetic layers in a soil profile can play different role in the immobilization of heavy metal contaminations.

A K/Ar study of structural and chemical changes of < 2 μm-sized minerals from fertilized soils

Balogh, K.[1*] & Kádár, I.[2]
[1]Institute of Nuclear Research, Debrecen, Hungary
([*]balogh@atomki.hu)
[2]Research Institute for Soil Science and Agricultural Chemistry, Budapest, Hungary

K/Ar dating is based on the measurement of radiogenic ^{40}Ar isotope formed by the radioactive decay of ^{40}K. The K/Ar clock starts (1) at the time of mineral formation, if this happens below the so called „closure temperature", or (2) when it cools below its closure temperature. Diagenesis and low grade metamorphism is dated mostly by K/Ar method using < 2 μm-sized minerals. Difficulties of interpretation of age data have been reviewed recently [1].

During erosion, transportation and deposition clay minerals retain their K/Ar age. The formal age of clay minerals of the Hungarian Plain is mostly Mesozoic. The influence of fertilizers on the structure and chemistry of clay minerals are summarized in [1]. Research of clay mineral transformations in fertilized soils is in progress in Hungary since the 70's [2,3].

During structural change the possible escape of ^{40}Ar(rad) and incorporation of K decrease the K/Ar "age". The samples are taken from soils treated with variable doses of N, P and K fertilizers for 35 years (Table 1). The site of the study is Nagyhörcsök, with calcareous chernozem loamy soil (20-23% clay, 5% $CaCO_3$, 3% humus in the upper 0-30 cm layer). The groundwater table was at a depth of 13-15 m, the water balance of the site was negative. The K-balance was between –2.4 and +4.9 t/ha at the end of the 35 years of the field trial. The NH_4-acetate + EDTA soluble K-content (column 3 in Table 1) showed K-deficiency and high K-supply of the plots.

Table 1: K/Ar ages of clay minerals in NPK treated soils

No.	*N*	*P*	*K*	*(1)*	*(2)*	*(3)*	*(K%)*	*Age±σ My*
1	0	0	0.00	1.88	-1.88	145	2.340	123.6±4.8
2	0	0	2.07	2.48	-0.41	235	2.542	115.1±3.6
3	0	0	4.15	2.67	+1.48	285	2.503	121.0±3.9
4	0	0	6.22	2.78	+3.44	407	2.679	115.7±3.7
5	1	0	2.08	3.47	-1.39	149	2.482	132.4±5.2
6	1	0	4.15	3.80	+0.35	197	2.443	130.9±5.1
7	1	0	6.22	4.22	+2.00	354	2.622	119.5±4.6
8	2	4	0.00	2.44	-2.44	94	2.193	127.4±5.1
9	2	5	0.00	2.00	-2.00	117	2.305	133.0±5.1
10	2	5	7.06	2.15	+4.91	754	2.975	107.5±4.2
11	2	5	7.06	2.35	+4.71	701	2.806	110.2±4.4

Given fertilizers: N0=0, N1=100, N2=200kg/ha/year (N dose); P0=0, P4=50, P5=100 kg/ha/year (P_2O_5 dose); K: t/ha/35years; (1): K uptake by plants in t/ha/35years; (2): K-balance in t/ha/35years; (3) K/soil (mg/kg); K%: in dated mineral

Data in Table 1 show that adding K decreases while N increases the "age". K added by fertilizers and trans-ported by the vegetation change the "age" similarly.

Clay mineralogy of the nickel laterite profiles associated with the Western Vardar ophiolite zone

Bermanec, V.[*], Strmić Palinkaš, S., Palinkaš, L.A., Žigovečki Gobac, Ž. & Kampić, Š.
Institute of Mineralogy and Petrography, Dept. of Geology, University of Zagreb, Croatia ([*]vberman@public.carnet.hr)

Two laterite profiles associated with the Western Vardar ophiolite zone have been investigated in order to estimate the formation conditions of the secondary minerals and the trace element behaviour during tropical weathering of serpentinite from the ophiolitic complex.

Nickel laterite deposit in the village Ba (44.15°N, 20.20°E), Serbia, has been formed by the weathering of serpentinite thrust over the Triassic limestone. The weathering of serpentinite in karstic environment produced a number of nickel-bearing minerals including nickeliferous clay minerals [1]. According to X-ray powder diffraction (XRPD) analysis the principal clay mineral is montmorillonite with cation exchange capacity (CEC) in the range between 70 and 73 mEq/100g. Gibbsite and minor amount of 7Å-halloysite occur as well.

The Ni-laterite weathering crust at Gornje Orešje locality (46.01°N, 16.22°E), Croatia, comprises, from the base up, the bed rocks (serpentinized harzburgite, massive apoharzburgitic serpentinite, apodunitic serpentine and schistose serpentinite); the saprolite zone (highly fractured and oxidized serpentinite) and the clayey zone [2]. Montmorillonite represents the most dominant clay mineral.

The following reaction illustrates the breakdown of serpentine (lizardite) into Mg-montmorillonite:

$$11\ Mg_3Si_2O_5(OH)_4 + 14\ Al^{3+} + 22\ H^+ \leftrightarrow$$
$$6\ [Al_2(Si_{3.67}Al_{0.33})O_{10}(OH)_2]Mg_{0.167} + 32\ Mg^{2+} + 27\ H_2O$$

Logarithmic activity diagram, constructed for standard conditions (p= 1 bar, t =25°C) according to thermodynamic data published by [3] and [4], indicates stability of montmorillonite at $log\ a(Al^{3+})/\ a(H^+)^3$ and $log\ a(Mg^{2+})/\ a(H^+)^2$ above 10 and 0, respectively (Fig. 1). Mobility of aluminium in form of Al^{3+} required decreased pH ($a(Al) = 10^{-6}$; pH < 4.4).

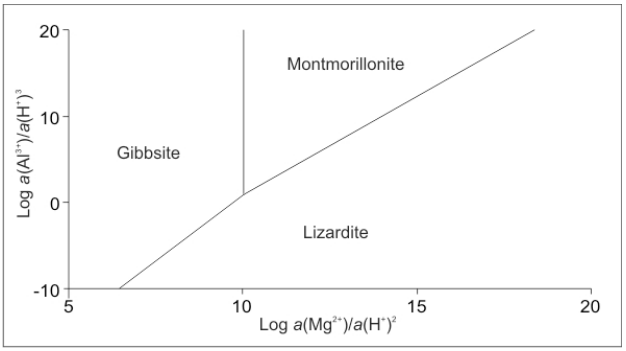

Fig. 1: Stability of Mg-montmorillonite, gibbsite and lizardite (p=1 bar; t=25°C).

Clay mineral alterations in a chronosequence of podzols on Alnö Island, Sweden

Bonatotzky, T.[1*], Haslinger, E.[2] & Ottner, F.[1]
[1]Inst. of Applied Geology, University of Natural Resources and Applied Life Sciences, Vienna, Austria
([*]theresa.bonatotzky@boku.ac.at)
[2]Energy Dept., Sustainable Building Technologies, AIT Austrian Institute of Technology, Vienna, Austria

Chronosequences are potent instruments for pedological investigations and testing pedological theories. Chronosequences are especially useful for soils that have developed on surfaces of known age, e. g. moraines, alluvial fans and terraces, lava flows and coastal sand dunes. Since the highest elevation above sea level on Alnö is 128 m at present, it was calculated that the emergence must have taken place between 7400 and 7700 years BP. As this is at the same time the beginning of terrestrial soil formation, the oldest soils on the island are subsequently between 7400 and 7700 years old. By considering the uplift of the land and the development of the shoreline, the age of a soil at a certain elevation above sea level can be determined.

Chronosequences are potent instruments for pedological investigations and testing pedological theories. Chronosequences are especially useful for soils that have developed on surfaces of known age, e. g. moraines, alluvial fans and terraces, lava flows and coastal sand dunes. Since the highest elevation above sea level on Alnö is 128 m at present, it was calculated that the emergence must have taken place between 7400 and 7700 years BP. By considering the uplift of the land and the development of the shoreline, the age of a soil at a certain elevation above sea level can be determined.

When studying soils, the examination of clay minerals is essential for determining their physical and chemical properties, as clays are often highly reactive. Clay minerals are useful for former and current weathering processes, because the weathering intensity depends on the contact area of the mineral particles and the liquid phase. It has been shown, that the rate of chemical weathering increases with decreasing particle size. The formation of clay minerals depends upon physicochemical conditions, parent material and environmental factors. Clay minerals in podzols are often formed by acidolysis, which occurs when the pH is lower than 5. The dominant clay minerals then are smectites, vermiculites, Al-intergrades and Al-chlorites.

The focus of the project is to elucidate the processes of pedogenesis in the Holocene from a clay mineralogical point of view. As clay minerals are sensitive to changes of their environment, they can be used as indicators for soil development during pedogenesis and, subsequently, as indicators for the soil age. The results of the clay mineralogical analyses and of the assessment regarding the applicability of the clay mineral distribution as relative dating method for soils, will be presented.

The effect of electrolytes on the surface layer formation of a basaltic glass

Dultz, S.[1*], Behrens, H.[1], Cramm, S.[2], Helsch, G.[2] & Deubener, J.[2]
[1]Institute of Mineralogy, Leibniz University of Hannover, Germany ([*]dultz@ifbk.uni-hannover.de)
[2]Institute of Non-Metallic Materials, Clausthal University of Technology,Clausthal-Zellerfeld, and Niedersächsische Technische Hochschule, Germany

Volcanic glasses, produced every year in high amounts by rapid cooling of magma, play an important role in the global and local cycling of numerous elements. The dissolution rates of natural glasses are affected by the composition of the surrounding solution. In presence of aqueous species that lead to the formation of Al-complexes, the dissolution rate of basaltic glass will increase [1]. In this study the zeta potential is used to determine the effect of different anions and cations on the surface layer formation of a basaltic glass.

Experiments were performed with a powder of a synthetic basalt glass with typical MORB composition, which has a mean particle size of 1.9 µm and a specific surface area of 1.7 m^2/g. For determination of electrolyte effects (e.g. NaCl, NaF, $Na_2C_2O_4$, Na_2SO_4, $Ca(NO_3)_2$, $Al(NO_3)_3$) on the zeta potential with time, 100 mg of sample were added to 200 ml of the solutions in the concentration range of 0.0001 to 0.005 mol/L. The zeta potential was determined together with the electrical conductivity of the solution (Zeta PALS, BIC).

The presence of F in the suspension resulted in a decrease of the zeta potential, indicating the adsorption of F on the surface of the basaltic glass (Fig. 1). This trend is strengthened at higher F concentrations indicating more extensive F adsorption. For non adsorbing electrolytes at higher ionic strength an increase of the zeta potential by the compression of the diffuse double layer is observed.

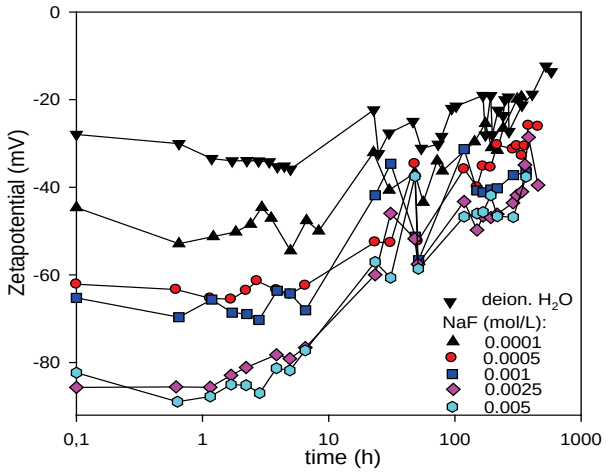

Fig. 1: Effect of NaF on the zeta potential of a basaltic glass in the time period up to 600 h.

With time zeta potential is increasing for all suspensions indicating that most probably Al and Fe in the surface layer are enriched. By the addition of divalent cations together with weakly adsorbing monovalent anions the point of zero charge is reached within the time period of 600 h at slightly acidic pH-values. Here a decrease in the dissolution rate can be assumed which is determined in currently running long term dissolution experiments.

SEM analysis of slickenside surfaces of smectitic soils of Hungary

Fuchs, M.[1] & Nyilas, T.[2*]
[1]Dept. of Soil Science and Agrochemistry, Szent István University, Gödöllö, Hungary
[2]Dept. of Mineralogy, Geochemistry and Petrology, University of Szeged, Hungary ([*]nyilas@gmail.com)

Smectitic soils develop special morphological characteristics under alternate wet-dry conditions determined by swelling pressure, occurring when the swelling clays adsorb water. The dilation of clays during hydration generates an abiotic stress resulting in special morphological features like slickensides [1], and also determines fertility, soil management practises and the success of crop production. These unique smectitic soils are classified as Vertisols according to the modern soil classification systems.

The slickensides, the most characteristic Vertisol phenomena, are polished and shiny ped surfaces, produced by one mass of soil sliding past another to relieve the stress generated by the swelling pressure. Surface characteristics of slickensides from a Vertisol of Kisújszállás, Hungary were studied on fractured, undisturbed blocks with planar orientation by Hitachi S-4700 scanning electron microscope.

The SEM analysis of the slickenside surfaces showed differences from the subjacent micromass of the ped interiors with stronger preferred orientation of clay particles, and increase in micropores. Micro-grooves approximately 4 to 20 µm wide (Fig. 1a) were detected according to the direction of the sliding, developed due to plastic deformation, or sand grains translated parallel to the direction of the shear failure. The stress reoriented clay particles resulted in a "face to face" clay alignment on surfaces of slickensides (Fig. 1b)

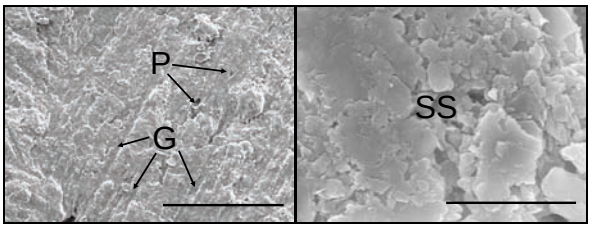

Fig. 1: Scanning electron microphotographs of slickenside surfaces (planar view) of Vertisol of Kisújszállás a) showing grooving (G) and pores (P) (bar length is 300 µm), and b) oriented clay on surface of the slickenside (SS) (bar length is 5 µm).

The presence of an oriented clay layer had direct impact on the orientation and size distribution of pores and cracks also. The presence of stress oriented clay features was resulted in smaller pore size and on slickenside surfaces. Based on the SEM analysis of the slickenside surface of the Kisújszállás Vertisol, the slickenside had pores that were generally less than 7 µm in diameter (Fig. 1a).

These characteristics could make slickensides act as semi-permeable barriers to solute transport, and effect hydrological, and chemical properties of Vertisols, determining agricultural and engineering use also. Thus the knowledge on morphology is essential to be able to make right decisions on suitable management.

Comparison of clay minerals in soils derived from basalts and phonolites under temperate climate of Lower Silesia, Poland

Łobczowski, W.[1*], Weber, J.[1], Tyszka, R.[1] & Kierczak, J.[2]
[1]Institute of Soil Science and Environmental Protection, Wroclaw University of Environmental and Life Sciences, Wroclaw, Poland ([*]wojciech.lobczowski@gmail.com)
[2]Institute of Geological Sciences, University of Wroclaw, Poland

Our study included six soil profiles derived from basalts and phonolites. Each rock was represented by 3 soil profiles. Objects were located in the Sudetes in the Lower Silesia Region, Poland (Fig. 1.). The investigated area lies under temperate climate, with temperatures 7-8.5°C and rainfalls of 650-700 mm. Soil samples were collected in upper parts of the old quarries, at elevation of 250 – 330 m a.s.l. Such approach allowed us to investigate only the effects of parent rock composition on soil properties and weathering products, and to eliminate effects of other soil forming processes. Analyzed soils represent cambisols with shallow profile. Soil samples in this study were collected from the top (A) and parent rock horizons (C) of each profile in order to determine possible differences in clay mineral composition.

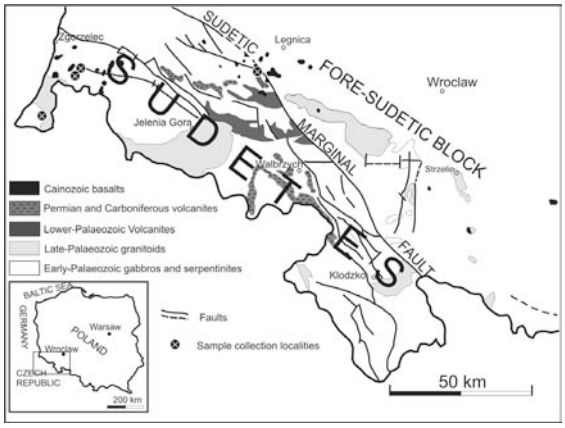

Fig. 1: Sitemap with location of sampling (based on Przybylski [1]).

The clay minerals in each sample were characterized by means of X-ray diffraction patterns and different proportions of clay minerals were observed in phonolites and basalts and also between different basalt types. Kaolinite and illite occur in all studied samples. In soils developed from phonolites kaolinite dominates, illite occurs only in small amounts and vermiculite amount is very low. It is consistent with kaolinite being the main weathering product of K-feldspar and feldspatoids, which are major components of phonolites.

Vermiculite is the dominant clay mineral in two of the investigated basalt derived profiles. Basalt, as a rock rich in Mg- and Fe-, should generally show presence of vermiculite in colloidal fractions in soils under temperate climate. In addition to vermiculite, XRD patterns revealed the presence of kaolinite and illite in the studied samples. In some profiles small amounts of smectites were also observed.

The results of our study showed that, under the temperate climate, weathering products of rocks largely depend on the original mineral composition of the parent rock.

The influence of clay on site characteristics in the Vienna Forest, Austria

Mayrhofer, M.[*], Wriessnig, K. & Ottner, F.
Institute of Applied Geology, University of Natural Resources and Applied Life Sciences, Vienna, Austria
([*]maria.mayrhofer@boku.ac.at)

The Vienna forest is situated in the very east of the Alps, on the western border of the Tertiary Vienna Basin. Covering 1,350 km^2, it is an important local recreation area for Viennese people and also serves as "Green Lung" for the City. In 2005, the Vienna Forest was also designated a Biosphere Reserve by UNESCO.

From Pleistocene till recent days the river Danube is still forming the landscape of the surroundings of Vienna. The following geological classification can be done:

- Gravel and sand from the Danube from Pleistocene till today
- Fine grained sediments like marls from Tertiary time in the Vienna Basin
- Sandstones from the Flysch zone and limestones from the Calcareous Alps
- Red marls – also named "Red Loams" - from the „Klippenzone" of the Ultrahelvetikum

During construction works in the western districts of Vienna (16th, 17th, 18th) extraordinary red loams from the above mentioned "Klippenzone" emerged. In parts of the Vienna forest these red loams are parent material for the pedogenesis.

The term „Red Loam" is generally - and colloquially - used for red soils and comprises Kalkrotlehme and Kalkbraunlehme according to the Austrian Soil Classification System as well as red marls.

Red marls are „Farb-Substratböden". Typical for those types of soil is that the profile of the soil is very much characterized by the colour of the parent material and the genetic differentiation of horizons is hidden. „Kalklehme" are very clayey soils coloured brown to red and developed from the residual material of weathered limestone.

By means of bulk and clay mineral analysis with XRD, STA, FTIR, grain size and further chemical analyses the amount and type of clay minerals in the soils will be characterized. The determined parameters are important for the water and nutrient regime of the forest soils.

The results of bulk and clay mineral analysis done by XRD show unexpected results. The content of clay is very high and reaches from 40 to 60 percent in the investigated samples. Some of them show high amounts of smectite and soil vermiculite and some contain illite and chlorite as well. Although the investigation sites are situated closely to each other, the mineralogical composition of the soils varies and shows different levels of weathering, which is a clear indicator for solifluction processes during the Pleistocene.

Organo - metal and organic matter characteristics of clays from East Maritza Coal Basin (Bulgaria)

Milakovska, Z.I.[1*], Filcheva E.G.[2] & Markova K.I.[3]
[1]Geological Institute, BAS, Sofia, Bulgaria
([*]zlatkam@geology.bas.bg)
[2]ISS "N. Poushkarov" Sofia, Bulgaria
[3]Sofia University "St. Kl. Ochridski", Sofia, Bulgaria

Ten core samples of Miocene black clays from two boreholes (East Maritza Coal Basin, Bulgaria) were characterised by their grain-size distribution, whole rock mineralogy and organic geochemistry. Organic matter composition and type were determined using modified method of Tyurin and Kononova [1,2] based on three extractions with: (1) mixed solution of 0.1 M $Na_4P_2O_7$ and 0.1 N NaOH; (2) 0.1 N NaOH; (3) 0.1 N H_2SO_4. Five fractions were received: 1-pyrophosphate, 2-basic, 3-acidic, i.e. fulvic acids (FA) aggressive fraction, 4-humic acids (HA) total, 5-HA free and/or bound to three valence cations. Humic acids optical characteristics were measured on SPECOL (absorption at λ 465 nm and 665 nm). Zinc and Al content in organo-metal complexes in the extractions were analyzed by means of ICP-OEM.

According to the textural characteristics the clayey sediments are mainly claystones (rarely clayshales) with sandy and silty admixtures up to 30%. Mixed-layered illite/smectite mainly, and kaolinite are the predominant clay minerals. Small amount of quartz and feldspar admixtures were also detected.

The samples studied differ considerably in their total organic carbon (Corg) content (the data fall in the range of 1.21-15.08 %) and do not show any dependence with depth. Non-extracted C_{org} varies from 66.89 to 88.43 %. According to the ratio C_{org} in HA to C_{org} in FA, organic matter is of a humic type in four samples, humic-fulvic - in three, fulvic - in two; and fulvic-humic - in one. In one sample HA were not extracted at all. Humic acids are bound mainly to alkaline earth ions (over 50%) in 7 samples. In two samples only, more than 50% of HA are free and/or bond to three valence cations. Very low content of the aggressive FA fraction (0.1 N H_2SO_4 extract) is characteristic for all samples studied - 0.30-1.61 % of C_{org}. The optical characteristics show that most of the HA are low molecular, low condensed ones, with high values of E_4/E_6 ratio. In three samples E_4/E_6 values vary from 2.16 to 2.74 that probably corresponds to more condensed aromatic cores of their HA.

Aluminium and Zn distribution in all fractions extracted varies irregularly, in a wide range, and independently with the depth. High mean Al values were measured for the pyrophosphate and FA aggressive fraction extracts, and low - for HA free and/or bond to three valence cations. The highest mean Zn values were detected for FA aggressive fractions, and the lowest - for the alkaline fractions. There is one sample (C_{org} - 13.33%) where maximum Al values for pyrophosphate, total and free/or three valences bound HA were measured. In another one (C_{org} - 15.08%) were detected maximum Zn values for basic extracts, HA total, and HA free /or bound to three valence cations.

Based on the result obtained one could suggest that Al in samples studied is bound mainly to HAs whereas Zn is bound mainly to FAs aggressive fraction. It could be also concluded that East Maritza Coal Basin black clays possess presumably low potential for mobile organo-metal complexes generation because the HA are bound mainly to alkaline earth ions.

Acknowledgements: The study is a part of project VU-11/06 financed by NSF, MES, Sofia, Bulgaria.

Changes of mineralogical paleoproxy indicators in a Quaternary loess–paleosol section at Beremend, Hungary

Raucsik, B.[1*], Varga, A.[2] & Újvári, G.[3]
[1]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary
([*]raucsik@almos.uni-pannon.hu)
[2]Hortseed Ltd., Mezőkovácsháza, Hungary
[3]Geodetic and Geophysical Research Institute, Hungarian Academy of Sciences, Sopron, Hungary

Weathering strongly affects mineralogy of sediments including loess deposits with intervening paleosols. A variety of semiquantitative tools has been developed to examine past weathering and pedogenesis, and to reconstruct both paleoenvironmental and paleoclimatic conditions at the time of paleosol formation.

In this study, mineralogical composition was analyzed on loess and paleosol samples from SE Transdanubia, Villány Hills, Hungary. The studied Beremend section represents the Old Loess Series (OLS; ~380–700? ka; Marine Isotope Stage (MIS) 11–17?) and partially the Young Loess Series (YLS; ~130–250? ka; MIS 5–7?) exposing three reddish brown forest soils (Be-S1, Be-S2, Be-S3; OLS) and a brown forest or forest steppe soil (Be-S4; YLS). Unconformities among sediments appear to be common.

The bulk mineral composition of sediments estimated from XRD data indicates that quartz and smectite are the dominant minerals. Interestingly, throughout both the loess and paleosol units, relative proportion of quartz shows no variation. Loess samples contain high amounts of calcite; additionally, dolomite occurs in all loess samples and in the Be-S4 samples. Illitic material together with chlorite is present in all samples but usually in small proportion. Albite, K-feldspar, kaolinite, and goethite are the typical minor components with amorphous material. Aragonite is present only in a single loess sample.

In the clay fraction of the sediments, varying amounts of smectite, illite, chlorite, and kaolinite are present. Paleosol samples can be characterized as smectite-rich compared to loess samples which contain higher amounts of illite. The entire section shows no obvious variation in kaolinite content. Chlorite content is generally low, and slightly decreases upwards.

The quartz-normalized bulk kaolinite content shows systematic variations with lithology, especially in the lower and middle part of the Beremend section (corresponding to OLS). The bulk kaolinite/quartz ratio increases upwards in loess horizons, whereas it decreases in paleosol layers. As a paleoproxy indicator, changes in bulk kaolinite/illite ratio (K/I) show significant differences between the Beremend paleosol ($K/I > 1$) and loess ($K/I < 1$) samples suggesting fluctuations in the intensity of coeval continental hydrolysis. Based on clay mineralogy, the same stratigraphic pattern in the K/I ratio is apparent. In the lower and middle parts of the section (OLS), however, the K/I ratios in paleosols are significantly higher than those of fossil soil Be-S4 (YLS). Synchronous changes in the values of smectite/illite (S/I), smectite/(illite+chlorite) (S/I+C), and smectite/kaolinite (S/K) ratios are also observed.

The relatively higher S/I, S/(I+C), and S/K ratios, observed in paleosols, suggest a strengthened chemical weathering and weak physical erosion. By contrast, lower ratios in loesses, corresponding to glacial periods, indicate intensified physical erosion and weakened chemical weathering. Fluctuation of erosion rate is also supported by variations of bulk kaolinite/quartz ratio. Significantly lower values of mineralogical proxy indicators in the upper part of the Beremend section, corresponding to the YLS, may indicate a climate deterioriation with decreasing rates in continental erosion and chemical weathering from the OLS to YLS in SE Transdanubia.

Origin of aluminium from salt efflorescence on sandstone exposures

Schweigstillová, J.[1*], Bruthans, J.[2] & Mikuš, P.[2]
[1]Institute of Rock Structure and Mechanics of the ASCR, v.v.i., Prague, Czech Republic ([*]finy@seznam.cz)
[2]Charles University in Prague, Faculty of Science, Prague, Czech Republic

Detailed study of salt efflorescence composition in many sandstone castellated rocks in the Middle Europe shows presence of Al-sulphates (alums), mostly on sandstone with clay sandstone matrix.

Isotopic composition confirmed the atmospheric origin of the salt efflorescence [1], but precipitation contains no aluminium [2]. Research in the sandstones of the Northwest Bohemia showed that sandstone vadose water may contain elevated concentrations of Al, Zn, and Cd [3].

Therefore, formation of alums can be explained by the partial dissolution of clay minerals or feldspars present in the sandstone matrix. Release of aluminium from these phases is facilitated by the low pH of the precipitation (pH 4–5) and also locally by organic acids, traces of which were found in the studied efflorescence by the use of infrared spectroscopy [1].

We studied several waters from vadose zone of sandstone and soil waters in one protected landscape area (PLA) from the Northern Bohemia (Czech Republic). Chemical composition of studied waters proved elevated content of aluminium, silica and few other ions compared to precipitation composition normalized to ET enrichment [4].

Study demonstrated that aluminium can be released from clay sandstone matrix (clay minerals or feldspars) or soil cover of sandstone. Presence of alums and other Al containing salt efflorescence is thus valuable indicator of vadose zone acidification, for example in Northern Bohemia.

The study of clay minerals from the granitoids soils developed in a temperate climate

Szadorski, J., Weber, J.[*], Tyszka, R., Dębicka, M. & Kocowicz, A.
Institute of Soil Science and Environmental Protection, Wroclaw University of Environmental and Life Sciences, Wroclaw, Poland ([*]jerzy.weber@up.wroc.pl)

Eight shallow soil profiles developed from different granitoids (leucogranite, granite, granodiorite and tonalite) were investigated, two from each rock type. The soil profiles were located in the Fore-Sudetic Block and the Sudetes, Lower Silesia, Poland (Fig. 1). To investigate only relationships between clay mineral and parent rock composition, and to avoid the effects of other soil forming factors, the profiles were located only on the top parts of hills 169 – 433 m a.s.l. and in similar climatic conditions, including rainfall 600-750 mm and annual average temperature 7.0 – 8.5 oC. The investigated soils were forest and meadow cambisols and leptosols. Two samples were collected from each of the eight profiles (the A and the parent rock horizons) to determine the possible variation in the composition of clay minerals within the profile.

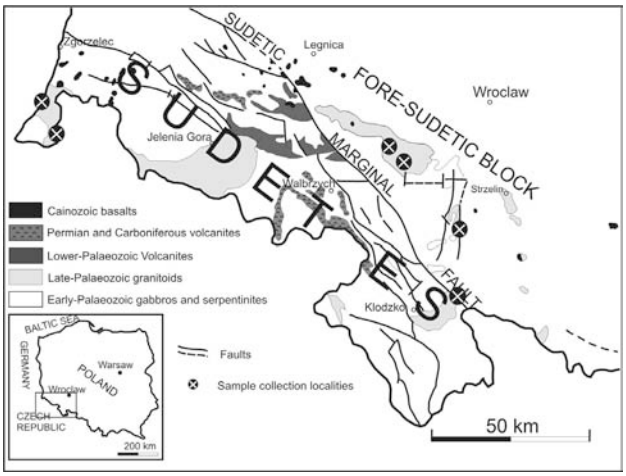

Fig. 1: Sitemap with location of sampling (based on Przybylski [1]).

The study of clay minerals showed that colloidal fraction of soil material – although developed from different granitoids and build up of different feldspars as well as different amounts of mafic minerals – consists of the same minerals. Illite, kaolinite and vermiculite are present in all of the examined profiles, but illite distinctly dominates in soils derived from leucogranite, granite and granodiorite, whereas vermiculite is the main clay mineral in tonalite derived soils, independently of the depth of the soil horizon. On the other hand, soils derived from leucogranite, granite and granodiorite reveal presence of vermiculite in the deeper horizons, while A horizons indicate significant decrease or lack of this mineral. This may suggest the process of transformation of vermiculite into illite, occurring over the time under conditions of temperate climate of Lower Silesia, SW Poland.

There were also differences in clay mineralogical composition between deeper horizons of soils derived from different kinds of granites. Vermiculite was observed in soil material derived from biotite-granite, while there were found only very weak evidence of this mineral in weathered material of two-micas-granite. This confirms that the presence of biotite in rock favours formation of vermiculite during the weathering processes.

The effect of hydrological conditions and pH on phyllosilicate transformations in pyrite-bearing schist weathering zone in Wieściszowice (Lower Silesia, SW Poland)

Uzarowicz, L.[1], Michalik. M.[2] & Bylina, P.[3*]
[1]Faculty of Geodesy and Cartography, Warsaw University of Technology, Warsaw, Poland
[2]Inst. of Geological Sciences, Jagiellonian University, Cracow, Poland
[3]Inst. of Ceramics and Building Materials, Warsaw, Poland
([*]p.bylina@isic.waw.pl)

Phyllosilicate transformations in acidic environment were investigated in the area of an abandoned pyrite open-pit mine in Wieściszowice (Lower Silesia, SW Poland) using XRD, FTIR, and SEM-EDS methods. The aim of this study was to determine the influence of hydrological conditions and pH of water on phyllosilicate transformations. Dry (well-drained) as well as wet (waterlogged) saprolite samples were investigated.

Parent rock of well-drained saprolites contained exclusively one kind of phyllosilicate: chlorite or mica. Thanks to this opportunity it was easier to determine a chlorite and mica alteration paths in highly acidic conditions (pH 2–3) separately. The chlorite schist consisted of chlorite, quartz, albite, calcite, and pyrite. Saprolite derived after chlorite schist is composed of sulfate minerals, predominantly slavikite (hydrous Mg and Fe sulfate), which it is probably formed at the expense of dissolved chlorite. Clay fraction of chlorite schist saprolite contained major chlorite and minor amounts of mica which could be redeposited from the higher part of the outcrop. Occurrence of chlorite in saprolite, even though its intense dissolution, may be caused by simultaneous physical weathering of parent rock.

Mica schist mainly consisted of dioctahedral micas: muscovite and paragonite, and quartz as well as minor amounts of albite, chlorite and pyrite. Mineral composition of mica schist saprolite is close to the parent rock with the exception of pyrite which completely weathered. Minor amounts of jarosite were also present. Clay fraction of the saprolite is composed of primary micas as well as secondary smectite, which is main component of fine grain fraction (< 0.2 μm). Presumably, smectite formed mostly at the expense of micas.

Wet samples were collected from extremely acidic Purple Pond (pH 2.7) and less acidic Blue Pond (pH 4.6). Purple Pond water contains large amounts of Fe (135 mg/l), Al (68 mg/l), Si (49 mg/l), and SO_4^{2-} ions (1740 mg/l). Content of these components in Blue Pond is significantly lower. Wet saprolites were evolved from the same parent rock – chlorite-mica schist. It consisted of quartz, albite, chlorite, muscovite, paragonite, and pyrite. Bulk mineral composition of the saprolites is similar to the parent rock, except pyrite, which is removed. Clay fraction of Purple Pond sediment contained large amount of smectite, whereas clay fraction from Blue Pond sample contained interstratified swelling mineral probably composed of smectite and vermiculite layers.

Phyllosilicate alterations in the area of Wieściszowice pyrite mine are stronger in dry conditions than in wet ones. This conclusion can be supported by presence of primary phyllosilicates as major components of clay fraction of wet saprolites as well as low amounts of secondary swelling minerals. In dry saprolites chlorite underwent intense dissolution, whereas dioctahedral micas were transformed into swelling clay mineral, mainly smectite. The pH of water is important factor influencing degree of phyllosilicate transformations in studied waterlogged saprolites. Data obtained during this study suggest that phyllosilicate alterations under the influence of extremely acidic waters of Purple Pond are more advanced than in the Blue Pond. Such feature suggests that the scale of phyllosilicate transformations is directly inversely correlated with pH value.

Mineral composition of the clay fraction in soils with a cambic horizon in the Czech Republic

Žigová, A.[1*], Šťastný, M.[2] & Krejčová, J.[3]
[1]Institute of Geology, AS CR, v.v.i., Prague, Czech Republic
([*]zigova@gli.cas.cz)
[2]Institute of Rock Structure and Mechanics, AS CR, v.v.i., Prague, Czech Republic
[3]Crop Research Institute, v.v.i., Prague, Czech Republic

Soils with a cambic horizon are commonly found in many regions of Central Europe. Processes leading to the formation of a subsurface cambic horizon are essentially the same in all climatic zones but the intensities of chemical and biological transformations are different. In the Czech Republic extensive research has been done on gneiss [1], granite and gabbrodiorite [2]. This study presents data about the effect of the parent material on mineral composition and basic properties of soils with the cambic horizon.

The research was conducted in agriculturally utilized areas. Soil profiles with a cambic horizon at the localities of Brodce (Cambic Leptosol on calcareous sandstone, 226 m above sea level, 50°20´ N, 14°52´ E), Humpolec (Haplic Cambisol on paragneiss, 523 m a.s.l., 49°33´ N, 15°21´ E), Náměšť nad Oslavou (Haplic Cambisol on paragneiss, 442 m a.s.l., 49°12´ N, 16°09´ E) and Vysoké nad Jizerou (Haplic Cambisol on orthogneiss, 680 m a.s.l., 50°41´ N, 15°23´ E) were selected for this study. Soil horizons and types were classified according to the World Reference Base for Soil Resources [3].

Samples were collected from excavated pits. Main soil properties from individual horizons, such as the particle size distribution, pH values, cation exchange capacity (CEC), organic carbon and nitrogen were analysed using common pedological methods. XRD tests were obtained on a Philips PW 3710 diffractometer. The analysis of the <1 μm fraction was performed on air-dried oriented samples, and then saturated in ethyleneglycol at 80 °C in a furnace for four hours and finally heated to 550 °C for four hours. Semiquantitative analysis was done basing on the areas of individual mineral basal peaks.

The values of pH are predominantly acid. Cambic Leptosol has a weakly acid pH in the upper part of soil profile and a basic pH further down in horizon Ck. The distribution of cation exchange capacity within the profile corresponds with the particle size distribution and content of organic carbon. Cambic Leptosol has a lower value of CEC than Haplic Cambisols.

Organic carbon content and nitrogen are higher in the upper part parts of the soil profiles. The highest values of organic carbon were documented at the localities of Humpolec and Vysoké nad Jizerou. On the other hand, the lowest organic carbon content was obtained at Brodce.

The analysis of the fraction <1 μm showed that the cambic horizon of Haplic Cambisol is dominated – among clay minerals – by illite and also by kaolinite (Humpolec) and by chlorite (Vysoké nad Jizerou). Cambic horizon of Leptic Cambisol has a higher content of kaolinite.

The results revealed differences in the formation of the cambic horizon. A major role is played not only by the parent material but also by other site-specific conditions.

Automated electron Diffraction Tomography (ADT) – a new technique for structure solution of nano-crystalline minerals

Mugnaioli, E.[*], Gorelik, T.E. & Kolb, U.
Institute of Physical Chemistry, Johannes Gutenberg-University, Mainz, Germany ([*]mugnaiol@uni-mainz.de)

Transmission electron microscope (TEM), providing imaging and diffraction information from the same volume, is a powerful tool to investigate nano materials where single crystal or powder X-ray diffraction fail. High resolution TEM can directly visualize structural features at atomic resolution, but demands high electron dose and may cause severe beam damage for frameworked and hydrated inorganic materials (like zeolites). In contrast, electron diffraction needs only a fraction of this electron dose and provides structural data with even higher resolution.

Normally, for a complete structure solution, three-dimensional experimental data are needed. Traditionally, the collection of three-dimensional diffraction data is performed by a tilt of a pre-oriented nano-crystal around a low index crystallographic axis. Diffraction patterns collected in such way are therefore oriented low index zones. This strongly limits the amount of accessible reflections and enhances dynamical effects, hampering the possibility of ab initio structure solution.

In order to reduce these problems and establish an automated routine for electron diffraction data collection and processing, we developed an Automated Diffraction Tomography (ADT) system. The full reciprocal space inside the tilt range limit of the microscope is recorded [1,2]. In order to get diffraction from areas down to 30nm and reduce the beam dose, nano-diffraction mode with mild electron dose settings is used. Crystal is imaged and tracked during the tilt in scanning transmission mode (STEM). Diffraction spots are sampled in non-oriented zones, drastically reducing the dynamical effects. Further improved intensity data come from a combination of ADT with electron beam precession techniques (PED) [3]. Cell parameter determination, three-dimensional reconstruction of reciprocal space and intensity integration are performed automatically with self-developed routines.

In the last two years a number of mineral structures have been solved by ADT. In all these cases, full *ab initio* structure solution was achieved by direct methods. A full kinematical approach was used for structure solution and refinement. The first simple test structure was $BaSO_4$ [4]. Subsequently real challenging cases were investigated. Structure solutions of natural and synthetic zeolites, as well as other large-cell nano-sized minerals, are excellent examples for ADT applications [5]. Synthetic analoga of high-pressure minerals obtained in diamond cell are another interesting area of investigation.

Focused ion beam-SEM and TEM applied to ore minerals: bridging micron- and nanoscales

Ciobanu, C.L.[1,2*], Pring, A.[1,2], Cook, N.J.[1,2] & Green, L.[3]
[1]University of Adelaide, Australia
([*]cristiana.ciobanu@adelaide.edu.au)
[2]South Australian Museum, Adelaide, Australia
[3]Adelaide Microscopy, Adelaide, Australia

Recent advances in electron microscopy techniques, and in particular sample preparation methods, offer an incredible opportunity to address ore-forming processes down to the nanoscale.

Ore minerals record their genetic histories via compositional and structural variations, and, in particular, textures and patterning observable at scales ranging from meters down to nanometers. The practical impasse in going from the micron-scale resolution of the electron microprobe (EPMA) down to the nanometer scale of the transmission electron microscope (TEM) on the same analysis spot has previously hampered attempts to link textures across these scales of observation. The recent breakthrough in TEM sample preparation using the latest generation of Dual Focused Ion and Electron beam (FIB-SEM) instrumentation enables this impasse to be overcome by allowing high-resolution examination of textures, compositions and structures at any chosen location on a sample and in unprecedented detail [1].

We will show results from practice with the Dual Beam FIB-SEM instrumentation at the Australian Microscopy and Microanalysis Research Facility, Adelaide, over the last two years, and in particular, use of the method to prepare FIB-TEM foils. Examples are drawn from the common sulphides (pyrite, sphalerite, Cu-(Fe)-sulphides and molybdenite and from chalcogenides in gold deposits (i.e. Bi-tellurides and sulphosalts).

The types of problems that can be addressed include:

- minor element incorporation,
- grain-scale redistribution of gold and
- recognition of overprinting events (e.g., disequilibrium encoded in stacking sequences of mixed-layer minerals.

The various difficulties that need to be overcome to use FIB-TEM methodology for ore minerals will also be summarised.

Quantitative electron diffraction and electron holography of magnetite at low temperature

Kasama, T.[1*], Harrison, R.J.[2], Church, N.S.[2], Nagao, M.[3], Feinberg, J.M.[4] & Dunin-Borkowski, R.E.[1]
[1]Center for Electron Nanoscopy, Technical University of Denmark, Kongens Lyngby, Denmark ([*]tk@cen.dtu.dk)
[2]Dept. of Earth Sciences, University of Cambridge, UK
[3]Advanced Materials Laboratory, National Institute for Materials Science, Tsukuba, Japan
[4]Institute for Rock Magnetism, Dept. of Geology and Geophysics, University of Minnesota, USA

The Verwey transition in magnetite is associated with an order-of-magnitude increase in magnetocrystalline anisotropy and a change in magnetic easy axis from cubic <111> to monoclinic [001] below ~120 K. Although numerous studies have suggested that magnetic domain walls in magnetite can interact with the ferroelastic twin walls that form at low temperature, no direct evidence for such interactions has been available. Here, we use transmission electron microscopy (TEM) to image both crystallographic features and magnetic microstructure simultaneously at the nanometer scale in synthetic multi-domain magnetite, which was prepared for TEM using conventional Ar ion milling.

We use selected-area electron diffraction and convergent-beam electron diffraction (CBED) to determine crystal symmetry and to identify crystallographic orientations. Energy filtering is used to improve contrast and visibility in CBED disks. The diffraction patterns show that the low-temperature phase has a monoclinic *C*-centered lattice with the *c*-glide plane perpendicular to the *b*-axis and is likely to belong to point group *m*, suggesting that the space group is *Cc*.

We use off-axis electron holography and Lorentz TEM to study the relationships between magnetic domain walls and ferroelastic twin walls in magnetite below the Verwey transition. One of the most striking features is the formation of magnetic domains that are related to "strain-contrast-free" twins. The magnetization direction orients along the monoclinic *c*-axis of each twin domain and changes by close to 90 at each twin boundary. Simulations of the recorded electron holographic phase images [1] are used to interpret the observed magnetic structures quantitatively. The ferroelastic twin walls are observed to resist even the application of a large field of 2T and the magnetic structures at remanence can then be restored. Therefore the twins may have a strong influence on the low temperature magnetic properties of magnetite. Our analysis takes into account the effect of mean inner potential contributions to the phase shift on magnetic induction maps in wedge-shaped TEM specimens.

Determination of chemical composition of planar defects in minerals using CEP method

Rečnik, A.[1*], Daneu, N.[1] & Walther, T.[2]
[1]Dept. For Nanostructured Materials, Jožef Stefan Institute, Ljubljana, Slovenia ([*]aleksander.recnik@ijs.si)
[2]University of Sheffield, United Kingdom

Different types of planar defects are present in practically all naturally occurring minerals. These defects form by different mechanisms and may, depending on their formation, contain small amounts of dopant elements. It is not uncommon that the dopant atoms occupy less then one atomic monolayer of the interstitial sites at the boundary. Various other situations, including solid solution (ss) of the dopant in the bulk for example, are possible and thus, chemical analysis of such complex situations is a challenging task. In order to cope with such problems we developed a novel method of analytical electron microscopy using energy-dispersive X-ray spectroscopy (EDS) or electron energy-loss spectroscopy (EELS) in a special geometrical setting. The proposed method is based on acquiring several EDS or/and EELS spectra with parallel electron probes placed concentrically on the analyzed interface. In order to eliminate the effect of specimen thickness the probe centre is maintained concentric for all measurements – concentric electron probe (CEP) method. We demonstrated that the CEP method is approximately 10^2-times more precise (small scatter of the data points) and 10-times more accurate (close to the actual value) than for example the spatial difference technique, allowing determination of down to ±0.1 atoms/nm^2, depending on the type of the solute element that is measured in the interface plane. Because of its high precision we could extend the use of this method not only to accurately measure the amount of the trace element on the interface but also to determine complex solute distribution profiles in the interfacial region. In this contribution we will demonstrate the advantages of the CEP method on three different minerals.

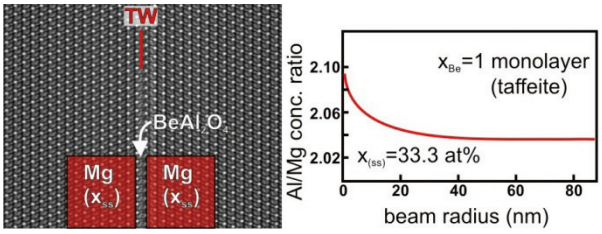

Fig. 1: Case 1 - Be-rich (111) twin boundary in spinel ($MgAl_2O_4$): the solute element (Mg) is present only in bulk, not at the boundary.

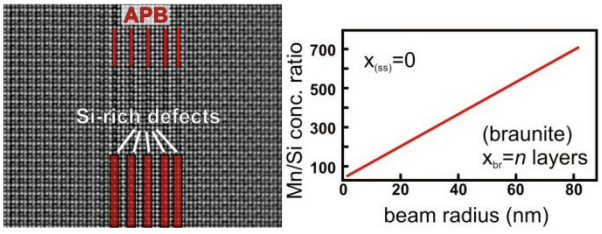

Fig. 2: Case 2 - (100) antiphase boundaries in bixbyite $(Mn, Fe)_2O_3$: the dopant element (Si) is present only at planar defects.

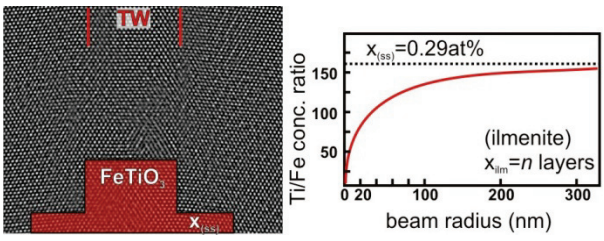

Fig. 3: Case 3 - Fe-rich (301) twin boundary in rutile (TiO_2): the case, where the dopant is present at the boundary and in the bulk (ss).

Direct observation of Th single atoms in thorite by Cs corrected STEM and metamictization process

Akai, J.[1*], Okunishi, E.[2] & Hayashi, H.[1]
[1]Dept. of Geology, Faculty of Science, Niigata University, Niigata, Japan ([*]akai@sc.niigata-u.ac.jp)
[2]JEOL Ltd, Tokio, Japan

In the early days of HRTEM application to material sciences, challenge to observe single atoms were on U and Th atoms in molecules. Recent progress in TEM is new development of Cs corrector-equiped HRTEM. This Cs corrector does not need ultra high accelerating voltage to attain high resolution, reducing spherical aberation (Cs). Using Cs corrected STEM-HAADF (Scanning Transmisson Eectron Microscopy-High Angle Anular Dark Field) images, we tried to observe Th single atoms in metamict thorite, ThSiO4. Furthermore, we examined thermal behaviour of recrystalization of metamict thorite.

STEM-HAADF conditions are as follows: scanning beam is 0.1 nm in diameter and 30 pA; incident beam angle, 25 mrad; receiving angle of diffraction by Anular Detector, 70-250 mrad. ED pattern of the metamict thorite is consisting of almost halo pattern. The halo does not correspond to utterly randomly amorphous state but some diffraction maxima in the halo were found. The diffraction maxima correspond to the positions of strong diffraction spots of thorianite ThO_2. In the HRTEM image, sometimes on the edge, thorianite crystal lattices are found, which may be due to recrystallization by electron beam irradiation. However, mostly amorphous structure is found. Cs-corrected STEM-HAADF image of thorite was taken. The image showed clear spotty patterns (Fig. 1). In STEM-HAADF image, atomic contrast is proportional to Z^2, where Z is atomic number. Thorite consists of Th, Si and O with very small amount of U substituting Th. Thorite composition with metamict state is one of the best sample for STEM-HAADF imaging of single atoms. So, it is reasonably interpreted that every white spots which arrows indicate in the photograph are mostly single Th atoms.

Then, series of STEM images in every 10 seconds were taken. The distribution pattern of the white spots is not the same as before, but changed: this may be due to migration of the Th atoms by electron beam irradiation energy. STEM-HAADF image may be depth sensitive.

Nano domain structures of the thorianite units in the metamict thorite were here suggested and such nano domain structure was dynamically moving if some energey was supplied. Observing newly formed structures and textures in heating experiment, structural changing process was suggested. New application of these textures and structures to geological tool supposing duration of metamictization will be discussed.

This trial of observation of the single atoms in minerals offers wide possibility of new application to mineral science in single atom-scale.

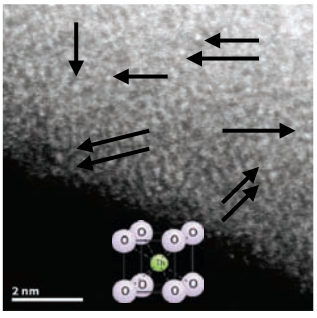

Fig. 1: Th single atoms in metamict thorite by STEM-HAADF.

HRTEM microstructural characterization of pictorial renderings and ground layers in cross section

Báez, M.I.[*], Baldonedo, J.L., Ramírez-Castellanos, J., Vidal, L. & García-Molina, M.J.
Complutense University, Madrid, Spain ([*]mibaez@art.ucm.es)

The intention of this contribution is to show the possibilities offered by high resolution transmission electron microscopy (HRTEM) for the characterization of artistic materials, particularly pigments and fillers, through examination of stratigraphic samples from real pictorial works. This kind of analysis can be applied to any type of painting or polychrome rendering – sculpture, easel painting, mural painting, etc. – and can be used to determine the precise nature of the crystalline species making up the layers.

For a HRTEM study, microsamples are prepared and then ultra-thin sections (50-100 nm) are cut from them; these sections must retain all the particles in the layers intact [1]. Point-to-point EDS microanalyses with HRTEM can be used to locate the elements in each particle; this information is completed by identification of crystalline species by ED. These data are based on a prior study using other microscopic techniques (LM, SEM/EDS). The ultimate objective is to complete a nanostructural characterization using high-resolution transmission electron microscopy (HRTEM).

In the study of pictorial renderings, the characterization of natural coloured earths is especially difficult owing to their peculiar characteristics; the composition of these pigments is highly complex and varied. In general, they are composed of iron oxides associated with various silicates along with other minerals. There are also other loads and products accompanying the material in its original composition, and in many cases there are also substances added by the artist. Many such secondary products are present in tiny quantities and not determined exactly in technical studies.

To demonstrate the possibilities of the technique, this paper presents the results of a study of three pictorial works composed basically of natural earths. Three examples are proposed, each corresponding to a different type of work: (A) red fragment of a mural painting from Mérida Archaeological Site ("Casa del Mitreo"), (B) greenish-brown marble stucco in the Palace of the Congress of Deputies in Madrid and (C) ochre ground layer from oil on canvas by P.P. Rubens (Prado Museum). Table 1 lists some of the representative results from each sample, indicating the principal mineral species characterized by EDS and ED/HRTEM.

Table 1: Mineral species characterized by ED/HRTEM

(A)	(B)	(C)
Calcium carbonate	Gypsum	Calcite (chalk)
Hematite	Calcite	Silica
Cinnabar	Iron oxide hydroxide	Orthoclase
Silica	Glauconite	Biotite
	Hematite	Anatase

These results have made it possible to differentiate the pigments and loads used in all the examples.

Acknowledgements: This work has been carried forward with funding from the Ministry of Science and Technology (Secretaría de Estado para las Universidades), National Plan for Scientific Research and Technological Development Projects (R&D) (Ref.: HUM2006-01847/ARTE).

Application of Patterson-method in electron crystallography

Cora, I.* & Dódony, I.
Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary (*corail diko@gmail.com)

Direct methods have become widespread in X-ray crystallography in the last century. A pioneer method for structure determination was developed by Patterson [1,2], that is called Patterson-method. In spite of its simplicity and efficiency it has gone out of interest today. The great advantage of the Patterson-method is that it provides a solid base for phase retrieve. However, resulted Patterson-maps for unit cells with large numbers of atoms still remain unresolved.

We simulated Patterson-maps in Wolfram Mathematica software package [3]. Our software reconstructs Patterson-maps using input data of (1) the measured diffracted intensity values, (2) projected charge density map (PCD) presented in any (text or image) formats and (3) atomic coordinates and unit cell parameters. This software has been converted into public Python language.

We tested the software on [001] projected mica polytypes comparing their experimental electron-diffraction based Patterson-maps to the corresponding simulated ones (Figs. 1–2). A Patterson-map is a reliable method for polytype identification.

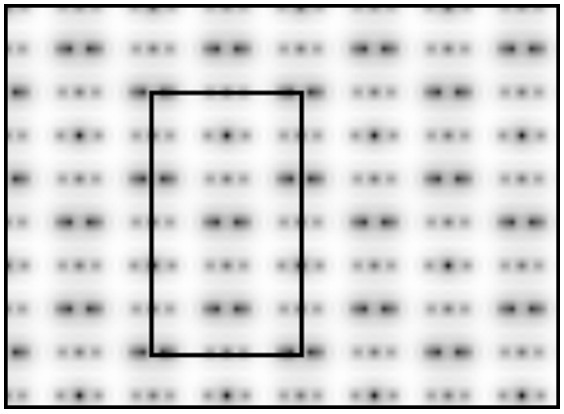

Fig. 1: Projected charge density map of 1M mica polytype (the unit cell is lined out).

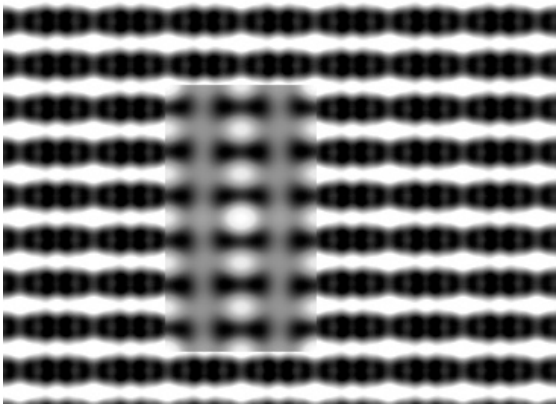

Fig. 2: Crystallographic data based (background) and corresponding experimental Patterson-map of the mica polytype presented above.

Burgers vector determination in deformed materials using the thickness-fringe method

Miyajima, N.* & Walte, N.P.
Bayerisches Geoinstitut, Universitaet Bayreuth, Bayreuth, Germany (*Nobuyoshi.Miyajima@uni-bayreuth.de)

Dislocation is the most important agent in dislocation creep that could become one of dominant deformation mechanisms in the Earth's mantle. Dislocations are line defects and defined by the line direction and the slip vector, Burgers vector, which are identified with these two directions as "screw", "edge" or "mixed" characters. The dislocation line can be visible by selecting diffraction conditions in TEM, but Burgers vector is invisible, to be not directly determined. So we need a proper method to determine it by using a TEM imaging technique

The thickness-fringe method, which was originally proposed by [1], has been performed in deformed materials under high pressure and temperature conditions. The advantage of the method is to enable a complete determination of the character of a dislocation Burgers vector (sign and magnitude) by counting the number of terminating thickness fringes at the extremity of a dislocation from a wedge-shaped thin-foil specimen in weak-beam dark-field (WBDF) TEM images. The visibility criteria, $\boldsymbol{g.b}$ = n ($\boldsymbol{g}$: diffraction vector, $\boldsymbol{b}$: Burgers vector and n: Integral) in TEM images are clearly demonstrated to be superior in unambiguity to conventional invisibility criteria, $\boldsymbol{g.b}$ = 0 [2], which can be comparable with large-angle convergent-beam electron diffraction techniques [3]. Large deviation error (s >> 0) in WBDF images, i.e. pseudo-kinematical diffraction conditions, is also an advantage compared to using $\boldsymbol{g.b}$ = 0 criterion for invisibility of dislocations in elastically anisotropic materials (i.e. almost natural minerals). In addition, the pseudo-parallel beam technique involves only a low-dose illumination of the specimen, which is a critical advantage in applications to sensitive high-pressure minerals to high electron doses.

In this talk, I present some examples of the Burgers vector determination of a perfect dislocation in a post-perovskite structured material [4] as well as partial dislocations in perovskite and olivine structured materials. The different types of dislocations could be distinguished from the dissociation of dislocation lines and the number of terminating thickness fringes in WBDF images (Fig. 1).

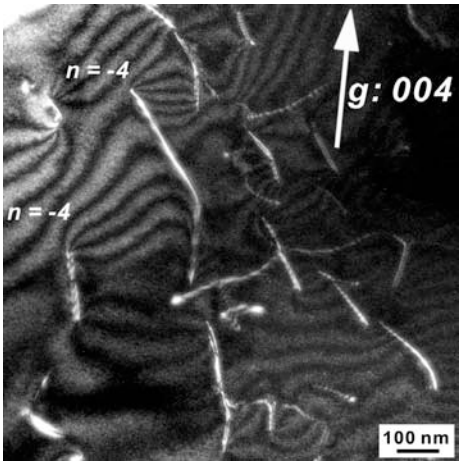

Fig. 1: Weak-beam dark-field TEM micrograph showing partial dislocations in a perovskite structured material.

([*]czank@min.uni-kiel.de)
[3]Dept. of Crystallography, Geological Faculty, Saint Petersburg State University, Russia

All earlier attempts to solve the structures of charoite and of denisovite by X-ray methods failed. Several reasons can be addressed for these failures: these minerals have large unit cells (~32x20x7 Å), low symmetries (monoclinic or triclinic) and complex chemical compositions, they consist of intimately intergrown randomly oriented nano-scaled fibres, they are systematically structurally disordered at the scale of few microns. Electron diffraction can provide high resolution structural data from single phase nano-crystals, but it is often biased due to strong dynamic effects and technical difficulties collecting complete data sets by manual tilt. Automated electron diffraction tomography (ADT) [1-3] provides a powerful and quick tool for more reliable, complete and reproducible electron diffraction data collection from single nano-crystals.

ADT is a combination of STEM imaging for crystal tracking and nano electron diffraction, possibly coupled with precession diffraction technique. ADT doesn't require sample alignment and zone-axis orientation, thus reducing significantly the electron dose on the sample and allowing quasi-kinematical intensity collection. The processing software allows full 3D reconstruction of reciprocal space, unambiguous cell parameter determination and automated reflection indexing and intensity integration. With ADT we were able to collect more than 8000 intensities for charoite as well as for denisovite. The quality of the data allowed to solve the structure of charoite [4] *ab initio* in one step by SIR2008 with a fully kinematical approach, namely with the same approach as used for single crystal X-ray data!

Denisovite has diffuse (100) lamellar disorder and probably exists with several polytype structures. The detected cell parameter **b** differs from the value given in the literature [5]. The unit cell of denisovite was found to be very close to that of charoite, but the two minerals differ in chemical composition, symmetry and intensity distribution. Although the structure is not solved yet, one can expect that the various dreier silicate chains and octahedral bands are arranged differently in charoite and denisovite.

Argon Ion Slicing (*ArIS*) of mineral and rock samples: a novel tool to prepare super large electron transparent thin films for TEM use

Stojic, A.N.[*], Brenker, F.E. & Tkalcec, B.J.
Geosciences Institute, Goethe University, Frankfurt/M., Germany ([*]stojic@em.uni-frankfurt.de)

We report the successful preparation of a 42,500 μm^2 large continuous TEM foil from a carbonaceous chondrite (Fig.1). *ArIS* is a broad ion beam technique similar to argon ion milling: But contrary to the latter *ArIS* benefits from an additional shielding device and therefore provides ultra-large continuous thin foils from polymineralic natural rock sample. *ArIS* was first used in material sciences and has been introduced to Earth and planetary sciences only recently [1,2]. TEM foils produced by *ArIS* do not show any amorphisation or sample distortion. Commonly used preparation techniques, like argon ion milling or ultramicrotomy, yield only small electron transparent areas (<< 500 μm^2) or show a strong mineral-dependent abrasion efficiency.

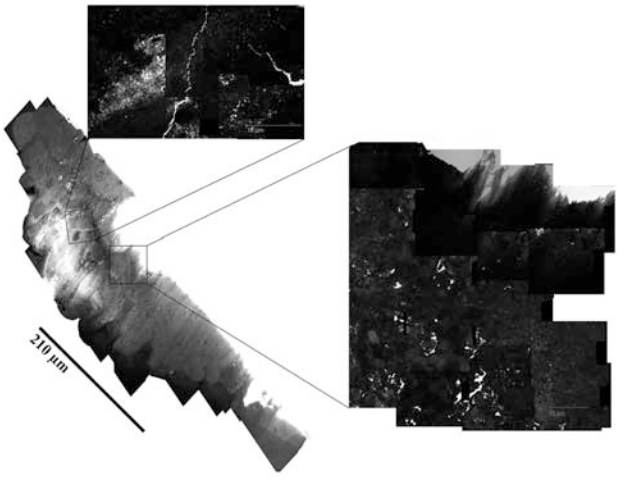

Fig. 1: Murchison (CM 2 carbonaceous chondrite) BF TEM thin film micrographs. To the right, two detailed zoom-ins of electron transparent area. Light grey area to the left is entirely electron transparent.

AriS was successfully applied on various geological samples, namely carbonaceous chondrites, carbonaceous rocks and eclogites.We obtained large (> 20.000 μm^2) continuous electron transparent areas. Based on the quality of the produced thin film and the size of the continuous electron transparent area obtained, *ArIS* is a promising new tool not only in planetary sciences. Next steps will be applying different analytical techniques on ArIS treated samples, such as NanoSIMS, EBSD, microprobe, Synchrotron-XRF and TEM.

Mineral spectroscopy: from gamma rays to microwaves

Rossman, G.R.
Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, USA (grr@gps.caltech.edu)

Mineral spectroscopy has been a thriving science for the past 50 years. What has been accomplished and what might the future bring? Gamma ray (Mössbauer) spectroscopy has moved from the laboratory to Mars where it has helped to identify the minerals on another planet. High intensity X-ray fluxes from synchrotrons are making great progress probing much of the periodic table at very small dimensions through the use of XANES and EXAFS. The human visual interface with the geological world has been nicely characterized through the study of the atomic causes of the colors of minerals. Gemmological laboratories now use a wide variety of spectroscopic methods to help identify gems, determine their treatments, and to determine origin.

For many years vibrational spectroscopy has contributed to the understanding of the structure and bonding in minerals. With convenient methods such as ATR, it has become a means of rapid and convenient phase identification. Infrared spectroscopy has also played a key role in understanding the role of hydrous components bound in minerals in the deep earth. Raman spectroscopy has become highly convenient and readily available. With the development of extensive libraries of mineral spectra, such as the one produced by the RRUFF project, Raman spectroscopy has become an extraordinarily useful tool for phase identification of minerals even down to sub-micrometer sizes. Future advances in time-resolved Raman spectroscopy that will help remove the interferences that arise from sample fluorescence will greatly increase the utility of the Raman method.

Thermal emission infrared spectroscopy has been widely used for phase identification in planetary exploration. Instruments for infrared and near-infrared spectroscopy are now studying several other bodies in the solar system from both orbit and on the ground.

Far-infrared spectroscopy has played much less of a role in mineral studies, but has proven of value with the increasing availability of high-intensity synchrotron sources, it role will surely increase. Astronomical infrared studies are also moving into the far-infrared with spacecraft orbiting high above the interferences of earth's atmosphere.

Spectroscopy in the microwave region has also played a role in the study of minerals and glasses. NMR spectroscopy has proven useful for establishing details about the local structure of Si in glass structures and the concentration of H in minerals. NMR is also used to examine the dynamic motion of atoms such as Na and H in solids. Electron paramagnetic resonance is exquisitely sensitive for probing low concentrations of paramagnetic ions in crystals. EPR also has played a key role in gathering information about color centers formed in minerals by natural radiation.

In the future spectroscopic tools will only increase in use, in the lab, in the field, and in space. Ever-smaller samples will be studied under ever-more extreme conditions of P and T. And, we will expand our definition of minerals as the spectroscopy of hydrocarbon 'minerals' and ices on other bodies such as Europa and Titan become prime objects of study through spectroscopic methods.

Spectroscopic investigations of alpha-particle haloes in mica- and chlorite-group minerals

Krickl, R.
Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria (robert.krickl@univie.ac.at)

Accumulated alpha-particle doses around radionuclide-bearing inclusions may cause noticeable changes in the physical and chemical properties of host minerals. These so-called radiohaloes have been observed in a number of minerals – the most well known examples being "pleochroic haloes" in sheet silicates. However, little is known on the processes involved in radiohalo formation and modern techniques of investigation were just recently introduced in this topic [1,2]. The presented results are part of a systematic study on natural radiohaloes in muscovite, biotite- and chlorite-minerals, as well as in artificially irradiated samples.

Optical absorption spectra were recorded at different radial distances from the radioactive inclusions, thus giving insight in different stages in radiohalo evolution. Altered absorption colours are mainly caused by a strong shift of the UV absorption edge to lower energies. Changes in the intensity of crystal field *d-d* and metal-metal charge transfer bands indicate radioinduced ionisation of Fe^{2+} to Fe^{3+}. Low to moderate doses cause darkening of the minerals due to intensified absorption in the visible region. Still higher doses result in "colouration reversal", caused by intensity loss of the smaller bands in the visible and near IR.

Polarised spectra of radiohaloes in chlorite (Fig. 1) exhibit an intensified absorption at ~16800 cm^{-1} which is very weak in the unirradiated mineral. This provides new evidence for the existence of this spectral feature (probably a Fe^{2+}-Fe^{3+} charge transfer band), which has hitherto been regarded as doubtful [3].

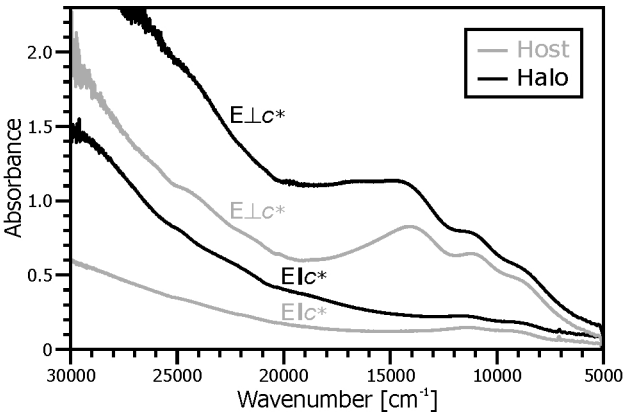

Fig. 1: Polarised optical absorption spectra of a radiohalo in chlorite from Turamdih/India (cf. [2]) in comparison to the unirradiated host (polished thin section, sample thickness 30 µm).

Changes in the structural state were investigated using Raman spectroscopy: Line scans show a very good correlation between the broadening of vibrational bands (interpreted as accumulation of radioinduced point defects) and the radial distance to the radioactive inclusion, corresponding to the modelled point defect density distribution within radiohaloes. Not all bands show a continuous decrease in band intensity with increasing irradiation dose: At low to moderate doses (in "darkened haloes" – see above) Raman bands at ~640 cm^{-1} (chlorite) and ~575 cm^{-1} (muscovite) exhibit a strong increase in intensity. At higher doses, starting with the onset of colouration reversal, they rapidly loose intensity and totally disappear.

The WURM project – a web-based freely available database of computed physical properties for minerals

Caracas, R.[1*] & Bobocioiu, E.[2]
[1]Laboratoire de Sciences de la Terre, Ecole Normale Superieure de Lyon – CNRS, Lyon, France ([*]razvan.caracas@ens-lyon.fr)
[2]Laboratoire de Sciences de la Terre, Ecole Normale Superieure de Lyon, France

This project aims to build a freely accessible web-based database of computed physical properties for minerals. The database provides for each mineral various physical properties: the crystal structure used in the calculation, the dynamical charges and the dielectric tensors, the refractive index, the Raman spectra with both peak position and intensity and the infrared spectra with peak position. Additional information comprises the parameters of the calculation, to ensure reproducibility of the results.

The vibrational information makes the bulk of the database and constitutes the major computational effort. For each vibrational mode in the zone-center we determine the frequency, the symmetry assignment, the atomic displacement patterns, and the Raman tensors. The Raman spectra are represented in both single crystal and powder with different possible laser polarizations. For the infrared modes we give both the TO and the LO components.

The database is freely available on the web at http://www.wurm.info and is highly interactive. Jmol-powered applets incorporated in the website allow the quick visualization of the crystal structure and of the atomic displacement patters of all vibrational modes.

Further developments include development of a virtual microscope on top of the computed refractive indexes and the analysis of the elastic properties based on the computed elastic constants tensor.

All the results are exclusively obtained from first-principles calculations performed using the local density approximation of density functional theory and density functional perturbation theory in the ABINIT implementation [http://www.abinit.org], based on planewaves and pseudopotentials.

Using Raman spectroscopy to determine the sulphur valance state and $S^{6+}/\Sigma S$ ratio in silicate glasses

Klimm, K.[1*] & Botcharnikov, R.E.[2]
[1]Inst. für Geowissenschaften, Goethe-Universität, Frankfurt, Germany ([*]klimm@em.uni-frankfurt.de)
[2]Inst. für Mineralogie, Leibniz-Universität, Hannover, Germany

Because sulphur (S) has several possible valance states (S^{2-}, S^{4+}, S^{6+}), the total S solubility in silicate melts is a function of fO_2 as the compositional controls on sulphide, sulphate and sulphite incorporation in the glass structure are different. At high fO_2, S^{6+} is dominant and more soluble in silicate melts than S^{2-} which is dominant at low fO_2 [1]. In subduction zones the fO_2 changes from reducing to more oxidising conditions during the rise of volcanic fluids and magmas [2]. Therefore it is crucial to determine the oxidation state of S to understand and model volcanic degassing processes. Until now the S speciation and $S^{6+}/\Sigma S$ in silicate glasses have mostly been determined using SKα wavelength shift measurements on the electron microprobe [1] or using XANES spectroscopy [3]. However, both methods are challenging and difficult to use as standard methods in quantifying accurately the $S^{6+}/\Sigma S$ because of either the low resolution of electron probe spectrometers or the restricted and costly access to synchrotron radiation sources. In addition it has been shown that the sulphur valance state in silicate glasses may change during electron beam exposure [4]. Here we show that Raman spectroscopy can be a cheap and relatively easy alternative method in determining the $S^{6+}/\Sigma S$ in silicate glasses.

Several hydrous sulphur bearing glasses synthesised at fO_2 ranging from QFM-2 to QFM+4 were investigated by Raman spectroscopy ranging from "natural" basaltic, andesitic to rhyodacitic compositions to more "technical" iron-free compositions such as soda-lime glass (SLG) and $K_2Si_4O_9$ (KSG). The presence of sulphate (S^{6+}) is marked in Raman spectra of oxidised synthetic and natural glasses similarly by bands at ~990 and ~1000 cm^{-1}, respectively. The presence of sulphide (S^{2-}) in Raman spectra of the reduced technical SLG and KSG glasses is marked by a band at 2574 cm^{-1} indicating that S^{2-} is present as HS^- in these glasses. Such a band is absent in the Raman spectra of reduced basaltic glass. However, an additional band appears in the Raman spectra of reduced basaltic glass at ~400 cm^{-1} when compared to Raman spectra of sulphur-free reduced basaltic reference glass and the "technical" Fe-free glasses indicating that S^{2-} is present as a metal-complex such as FeS. This is also confirmed by Raman spectra of SLG and KSG glasses that have been doped with Fe showing a band at 400 cm^{-1} besides the band at 2574 cm^{-1}. The band at 400 cm^{-1} systematically increase while the band at 2574 cm^{-1} decrease with decreasing S/Fe from 2 to 0.5 at constant fO_2 indicating that the quantities of dissolved S complexes shift from HS^- to FeS dominated. In all glasses and at intermediate fO_2 both species S^{6+} and S^{2-} can be identified. The intensities of the bands at 990 and 1000 cm^{-1} indicating the presence of S^{6+} increase and the intensities of the bands at 2574 or 400 cm^{-1} indicating S^{2-} decrease systematically with increasing fO_2. The relative abundances of each complex and the $S^{6+}/\Sigma S$ can be quantified by integrating the intensities of each band.

The results shown here demonstrate the potential of Raman spectroscopy in determining and quantifying the sulphur valance state in silicate glasses. In addition the results indicate that S^{2-} is dissolved as completely different complexes when comparing synthetic iron-free and natural iron-bearing silicate glass compositions.

Mössbauer spectroscopy with a high velocity resolution in the study of iron nickel phosphides extracted from Sikhote-Alin meteorite: an analysis of iron and nickel occupation of the M1, M2 and M3 sites

Oshtrakh, M.I.[1*], Larionov, M.Yu.[1], V.I. Grokhovsky, V.I.[1] & Semionkin, V.A.[1,2]

[1]Faculty of Physical Techniques and Devices for Quality Control, Ural State Technical University – UPI, Ekaterinburg, Russian Federation ([*]oshtrakh@mail.utnet.ru)

[2]Faculty of Experimental Physics, Ural State Technical University – UPI,, Ekaterinburg, Russian Federation

Mössbauer spectroscopy with a high velocity resolution demonstrated new possibilities in the study of various iron bearing minerals in meteorites [1,2]. Therefore, this technique was applied to the study of iron nickel phosphides $(Fe,Ni)_3P$ extracted from Sikhote-Alin iron meteorite. It is well known that artificial Fe_3P and meteoritic $(Fe,Ni)_3P$ have the unit cell with 24 metal atoms in three crystallographically non-equivalent sites M1, M2 and M3, 8 atoms in the each site, which in the case of meteoritic phosphides occupied by Fe and Ni in different way for two different types of phosphides in various meteorites [3].

We studied schreibersite and rhabdites, two types of $(Fe,Ni)_3P$ extracted from Sikhote-Alin meteorite mechanically and electrochemically, respectively. These phosphides were studied using Mössbauer spectroscopy in the temperature range of 295–90 K with automated precision Mössbauer spectrometric system with a high velocity resolution [4]. Measured spectra were different for schreibersite and rhabdites. Nevertheless these spectra fitted on the basis of model [5] using 6 magnetic sextets 3 pairs of which were related to the M1, M2 and M3 sites and paramagnetic doublet. Basing on the relative areas of spectral components related to the each site and the results of chemical analysis of schreibersite and rhabdite we evaluated average numbers of Fe and Ni atoms in the M1, M2 and M3 sites of both schreibersite and rhabdite. These numbers for schreibersite were 8 Fe (M1), 3.8 Fe, 4.2 Ni (M2) and 2.9 Fe, 5.1 Ni (M3) while for rhabdite these numbers were 5.5 Fe, 2.5 Ni (M1) and 3.5 Fe, 4,5 Ni (M2 and M3). Using the structures of schreibersite and rhabdites determined in [6] and average numbers of Fe and Ni atoms in the sites we evaluated nearest environment for the each site in both phosphides. The obtained differences were considered as a reason of different Mössbauer hyperfine parameters for various sites in two phosphides.

The angular dependence of *K* pre-edge in cubic compound: XAS experiments and *ab initio* calculations

Bordage, A.[1,2*], Brouder, Ch.[2], Cabaret, D.[2], Juhin, A.[2], Balan, E.[2] & Glatzel, P.[3]

[1]Laboratoire des Géomatériaux et Environnement, UPEMLV, Marne la Vallée, France ([*]amelie.bordage@impmc.jussieu.fr)

[2]Institut de Minéralogie et de Physique des Milieux Condensés, Univ. Paris 6 et 7, IRD, IPGP, Paris, France

[3]European Synchrotron Radiation Facility, Grenoble, France

The features in *K*-edge X-ray absorption spectra of transition metal cations provide information about their crystallographic environment and electronic structure in minerals. Fine details can be revealed from the pre-edge features, which depend on the valence state and site symmetry of the absorbing atom, by performing measurements for different orientations of a single with respect to the incident beam [1].

Here we present an experimental and theoretical study of the angular dependence of *K* pre-edge in cubic compounds with the case of the V-bearing garnet-grossular $Ca_3Al_2(SiO_4)_3:V^{3+}$. In such a cubic crystal, the angular dependence of the V *K* pre-edge is expected to arise from that of pure electric quadrupole transitions ($1s \rightarrow 3d$) [2,3]. V *K*-edge High Energy Resolution Fluorescence Detection X-ray Absorption Spectroscopy (HERFD-XAS) [4] spectra were recorded on ID26@ESRF for different orientations of a single crystal, in order to reconstruct the complete angular dependence (Fig. 1) and to assess the importance of quadrupolar transitions [5]. Compared with conventional XAS, HERFD-XAS leads to a significant sharpening of the pre-edge features, which facilitates the separation of the pre-edge from the main edge [6].

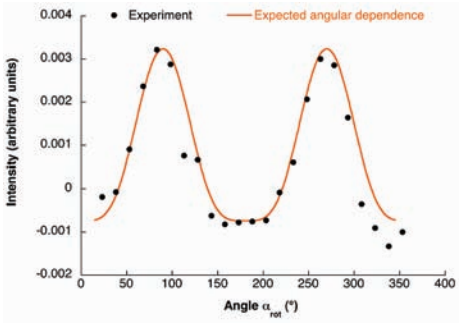

Fig. 1: Experimental (dots) and theoretical (orange line) angular dependence of the V *K* pre-edge in tsavorite.

In parallel, the theoretical X-ray absorption spectrum of V^{3+} in this garnet-grossular was determined by monoelectronic *ab initio* calculations, based on the Density Functional Theory. The comparison between experimental and calculated data makes it possible to obtain accurate information about the crystallographic and electronic structures of V^{3+} in garnet [5]. In particular, it provides quantitative information about the relaxation of the crystal structure around the impurity, a key parameter for understanding the mechanisms controlling the incorporation of colouring trace elements in minerals.

EXAFS-derived crystal-chemistry of Zn in di- and trioctahedral phyllosilicates

Juillot, F.[1*], Morin, G.[1], Hazemann, J.L.[2], Proux, O.[2], Belin, S.[3], Briois, V.[3], Brown, G.E.[4] & Robert, J.-L.[1]
[1]Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), UMR CNRS 7590, & Universités Paris 6/7-IPGP, Paris, France ([*]juillot@impmc.jussieu.fr)
[2]European Synchrotron Radiation Facility (ESRF), Grenoble, France
[3]Synchrotron SOLEIL, Saint Aubin, France
[4]Dept. of Geological & Environmental Sciences, Stanford University, Stanford, USA

Numerous studies have emphasized the importance of M^{2+} (Fe, Zn, Co and Ni) and M^{3+} (Fe, Al) ions incorporation in phyllosilicates in contaminated soils and sediments [1-3 and references therein]. Understanding the behavior of these trace elements in natural impacted systems then strongly depends on our capacity at characterizing the actual crystal-chemistry of these ions in phyllosilicates. For instance, incorporation in di- or trioctahedral species could yield important information on the origin (natural vs. anthropogenic) of the trace element studied. Indeed, the slow kinetics of crystallization of dioctahedral phyllosilicates at room temperature strongly suggests that trace elements incorporated within their octahedral sheets likely derive from anthropogenic sources. At the opposite, occurrence of trace elements within the octahedral sheets of a trioactahedral phyllosilicate in an impacted soil is a strong support for an anthropogenic source for these elements. In addition, the actual distribution of trace elements within the octahedral sheets of phyllosilicates (randomly distributed vs. clusterized) can also yield useful informations on the environmental conditions (temperature, pH) that prevailed during the formation of these mineral species.

The aim of the present study was to collect structural information about the crystal-chemistry of Zn^{2+} ions incorporated at trace levels within the octahedral layers of various natural and synthetic di- and tri-octahedral phyllosilicates (kaolinite, talcs, phlogopite, muscovite). Zn was chosen because this element is the most frequently observed in impacted soils. Due to the low Zn content of the samples investigated (as low as 40 ppm), EXAFS spectroscopy was used to obtain information about the local structural environment of Zn and analysis of these data with *ab initio* FEFF 8 calculations allowed to derive spectroscopic features characteristic of Zn incorporated within the octahedral sheets of phyllosilicates [4]. Changes in these specific features are discussed with respect to Zn concentration and the nature (di- or tri-) of the octahedral sheets. Particular attention was paid to Zn ordering in the trioctahedral sheets in order to try to distinguish between ordered vs. randomly distributed Zn^{2+} ions.

Results indicate that EXAFS spectroscopy is a powerful tool to improve our capacity at deciphering between incorporation of trace elements within di- or tri-octahedral phyllosilicates in impacted soils or sediments and, in turn, to help our understanding of the behavior of these elements in these systems.

Health effects of quartz: crystal chemical insights from a multianalytical approach

Di Benedetto, F.[1*], Capacci, F.[2], D'Acapito, F.[3], Fornaciai, G.[1], Montegrossi, G.[4], Innocenti, M.[1], Pardi, L.A.[5] & Romanelli, M.[1]

[4]Inst. for Geosciences and Georesources, CNR, Florence, Italy
[5]Inst. for Physico-Chemical Processes, CNR, Italy

The International Agency for Research on Cancer rated crystalline Silica (inhaled in the form of quartz or cristobalite from occupational sources) as “carcinogenic to humans”, since 1997. There is a general agreement in relate the health effects of crystalline silica to the presence of inorganic radicals, especially if generated during the formation of fresh surfaces. However, effectiveness of biological response to silica exposure can depend on several physical and chemical boundary conditions: among them, the presence and crystal chemistry of heteroions on quartz surface, as e.g. Fe.

This study is aimed to gain a deep insight in crystal chemical features of both inorganic radicals and Fe species in (or associated to) quartz, and to monitor their changes during mechanical and chemical activation performed both under laboratory conditions or during industrial processes. This goal has been pursued through a combined multianalytical spectroscopic approach, including EPR, ESE spectroscopy, XAS and ReflEXAFS a the Fe-K edge, combined with Atomic Force Microscopy.

The results of the present investigation allowed to set up a new method to quantify inorganic radical species having a relevant Zeeman anisotropy. At the same time, a specific interaction between Si-related radical and clay associated phases during the wet ceramic production.

On the other hand, Fe, independently on the valence state, was observed to tend to precipitate forming nanosized oxide particles at the quartz surface, even in concentrations nominally covering just a fraction of a monolayer. Moreover, during the characterisation of mechanically activated samples under laboratory conditions, we faced a singular redox trend: a partial reduction of Fe after mechanical crushing in laboratory. Due to the very low amount of Fe, we tentatively ascribed this aspect to the presence of reducing species in the bulk samples

Formation of the E_1' centre in natural quartz and applications to dating and environmental research

Toyoda, S.[1*], Usami, T.[1], Yamamoto, Y.[1] & Nishido, H.[1]
Okayama University of Science, Okayama, Japan
([*]toyoda@dap.ous.ac.jp)

The E_1' centre in crystalline quartz is one of the fundamental paramagnetic defects in quartz where an unpaired electron is at an oxygen vacancy, detected by electron spin resonance (ESR, same as electron paramagnetic resonance, EPR). Its model for the atomic configuration has been extensively studied [1] since the discovery of the centre, while its formation process in natural quartz has not well been established. Unlike the other paramagnetic defects, the intensity of the E_1' centre increases on heating as was found at the early stage of the studies of this centre [2]. It was suggested to explain this increase that electronic holes in aluminium hole centres (an electronic hole trapped at an aluminium ion replacing silicon) are transferred to oxygen vacancies with two electrons (Si–Si bond) [3].

In the present study, we show detailed experimental results to confirm this electronic process on several natural quartz samples with varying aluminium concentrations. The slices of the samples were irradiated with 4 MeV electrons to create oxygen vacancies in them. After crushing, the samples were measured by ESR spectrometer at liquid nitrogen temperature to obtain the intensity of the aluminium hole centre, $[AlO_4]^0$. The samples were subsequently heated at 300°C for 15 minutes to maximize the intensity of the E_1' centre. The number of the E_1' centres formed in quartz were measured at room temperature. The number of the E_1' centres increased with an increase of the concentration of the aluminium hole centres, while they saturated above a certain amount of the aluminium hole centres where the saturating level is a function of electron dose, as shown in Fig. 1. This saturation level indicates the number of oxygen vacancies, the precursors of the E_1' centres, in quartz [4].

It was already shown that the number of the oxygen vacancies measured as the intensity of the E_1' centre is an indicator useful to discuss the origin of the aeolian dust [5] which is based on the correlation between the number of the oxygen vacancies in quartz and the age of the host granite [6]. The method was applied to loess samples in Japan to find that the source of the aeolian dust coming to the northern part of Japan in MIS2 was different from that in MIS 1 [5]. The results on the deep sea sediments in MIS 1 and 2 in Pacific Ocean will be presented.

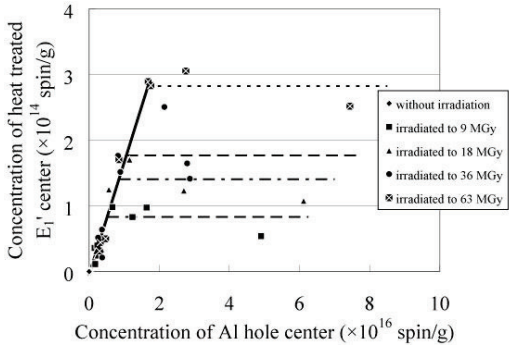

Fig. 1: Correlation between the number of the aluminium centres and that of the E_1' centres after the heat treatment.

Vibrational spectroscopy of kosnarite-like zirconium and hafnium phosphates with rare-earth elements

Borovikova, E.Yu.[1*], Bykov, D.M.[2] & Kurazhkovskaya, V.S.[1]
[1]Geology Faculty, Moscow State University, Moscow, Russia ([*]amurr@mail.ru)
[2]Dept. of Chemistry, Nizhni Novgorod State University, Nizhni Novgorod, Russia

Double anhydrous orthophosphates of the compositions $R^{III}_{0.33}M_2(PO_4)_3$, where M = Zr, Hf, and R^{III} = La – Lu, Y, belonging to the structure type of kosnarite $KZr_2(PO_4)_3$ (the synthetic analogue is sodium zirconium phosphate $NaZr_2(PO_4)_3$, NZP, Nasicon), have been synthesized in a crystalline state by precipitation method and characterized by Raman and infrared spectroscopy in a mid and far region. These phases are known to possess low coefficients of thermal expansion, ionic conductivity and luminescent properties [1-3]

Most of these compounds crystallize in sp.gr. $P\bar{3}c1$ [4], but the structure of $La_{0.33}Zr_2(PO_4)_3$ has been determined in the sp. gr. $P\bar{3}$ [5]. Factor group analysis has been carried out for space groups $P\bar{3}$ and $P\bar{3}c1$. The assignment of the stretching and bending vibrations of the PO_4 unit has been made. Detailed assignment of the external modes is difficult, because of the greater number of predicted signals compared to the low number of observed bands in the spectra. However, the study of Raman and infrared spectra of corresponding Zr and Hf compounds shows that some bands exhibit an evident Hf - Zr mass effect and can be assigned to M^{IV} translations: 340, 312, 277 cm^{-1} in the Raman spectra and 345, 326, 310, 270 cm^{-1} in the IR spectra. Also two overlapping bands at around 157, 146 cm^{-1} in IR spectra of $La_{1/3-x}Yb_xZr_2(PO_4)_3$ solid solutions show the La-Yb mass effect, so they can be assigned to M^{III} translations.

Despite the similarity of the spectra of $M^{III}_{0.33}Zr_2(PO_4)_3$ with M^{III} = Ce – Yb (sp.gr. $P\bar{3}c1$) and $La_{0.33}Zr_2(PO_4)_3$ (sp.gr. $P\bar{3}$), they have certain distinctions, which become especially visible in the Raman spectra in the regions of stretching and symmetric bending ν_2 vibrations. Another difference in the Raman spectrum of $La_{0.33}Zr_2(PO_4)_3$ is the change in the region corresponding to Zr^{IV} translations and the appearance of an additional band at 106 cm^{-1}, which presumably relates to La^{III} translation in positions with site symmetry C_3 (0.18 of La atoms). The bigger number of overlapping bands in both Raman and IR spectra of $La_{0.33}Zr_2(PO_4)_3$ leads to their lower resolution, compared to spectra of the other compounds.

The morphotropic transition from $P\bar{3}$ to $P\bar{3}c1$ in the series $La_{1/3}Zr_2(PO_4)_3$ - $Yb_{1/3}Zr_2(PO_4)_3$ was shown to appear at the ratio Yb/(La+Yb) of approximately 70-80% (corresponding to $La_{1/18}Yb_{5/18}Zr_2(PO_4)_3$), where the maximum of ionic conductivity has been observed.

Infrared spectroscopy of minerals: modern trends and prospect

Chukanov, N.V.[*] & Dubovitskiy, V.A.
Institute of Problems of Chemical Physics, RAS, Chernogolovka, Russia ([*]chukanov@icp.ac.ru)

Traditionally, the application of IR spectroscopy in mineralogy is reduced to the determination of wavelengths or frequencies of absorption maxima. These values are brought in correspondence with normal vibrations of different chemical bonds or covalently-bonded groups of atoms. Another approach, also based on the use of discrete band maxima, is applied to obtain correlations between vibration frequencies and different characteristics of minerals (hydrogen bond strengths, degree of isomorphous substitutions *etc*.). In particular, correlations of this type have been used by us to determine the degree of condensation of polyhedra in crystal structures of minerals and to identify silanol groups in silicates.

Unlike traditional treatment of infrared spectra (IRS) of minerals as a number of discrete absorption bands, our new approach (full-profile analysis [1]) is based on the consideration of the whole spectral curve within a certain range of frequencies. Spectral curves are considered as elements of a multidimensional vector space. The key point of the method consists of best fitting of analyzed spectrum by nonnegative linear combination of known samples from the base set. This approach is numerically stable due to the application of the concepts of integral error functional and generalized positive solution. Automated data processing is possible with a practically unlimited base set of reference spectra. The application of full-profile IRS analysis makes it possible to avoid the combinatorial stage from the procedure of identification of minerals. On the basis of this approach, an IRS-based quantitative criterion of crystal-chemical similarity (CCS) can be introduced for pairs of minerals to be compared. CCS can be expressed as the normalized square deviation of an analyzed spectrum from a reference spectrum, or from an approximating nonnegative linear combination of reference spectra. Being based on empirical spectroscopic data, this criterion reflects real crystal-chemical relationships: pairs of minerals with similar structure type have the lowest CCS values. Within a given structure type, CCS characterizes compositional relationships.

In order to make full-profile IRS analysis a customary method in mineralogical investigations, during the last 20 years a representative collection of IRS of well-characterized mineral samples was built. It includes about 3000 spectra of more than 2200 mineral species. In the frame of this work, an IRS database was created and more than 100 new minerals have been discovered.

Numerous examples of the application of traditional ("fingerprint"), correlation and full-profile IRS-based approaches to the analysis of fine crystal-chemical features of minerals are given. The latter method is most effective for the identification of mineral species belonging to complex mineral groups (like cancrinite and eudialyte groups), as well as for the quantitative analysis of polymineral mixtures.

Acknowledgments: This work was financially supported by Russian Foundation for Basic Research (grant No. 09-05-12001-ofi_m).

Single-crystal, polarized-light, FTIR spectroscopy of arrojadite

Della Ventura, G.[1*], Bellatreccia, F.[1], Cámara, F.[2], Oberti, R.[2] & Chopin, C.[3]
[1]Dipto. Scienze Geologiche, Univeristy Roma Tre, Italy, ([*]dellaven@uniroma3.it)
[2]CNR-IGG, UOS Pavia, Italy
[3]Laboratoire de Geologie, ENS-CNRS, Paris, France

Arrojadites are extremely complex phosphates which are typically found in granitic pegmatites or hydrothermal veins. Their occurrence in metamorphic rocks [1] suggests wide conditions of formation for these minerals. The crystal structure and crystal chemistry of arrojadite have been debated for several decades, until [2] and [3] re-examined a set of samples from various occurrences and revised the structural model, the formula and the nomenclature of the group. One key aspect in the new crystal-structural model for arrojadite is the presence of three OH-groups [2]: two of these (O-H1 and O-H2) are very similar in local octahedral environment, crystallographic orientation and hydrogen-bond system. In contrast, O-H3 is connected with the apical oxygen of a newly defined tetrahedron in the structure, and is involved in a bifurcated hydrogen bridge with surrounding oxygen atoms. The Raman spectra reported in [2] show two higher-frequency, intense and convoluted bands which were assigned to specific local environments of OH1 and OH2; an additional low-frequency, broad and weak feature in the spectra (Fig. 1, left) could not be assigned with certainty. The FTIR spectra collected in the course of present work on various samples studied in [2], are similar to the Raman spectra in the higher-frequency 3600-3500 cm^{-1} range, with two intense and multi-component bands. In contrast, in the lower-frequency region, FTIR shows a very intense and broad absorption extending from 3500 to 2900 cm^{-1} (Fig. 1, right).

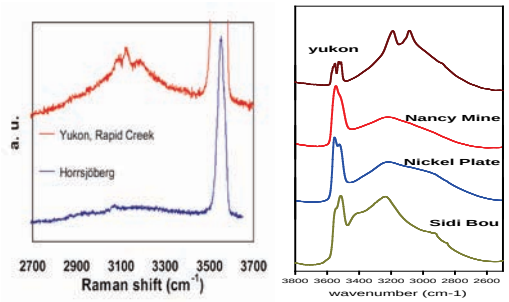

Fig. 1: Raman (left) and FTIR (right) spectra of arrojadites

The FTIR spectrum of arrojadite from Rapid Creek (Yukon) shows also an intense doublet at 3190-3087 cm^{-1} (Fig. 1 right, top) which can be assigned to NH^{4+} groups, as confirmed by EMPA only in this sample. The orientation of the absorber (i.e. the O-H bond) with respect to the crystallographic axis can be determined from polarized-light measurements along the principal optical direction [4]. For the arrojadite studied here, the data are consistent with assignment of the higher-frequency components to the O-H1 and O-H2 groups obtained from the X-ray structure refinements even in the case of partial occupancy, while the assignment of the broad band to the H-O3 group proposed by [2] needs further work. No evidence of molecular water is present in the NIR 4000-6000 cm^{-1} region.

Conservation of Egyptian blue pigments from the Pharaonic and the Gallo-Roman periods

Farges, F.[1,2*] & Etcheverry, M.-P.[3]
[1]LMCM, Muséum National d'Histoire Naturelle, Paris, France ([*]farges@mnhn.fr)
[2]Dept. of Geological and Environmental Sciences, Stanford University, Stanford CA, USA
[3]LRMH, Champs sur Marne, France

Combined µ-XRF and µ-XAFS experiments were performed on four historical Egyptian blue samples. Those two samples illustrates opposite conservation conditions over thousands of years: (1) dry desertic solids with periodic floadings (Nilus river) and (2) constantly wet conditions (Rhône river) since the Gallo-Roman period (France).

The first two samples are coming from the Ancient Egypt: (a) a blue sintered pigment from Karnak (dated 1500 BC) and (b) a copper-rich enamel from a goddess Sekhmet statue (similar age). The two other samples are sintered vitro-ceramics (Gallo-Roman, ca -50AC to +100 BC) from the Lyon area in France: (c) "Rue des Farges" (downtown Lyon), and (d) "St. Romain-en-Gal" (Vienne area).

µ-XRF an µ-XAFS spectra were collected at the Cu K-edge at the Advanced Light Source (Berkeley, UA), operating at 2.4 GeV and 800 mA currents. We used Si(111) double crystal monochromators and KB mirrors. Energetic and lateral resolution are ~1.5 eV and 10 µm, respectively. Samples were polished and set in air while the Kα of Cu was collected using a single-element, solid-state Si detector. µXRF maps were collected (1 second/pixel) while µ-XAFS spectra were collected with 2 sec/point, 0.5 eV steps from 8900 to 9900 eV.

The present report shows that copper is present as cuprorivaïte (samples a, c and d) and as a glassy copper-rich amorphous matrix (samples b, c and d). When polarization effects are accounted for, all XANES for sample (a) are consistent with that of a synthetic cuprorivaïte. In the glassy matrix (samples b, c and d), copper is fully oxidized. This is contrast to the redox of copper in contemporary synthetic glasses prepared under oxidizing conditions (which should show Cu(I) and Cu(II)). Hence, copper has been oxidized in samples b, c and d. In sample d, copper is polymerized as an intergrowth of chrysocolla and tenorite (i.e., $CuOOH/SiO_2$ and CuO). Then, the effect of low temperature weathering of Cu-glasses over thousand of years tends to produced highly enriched domains (spatially highly segregated) in copper. These domains progressively form tenorite crusts as the expense of spertiniite ("chrysocolla") precipitates, which are produced at the rims of weathered domains, themselves enriched in insoluble elements (such as Si and Al).

The binding state of indium and tin in natural sulphides: first results of a comparative study by X-ray absorption spectroscopy at the *L*-edge

Figueiredo, M.O.[1,2] & Silva, T.P.[2,1]
[1]CENIMAT/I3N, Dept of Material. Science, Faculty of Sciences andTechnology, New University of Lisbon, Caparica, Portugal (*ondina.figueiredo@ineti.pt)
[2]Laboratório Nacional de Energia e Geologia I.P. (LNEG), U. Mineral Resources and Geophysics, Alfragide, Portugal

One electron makes the difference between the outer shell of In and Sn, two scarce metals with very distinct crystal chemical behaviour in the Earth's crust: indium is clearly chalcophile, very seldom forming specific minerals and occurring mainly dispersed within excess-metal polymetallic sulphides, while tin is markedly lithophile and currently present as stannic oxide.

Indium is nowadays widely used in many technologic fields (low melting-temperature alloys, solders and various «high-tech» devices like liquid crystal displays (LCD), organic light emitting diodes (OLED), transparent flexible thin-films of ionic amorphous oxide semiconductors (IAOS), photovoltaic cells with increased efficiency based on $Cu(In,Ga)Se_2$ (CIGS). As a consequence, indium consumption is expected to increase in the near future, centring a special interest on the improvement of its exploitation from polymetallic sulphide ores, along with its recycling technology.

Indium recovery stands mostly on zinc extraction from the natural cubic sulphide – sphalerite, the prototype of so-called «tetrahedral structures» where metal ions fill half of the available tetrahedral sites within the cubic closest packing of sulphur anions. Such anionic array is thus particularly suitable to accommodate poly-cations in close edge-sharing tetrahedral sites [1,2], as occurs in excess-metal copper sulphides (e.g., bornite, ideally Cu_5FeS_4), recognized to be relevant In-carrier minerals in many polymetallic sulphide ore deposits. A similar situation holds for the tetrahedral $[Sn_2S_6]$ cluster in special meso-structured semiconductors [3].

X-ray absorption spectroscopy at the *L*-edges (arising from $s,p \rightarrow d$ transitions) is a suitable methodology for probing unoccupied density of states and *s-p* orbital hybridization [4]. Accordingly, a comparative study of In and Sn by X-ray absorption near-edge spectroscopy (XANES) at the L_3-edge was undertaken at the ESRF (European Synchrotron Radiation Facility in Grenoble/France) using the instrumental set-up of beamline ID21.

Beyond two edge shoulders ascribed to $2s \rightarrow 5p$ transitions that were also observed in the In L_3-edge spectra of wurtzite-type indium nitride [5], a third weak white line was noticed at lower energy (3,730 eV) in the XANES spectra collected from a polymetallic ore sample. An identical pattern of pre-edge details was detected in Sn L_3-edge XANES spectra collected at the same irradiated point – an expectable result in view of earlier data [5]. However, a single intense «white line» at 3,730 eV was noticed in a faint In L_3-edge XANES spectra collected at another point of the same ore sample but the impossibility of clearly identifying the nanoscale phase hosting indium has hindered a full interpretation of X-ray absorption data. Further work is in progress focusing on coexisting indium and tin.

Sulfur speciation in silicates: an X-ray absorption spectroscopy study

Göttlicher, J.
Karlsruhe Institute of Technology, Institute for Synchrotron Radiation, Eggenstein-Leopoldshafen, Germany
(joerg.goettlicher@iss.fzk.de)

There is still ambiguity on sulfur speciation in some silicate minerals, especially for minerals that are characterized by cages in its structure (like sodalite group minerals). Several minerals from different localities like

- lazurite ($(Na,Ca)_8[(S,SO_4,Cl_2)|Al_6Si_6O_{24}]$),
- hackmanite ($Na_8[Al_6Si_6O_{24}](Cl_2,S)$,
- afghanite ($(Na,Ca,K)_8[(Cl_2,SO_4,CO_3)_3|Al_6Si_6O_{24}]x0.5H_2O$),
- nosean ($Na_8[SO_4|Al_6Si_6O_{24}]$),
- hauyne ($(Na,Ca)_{4\text{-}8}[Al_6Si_6(O,S)_{24}](SO_4,Cl)_{1\text{-}2}$) and
- davyne ($(Na,K)_6Ca_2[(Cl_2,SO_4)_2|Al_6Si_6O_{24}]$)

have been investigated by x-ray absorption spectroscopy at the sulfur K-edge in order to get information on sulfur valence and moleculare structure.

The measurements have been performed at the X-ray Beamline for Environmental Studies (SUL-X) of the synchrotron radiation source ANKA in Karlsruhe in normal focus and partly in microfocus to separate signals from minerals when they are inter-grown with other sulfur containing phases.

The X-ray absorption near edge structure (XANES) spectra are classified with respect to pre-edge features and edge structures. Hackmanites for example show a sharp pre-edge at the lowest energy so far recognized in S K-edge x-ray absorption spectra [1]. Lazurites are characterized by a sulfate resonance and spectral features that indicate reduced sulfur species. Ultramarine color pigments show two types of spectra, both indicate reduced reduced sulfur species, too.

Besides the above mentioned minerals and color pigments helvine ($Mn_4Be_3[S|(SiO_4)_3]$), vishnevite ($(Na,K)_8[(SO_4,CO_3)|Al_6Si_6O_{24}]x2H_2O$) and other non-tectosilicates like ellestadite ($Ca_5(SiO_4,PO_4,SO_4)_3(F,OH,Cl)$) have been included in the study.

The results will be compared with non-silicate compounds and minerals where sulfur is the main constituent, like elemental sulfur, iron sulfides and different sulfites and sulfates.

A first attempt to gain structural information on sulfur in silicate minerals using S K-edge Extended Fine structure (EXAFS) spectroscopy will also be discussed.

Long-wavenumber infrared study of tourmalines from tin deposits in Russia

Ivanov, V.V.[1*], Narnov, G.A.[1], Kononov, V.V.[1] & Gorelikova, N.V.[2]
[1]FEGI FEB RAS, Vladivostok, Russia ([*]dom101@mail.ru)
[2]IGEM RAS, Moscow, Russia

Tourmaline is an important petrogenetic indicator of different geological events because it can incorporate by total or partial substitution a great variety of chemical elements depending on the geological setting [1]. The chemical composition of the tourmaline group minerals is represented by the general formula $XY_3Z_6(Si_6O_{18})(BO_3)_3(OH, F)$ [2]. An important method that can be used to explain crystal chemical features of tourmaline is infrared (IR) spectroscopy. We revealed the connection between the cation composition of tourmalines and the features of IR spectra of the mineral group in the long wavenumber range (400-220 cm^{-1}) because this range has not been studied at all for tourmalines.

IR spectra of tourmalines are characterized by clear absorption bands in the studied interval. In spectra of schorls the characteristic absorption bands are the following: 370, 330, 300, 273, 229 cm^{-1}. Besides, a shoulder at 263 cm^{-1} and a poorly defined band at 250 cm^{-1} were found. IR spectra of dravites are dominated by the bands at 373, 329-322, 274, 229 cm^{-1}, and also shoulders at 348, 308, 259 cm^{-1}. Elbaites are characterized in IR spectra by maxima at 372, 354, 226 cm^{-1} and shoulders at 348 and 239 cm^{-1}. IR spectra of intermediate members of schorl-dravite range have characteristic bands at 320, 269 and 224 cm^{-1}. A common feature of all spectra of tourmaline varieties is the presence the major broad band at 340-290 cm^{-1}, including one or two maxima. The absorption band with maximum at 330 cm^{-1} is typical of schorls, 229-222 cm^{-1} is for dravites, 319 cm^{-1} for schorl-dravites. The comparison of IR spectra and the chemical composition of different tourmaline varieties suggest that bands in this range should be conditioned by the variable cation content in the mineral structure.

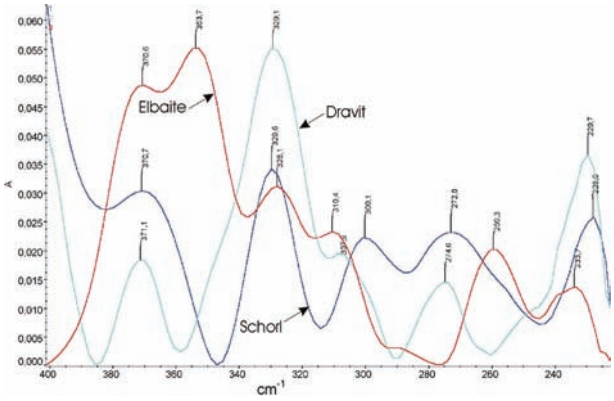

Fig. 1: Typical IR spectra of schorl, dravite and elbaite.

High-pressure Raman spectroscopic studies of ulvöspinel Fe_2TiO_4

Kyono, A.[*], Yamanaka, T., Ahart, M., Mysen, B.O., Mao, H.K. & Hemley, R.J.
Geophysical Laboratory, Carnegie Institution of Washington, Washington D.C., USA ([*]akyono@ciw.edu)

We report in situ Raman spectroscopic studies of ulvöspinel in a diamond-anvil cell under hydrostatic conditions up to 57 GPa at room temperature. There are five first-order Raman active modes ($A_{1g} + E_g + 3F_{2g}$) in the *Fd3m* space group of the spinel structure. Two strong modes at nearby 500 (F_{2g}) and 700 cm^{-1} (A_{1g}) are observed both at ambient and at high pressure conditions (Fig. 1). The remaining three modes could not be observed unambiguously in the measurements. The peak positions and shapes of the Raman spectra agree well with previously published data measured under ambient condition [1].

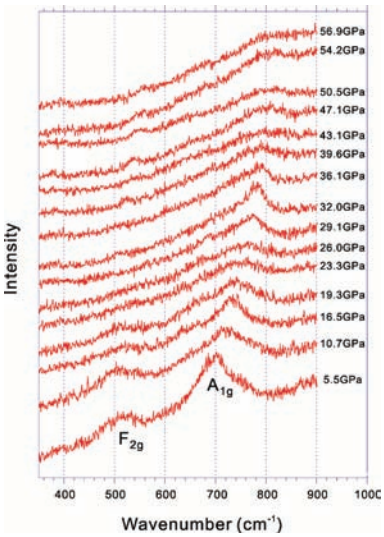

Fig. 1: Pressure dependence of the Raman spectra of ulvöspinel Fe_2TiO_4 under compression up to 54 GPa.

With increasing pressure, the frequencies of the two strong bands A_{1g} and F_{2g} increase continuously up to 13 GPa with pressure derivatives of 2.6 and 1.4 cm^{-1}/GPa, respectively. There is no obvious degradation of crystal symmetry or structural change within this pressure range. These two frequencies gradually decrease with increasing pressure. Above 10 GPa, these peaks broaden and reduce their intensities with pressure. Then, the F_{2g} symmetry mode completely disappears at a pressure of 20 GPa. According to high-pressure X-ray diffraction experiment results [2], the ulvöspinel undergoes a series of transformations: cubic to tetragonal, tetragonal to orthorhombic, and orthorhombic to orthorhombic. At first, the transformation from cubic to tetragonal takes place at 9 GPa. Second, orthorhombic occurred at 13 GPa remains stable up to 48 GPa. New high-pressure phase occurs above 48 GPa. The orthorhombic phase has four Raman active modes ($A_g + B_{1g} + B_{2g} + B_{3g}$). The pressure-induced phase transition from cubic to orthorhombic is accompanied by transformation of the A_{1g} and F_{2g} modes of the cubic into the A_g and $B_{(1,2,3)g}$ modes in the orthorhombic. It seems reasonable to suppose that the remaining peaks above 20 GPa result from the A_g mode in the orthorhombic phase transformed from cubic ulvöspinel.

Water speciation in silicate melts: a high temperature Raman spectroscopy study

Le Losq, C.[1], Moretti, R.[2] & Neuville, D.R.[1*]
[1]CNRS-IPGP, Physique des Minéraux et des Magmas, Géochimie et Cosmochimie, Paris, France ([*]neuville@ipgp.jussieu.fr)
[2]Istituto Nazionale di Geofisica e Vulcanologia, sezione di Napoli – Osservatorio Vesuviano

In addition to temperature, pressure and main chemical components, volatiles exert a strong influence on the physical properties of magmas. In particular, water plays a fundamental role in the dynamics and evolution of magmas in the deep interior and during volcano eruption. However, water speciation in silicate melts is not fully understood. Infrared spectroscopy had provided some valuable information about the H_2O/OH^-

SiO_2	Al_2O_3	FeO	MgO	H_2O_{calc}
43.89	2.33	4.18	35.74	13.86

speciation. We know that this speciation is a function of temperature and water contents of melts. It can be very interesting to know it from *in situ* experiments. This can be done using Raman spectroscopy.

Raman spectra are composed of i) a low-wavenumber region which corresponds to vibrations of the silicate network (0-1500 cm^{-1}), and ii) a high-wavenumber region which correspond to the OH^- stretching vibration and H_2O molecular vibration (3100-3750 cm^{-1}). We have performed a first set of *in situ* experiments using a micro-furnace at ambient pressure. We have observed an evolution of the high-wavenumber region as a function of time and temperature. New Raman peaks can be distinguished, particularly near 3650-3700 cm^{-1}. In this communication, we will present our first results on this subject and then discuss them in terms of relation between water and the silicate network.

The polarized spectra (400 – 1600 nm) of antigorite from Aldina Reka (Serbia)

Logar, M.[*], Poharc-Logar, V. & Erić, S.
Dept. of Mineralogy and Crystallography, FMG, University of Belgrade, Serbia ([*]milogar@eunet.rs)

Looking at the available literature [1] it seems that the colour origin of serpentine minerals needs additional study. We couldn't find data on polarized spectra of antigorite. Only one unpolarized spectrum has been published until now [2].

Antigorite from Aldina Reka [3] occurs in the veins as a rod-like aggregate with perfect parting parallel to elongation. Microscopic observations reveal lath-like crystals with apparent pleochroism of a changing green hue (Fig. 1). The chemical analysis (SEM EDX) at the thin-section points where the spectra have been measured are listed in Table 1.

Table 1: Chemical analysis (SEM EDX) of antigorite (wt%)

The spectra of two vibration directions have been measured installing the microscope (Leitz with Nicol prism) in the optical path of the computer controlled monochromator. The chopped signal, synchronized and amplified by lock-in amplifier, was recorded to the computer. Between 400 and 1600 nm 1039 points were measured with the FM tube, Si and InGaAs photo-diodes, using 0.03 mm slit. The spectra have been measured through four different points of the thin-section area (0.5 mm thickness). No significant difference among the four spectra was observed.

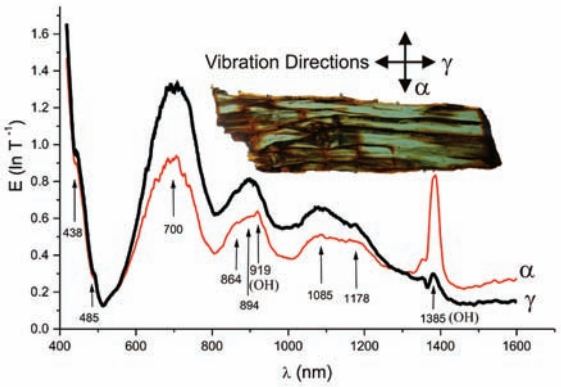

Fig. 1: The polarized spectra of antigorite (green parts).

Absorption peaks found in the spectra can be separated into three groups in accordance with their origin. 1) Polarization-dependent overtones of (OH) stretching vibrations at: 1385 nm (7220 cm^{-1}, $\Delta\upsilon=2$) and 919 nm (10893 cm^{-1}, $\Delta\upsilon=3$). 2) Polarization-independent d-d electron transitions due to octahedral Fe^{2+} calculated for Racah parameters B=750 and C=3250 cm^{-1}: Jahn-Teller separated $^5E(D)$ at 1085 and 894 nm; two spin-forbidden $^3T_1(H)$ at 1178 nm and $^3T_2(H)$ at 867 nm. 3) Polarization-dependent Fe^{2+}- Fe^{3+} charge-transfer band at 700 nm, which produce the pleochroism.

Spin-forbidden Fe^{3+} d-d transitions is not resolved except the shoulder at 438 nm which could be the $^4A_1$,$^4E(^4G)$.

Matrix-infrared spectroscopy as a tool to monitor admixtures in minerals

Marinova, D.[1*], Wildner, M.[2], Stoilova, D.[1] & Georgiev, M.[3]
[1]Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria
([*]d.manasieva@gmail.com)
[2]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria
[3]Dept. of Inorganic Chemistry, University of Chemical Technology and Metallurgy, Sofia, Bulgaria

Matrix-infrared spectroscopy provides important information about the type of the admixtures included in minerals, either as isomorphous (isodimorphous) substitutions or as distinct phase inclusions. The vibrational spectra of distinct phase inclusions are similar to those of the respective neat compounds. However, the vibrational spectra of isomorphously included guest ions are essentially determined by both the site-symmetry, which is assumed to be the same as that of the respective host ions (substitutional type of mixed crystals), and the potential at the lattice sites where the guest ions are located, as shown by the extend of energetic distortion of the matrix-isolated ions.

In the present study, several phases belonging to the large number of natural and synthetic compounds with kröhnkite-type chains have been synthesized as model phases. The crystal structures of $Na_2Me(SeO_4)_2\cdot 2H_2O$ (*Me* = Co, Ni, Zn, Cd) and $K_2Me(CrO_4)_2\cdot 2H_2O$ (*Me* = Zn, Cd) were determined from X-ray single-crystal diffraction data and those of $K_2Me(CrO_4)_2\cdot 2H_2O$ (*Me* = Co, Ni) by X-ray powder diffraction. The structures are build up from $MeO_4(H_2O)_2$ octahedra and XO_4 tetrahedra forming infinite kröhnkite-type octahedral-tetrahedral chains, which are linked by alkali cations to layers and further to a three-dimensional framework via hydrogen bonds. The sodium cobalt, nickel and zinc compounds as well as the potassium cobalt, nickel and cadmium compounds crystallize in the triclinic space group $P\bar{1}$ (type A), the sodium cadmium selenate in the monoclinic space group $P2_1/c$ (type D), and the potassium zinc chromate in the monoclinic space group $C2/c$, thus representing a new structural type (type H).

The vibrational behavior of SO_4^{2-} guest ions included in these chromate and selenate matrices has been studied by infrared spectroscopy. It has been established that the extent of energetic distortion of the SO_4^{2-} guest ions as deduced from the values of $\Delta\nu_{as}$ (site-group splitting) and $\Delta\nu_{max}$ (the difference between the highest and the lowest wavenumbered components of the stretching and bending modes), depends on both the electronic configurations of the Me^{2+} ions and the degree of covalency of the respective Me^{2+}–O bonds. The matrix-isolated SO_4^{2-} guest ions are stronger distorted in the selenates than in the chromates due to the smaller unit-cell volumes of the selenate host compounds as compared to those of the chromate ones and the different ionic radius of the K^+ and Na^+ ions. The smaller Na^+ ions cause a stronger electrostatic field (shorter Na–O bonds), thus leading to remarkably larger values of $\Delta\nu_{as}$ and $\Delta\nu_{max}$ of the guest ions in the sodium compounds.

The temperature stability of quaternary precipitations remanence

Mashukov, A.V.[*], Onufrienok, V.V. & Mashukova, A.E.
Siberian Federal University, Krasnoyarsk, Russia
([*]AVMashukov@)sfu-kras.ru)

The natural remanence, in whose formation a great role is played by iron compounds, is source of information about the value and direction of the ancient magnetic field as well as physicochemical conditions of rock formation.

To reveal the conditions determining the specific character of the quaternary precipitations remanence of the Yenisej river, there were investigated their magnetic and structural properties. The value of the alternating magnetic field, which half reduces the remanence of the samples, makes up 16 kA/m, the coercive force is 30 A/m and the saturation magnetization is more than 800 A/m. In table 1 there are given the values of relative magnetization J/J_0 at different temperatures.

Table 1: Relative magnetization at different temperatures

°C	100	200	300	350	400	450	500	550	595
J/J_0	0.95	0.99	0.95	0.96	0.93	0.93	0.75	0.7	0

To reveal the minerals - magnetization carriers by using a magnetic separation method, there were singled out three fractions by strong-magnetic (1), weak-magnetic (2) and non-magnetic.(3) (Table 2).

Table 2: Parameters of the samples according to the Mossbauer spectroscopy data

Percentage of the samples	Fraction 1	Fraction 2	Fraction 3
Fe_3O_4	87,3±0,2	-	-
Fe_2O_3	0,7±0,7	21,3±0,7	-
FeO	4,7±0,3	36,4±0,1	53,1±0,05
FeOOH	8,0±0,2	42,3±0,2	46,9±0,05

One can see from table 2, that the basic ferruginous mineral in the fraction (1) is magnetite. Hematite is probably located on the surface of magnetite grains. The isomer shifts testify to different surrounding of radiating and absorbing nucleus and to different iron ion valency. The carriers of the fraction (2) magnetization are hematite grains. The compounds FeOOH and FeO do not give any contribution into remanence. The isometric shift and the quadrupole splitting of these compounds are identical with those for the weak-magnetic fraction.

The precipitation with desired deposition conditions in the Earth magnetic field were investigated by using X-ray straight pole figures method for the exploring of the crystallographic ordering effect. The intensity values of the precipitation with magnetic particle size are shown in table 3.

Table 3: Dependence of intensity on particle size

Fraction	1	2	3	4	5
Fe_3O_4 particle size d, mcm	0 ÷ 8	9 ÷ 32	33 ÷ 64	65 ÷100	150 ÷200
Intensity	1,9	1,8	1,4	1,2	1,1

Thus, the Mossbauer spectra make it possible to determine the types of magnetic minerals in complex compounds. Their identification enables to reveal the stability of remanence in geological time scales.

Comparative diffraction and spectroscopic study of the stannite – kesterite – kuramite system

Schorr, S.[1*] & Evstigneeva, T.L.[2]
[1]Institute of Geological Sciences, Free University Berlin, Germany ([*]susan.schorr@fu-berlin.de)
[2] Faculty of Physics, M.V. Lomonosov Moscow State University, Moscow, Russia

The pseudoternary Cu_2FeSnS_4 (stannite) – Cu_2ZnSnS_4 (kesterite) – Cu_3SnS_4 (kuramite) system have been studied by a combination of neutron powder diffraction, EXAFS and Moessbauer spectroscopy.

Stannite and kesterite have structural models derivative of that of chalcopyrite, $CuFeS_2$, the archetype of the extensive family of I-III-VI chalcogenide semiconductors. Chalcopyrite, in turn, has a structural model simply derivative of that of sphalerite, ZnS. The chemical change from ZnS to quaternary chalcogenides is accomplished by successive specialization of cation sites, with a consequent lowering of the overall symmetry of the structure. From $Fm3m$, sphalerite, a tetragonal space group, $I\bar{4}2d$ characterizes chalcopyrite, stannite and kesterite are also tetragonal. Although Fe and Zn have similar chemical behaviour in this materials, crystal chemistry of both ions is significantly different and induces structures in different space groups, $I\bar{4}2m$, stannite and $I\bar{4}$, kesterite. The copper tin sulphide kuramite, $Cu(I)_2Cu(II)SnS_4$, crystallizes in the stannite type structure, where the two Fe and Cu cation sites are occupied just by Cu. A relevant consequence is that Cu(II), necessary in this phase to achieve the charge balance, can not be identified in a single site.

The diffraction and spectroscopic techniques used contribute different aspects to this study: neutron diffraction is mainly devoted to investigate the metal distribution in the cation sites [1]. ^{57}Fe and ^{119}Sn Moessbauer spectroscopy allows to determine the valence state and atom coordination of iron and tin atoms in the structure [2,3]. EXAFS is a X-ray spectroscopy technique which allows the determination of bond distances locally and gives also a hint to the charge state of iron [4].

The presentation will give a comparative discussion of average and local bond distances in the stannite – kesterite – kuramite system, achieved by diffraction and spectroscopy, respectively. Furthermore the valence state of iron, determined by two different spectroscopic techniques, will round the presentation.

ESR dating of barite in hydrothermal chimneys of deep sea floor

Toyoda, S.[1*], Sato, F.[1], Okumura, T.[1], Ishibashi, J.[2], Nakai, S.[3] & Kumagai, H.[4]
[1]Dept. of Applied Physics, Okayama University of Science, Okayama, Japan ([*]toyoda@dap.ous.ac.jp)
[2]Kyushu University, Fukuoka, Japan
[3]University of Tokyo, Japan
[4]Japan Agency for Marine-Earth Science and Technology, Yokosuka, Japan

Barite ($BaSO_4$), the most common barium mineral, occurs principally as gangue mineral in hydrothermal polymetallic ore deposit. In this study, electron spin resonance (ESR) dating method was applied to marine barite formed in deep sea hydrothermal systems.

We used barite chemically extracted from the portion taken at the basal part of a hydrothermal chimney, consisting of barite, sphalerite and pyrite, at the Archaean site (12°56.4'N, 143°37.9'E) in South Mariana spreading centre. The sample was taken at the time of the dive, YK05-09 cruise by deep-sea submersible vehicle (DSV) Shinkai 6500 performed by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC). ESR spectra were observed using a JEOL PX-2300 at room temperature with a microwave power of 1 mW, the modulation frequency of 100 kHz, and modulation amplitude of 0.1 mT.

The ESR spectrum of marine barite, shown in Fig. 1, is characterized by an electron-type center with g values of 2.0034, 2.0022 and 1.9995 probably attributed to SO_3^- [1]. The signal intensity was enhanced by gamma ray irradiation in the dose range from 110 to 2600 Gy. The accumulated natural dose of 232 Gy was obtained by extrapolating the saturation curve to zero ordinate after fitting a curve to the dose response of the ESR intensity. The ^{226}Ra activity of the barite was measured by gamma ray spectrometry using a low background germanium detector. The Ra concentrations were 7.72 Bq/g, while those of Th series and K_2O were not detected. The natural dose rate was calculated to be 303 mGy/y. The age of the sample was estimated to be 765 years. Barite seems to be a useful mineral for dating hydrothermal activities in the sea floor, however, the age was not consistent with the value obtained by ^{226}Ra-^{210}Pb dating method.

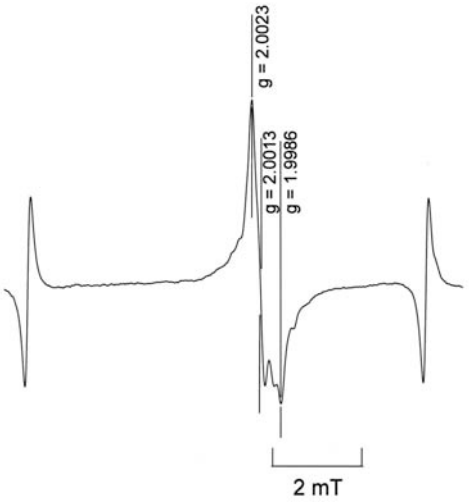

Fig. 1: The ESR signal observed in marine barite. The signal is attributed to SO_3^- radical.

Local structure analysis of tektite by Ti K-edge EXAFS spectroscopy

Wang Ling[1], Yoshiasa Akira[1*], Okube Maki[2], Murai Kei-ichiro[3] & Takeda Takashi[4]
[1]Graduate School of Sciences and Technology, Kumamoto University, Kumamoto, Japan
([*]yoshiasa@sci.kumamoto-u.ac.jp)
[2]Materials and Structure Laboratory, Tokyo Institute of Technology, Yokohama, Japan
[3]Dept. of Advanced Materials, Institute of Technology and Science, the University of Tokushima, Japan
[4]National Institute for Materials Science, Tsukuba, Japan

Local structure of tektite was studied by extended X-ray absorption fine structure (EXAFS) spectroscopy. We have carried out Ti K-edge EXAFS measurements to get information about the local structure and chemical state of Ti in many species with different localities, sizes and colours in tektites of Hainanite, Indochinite, Philippinite, Australite, Bediasite and Moldavite. We have determined the precise local Ti-O bonds in tektite. We also prepared several reference titaniferous minerals.

Tektites have different local structures of Ti. The pattern of XANES spectra has something that looks like high-temperature TiO_2-SiO_2 glass, TiO_2 anatase and $CaTiO_3$ perovskite. All samples show the valence of Ti is 4^+. Based on the local Ti-O distances, coordination numbers and radial structure function determined by EXAFS analyses, we classified the tektites in three types: Type I, Ti occupy 4-fold coordinated tetrahedral site and Ti-O distances are 1.84-1.79 Å; Type II, Ti occupy 5-fold trigonal bi-pyramidal or tetragonal pyramidal site and Ti-O distances are 1.92-1.89 Å; Type III, Ti occupy the 6-fold octahedral site and Ti-O distance is 2.00-1.96 Å. Farges & Brown [1] discussed the coordination number of Ti in tektite according to the pre-edge XANES pattern and concluded all tektites have 4-fold coordination. Though, we have found some tektites with 5- and 6-fold coordinated Ti. Ti occupies the TiO_6 octahedral site in many titanium minerals at ambient conditions. This study indicates that the local structure of Ti should be changed in the impact event and the following stage. Tektites splashed to the space and travelled in several kinds of processes and routes, which lead to different temperature and pressure history. Local structure of Ti should be related with the temperature, pressure, quenching rate, sizes of impact meteorite and size of falling melts. As a result, there are some difference in the bonding structure of Ti atoms and arrangements of neighbouring oxygen.

Table 1: Classification of titanium local structure in tektites based on the local Ti-O distances, coordination numbers determined by EXAFS analyses

	Tektites	Coordination number	Ti-O distance (Å)
Type I	Hainanite	4	1.790(4)
	Indochinite	4	1.812(5)
	Bediasite	4	1.835(3)
Type II	Australite	5	1.890(5)
	Philippinite	5	1.920(5)
Type III	Moldavite	6	2.001(4)

IR spectroscopy: quantitative determination of the mineralogy and bulk composition of fluid microinclusions in diamonds

Weiss, Y.[1*], Kiflawi, I.[1,2] & Navon, O.[1]
[1]The Fredy and Nadine Herrmann Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel
([*]yakov.weiss@mail.huji.ac.il)
[2]Department of Physics, King's College, London, UK

Infrared (IR) spectroscopy is commonly used to determine the concentration and aggregation of nitrogen in diamonds, as well as the presence and concentration of other impurities. In the case of fibrous diamonds, where high density fluids (HDFs) were trapped in myriads of microinclusions, the geometrical arrangement of the inclusions in the diamond is very favorable for IR measurement. The trapped phases are all only a few tens to hundreds of nanometres in size, and are dispersed in the diamond matrix just as mineral powders are dispersed in KBr pellets commonly used in IR measurements. To translate the absorption by the common secondary phases in the microinclusions to their absolute concentration in the diamond or relative abundance in the microinclusions themselves, we determined the absorptivities of 8 minerals (Table1).

Table 1: Mineral IR absorptivity

Mineral	Band [(a)]	ε [(b)]
Garnet	967	1049
Apatite	1049	2590
	605 [(c)]	800
Olivine	894	418
Calcite	1433	739
Dolomite	1442	921
Magnesite	1451	563
Quartz	1084	418
	800 [(c)]	102
Phlogopite	1006	861

[(a)]Main IR band (cm^{-1}); [(b)]Absorptivity (AU·Liter/mole·cm); [(c)]Small IR peak used for the calculations in some of the diamonds.

Using these absortivities we determined the concentrations of the secondary minerals in 13 diamonds that carry carbonatitic to silicic HDFs, as shown by previously EPMA and IR analyses. Normalizing the concentrations to 100% yields the relative concentration of each mineral in the microinclusions, it also annuls the effect of the number-density of microinclusion, which may vary even within a single diamond. Combining the relative abundance with the composition of each mineral in the microinclusions, we calculated the concentration of SiO_2, Al_2O_3, P_2O_5 and MgO+CaO+FeO+BaO+Na_2O (water and CO_3^{-2} free basis) of the bulk HDF and found very good agreement with the EPMA data for the same diamond. These results, together with a +8% corrections to the absorptivity of water [1,2] due to salinity, show that the hydrous solution make up ~10% of the high-Mg carbonatitic HDFs, reach 20-25% in the intermediate ones and, in general, become somewhat drier in the highly silicic compositions.

Although the EPMA adds valuable data on specific oxides and Cl, our results show that IR spectroscopy alone can be used as a semi-quantitative method to determine carbonatitic to silicic HDF compositions in microinclusions-bearing diamonds. Combining EPMA and FTIR a full characterization of the major constituents is achieved, including carbonate and water content.

Synchrotron radiation techniques applied to Earth Sciences samples. Why and how?

Testemale, D.
Institut Néel and FAME beamline at ESRF, Grenoble, France
(denis.testemale@grenoble.cnrs.fr)

Synchrotron radiation techniques have been used more and more widely in the Earth Sciences community: the intensity, energy and size characteristics of this radiation, the development of the detection systems and of the numerical analysis tools are the core of a broad range of applications, particularly suitable for the Earth Sciences samples. Those samples, whether natural or synthetic, are indeed typically heterogeneous and/or at low concentrations and/or of small size, and can be sometimes challenging to analyze.

Through various examples, this presentation will attempt to give an introductory overview of the research areas and problematics where synchrotron radiation techniques are particularly useful, if not mandatory. It will also expose the relevant techniques (X-ray spectroscopy, scattering, tomography, etc.) and the nature of the information retrieved (atomic structure, electronic structure, redox state, elemental concentration, imaging, etc.). Emphasis will be given on recent developments in *in situ* experimentation and on the variety of sample environments available by X-rays experimentation.

Finally, the particular example of metal mobility and fluid/rock interactions at hydrothermal conditions will be presented and also exploited to emphasize the need for complementary numerical techniques.

The oxidation state of vanadium in titanomagnetite determined by HERFD-XAS spectroscopy

Bordage, A.[1,2*], Balan, E.[2], de Villiers, J.P.R.[3], Juhin, A.[2], Glatzel, P.[2] & Brouder, Ch.[2]
[1]Laboratoire des Géomatériaux et Environnement, Univ. Paris-Est Marne la Vallée, Marne la Vallée, France

[2]Institut de Minéralogie et de Physique des Milieux Condensés, Univ. Paris 6 et 7, IRD, IPGP, Paris, France
[3]Dept. of Materials Science and Metallurgical Engineering, University of Pretoria, South Africa
[4]European Synchrotron Radiation Facility, Grenoble, France

Vanadium is an example of multivalent impurities as it occurs in three redox states (+III, +IV and +V) in magmatic systems. It makes it a valuable geochemical probe, providing useful information about redox conditions during natural processes. Vanadium is extracted from titanomagnetite ($Fe_{3-x}Ti_xO_4$), found as massive discrete layers in the Bushveld Complex (South Africa). However, the crystallization process of these layers is still poorly understood. The oxidation state of vanadium may be a potential benchmark to get new information.

K-edge X-ray Absorption Spectroscopy (XAS) is a powerful tool to investigate the electronic structure and crystallographic environment of a transition metal cation occurring at low concentration in minerals. In particular, the energy and relative intensity of pre-edge features depend on the valence state and site symmetry of the absorbing atom [1]. However, in the case of V-bearing titanomagnetite, the high level of titanium (~15wt% TiO_2) compared to that of vanadium (~1.5wt% V_2O_3) hinders the use of conventional XAS measurements: the pre-edge features are masked by a very high background due to the Ti fluorescence [2]. High-Energy Resolution Fluorescence Detected–XAS (HERFD-XAS) [3] overcomes this problem: a single fluorescence line, selected by a high-resolution emission spectrometer, is recorded while scanning the incident energy range [4]. The fluorescence resulting from Ti is thus filtered out and the spectral resolution of the pre-edge and edge features is substantially improved.

We present here a HERFD-XAS study of natural and synthetic samples of V-bearing titanomagnetites. V *K*-edge spectra have been recorded, selecting the V $K\alpha_1$ fluorescence line, on ID26 beamline at the ESRF (Grenoble, France). The pre-edge features indicate the presence of V^{3+} and V^{4+} under various proportions, as observed in a study of V-bearing titanomagnetite from another locality of the Bushveld Complex [5]. The V^{4+}/V^{3+} ratio depends on the oxygen fugacity and its variations are also observed as a function of the stratigraphic height within the Main Magnetite layer of the Bushveld Complex. These variations with depth suggest variations of the redox conditions during the crystallization of the main magnetite layer [2].

Structural role of Ti and Zr in the nucleation of aluminosilicate glasses by X-ray absorption spectroscopy

Cormier, L.[1*], Dargaud, O.[1,2], Galoisy, L.[1], Calas, G.[1] & Jousseaume, C.[2]
[1]Institut de Mineralogie et Physique des Milieux Condensés, CNRS, Université Pierre et Marie Curie, Université Paris Diderot, IPGP, Paris, France ([*]cormier@impmc.upmc.fr)
[2]Saint-Gobain Recherche, Aubervillier, France

Nucleation plays a central role in the crystallization of igneous and metamorphic rocks and in the making of commercial glass-ceramic materials. The nucleation control is usually achieved by adding nucleating agents, typically ZrO_2 or TiO_2, but their structural role is still poorly understood.

We present an X-ray absorption spectroscopic investigation of the Zr and Ti environment in aluminosilicate glasses and glass-ceramics using Zr K- and L-edges and Ti K-edge. We determine the Zr and Ti environment in MgO-Al_2O_3-SiO_2 glasses, showing their difference with other silicate or aluminosilicate systems. The structural variation around Zr and Ti is followed using both ex situ and in situ experiments in relation with the formation of the first crystalline nanophases. The importance of the initial glassy state is emphasized by our study and the XAS results also allow a better characterization of the primary crystals.

In situ high temperature X-ray absorption investigation at the Na, Ca, Al and Si-edges in melts

Neuville, D.R.[1*], de Ligny, D.[2] & Henderson, G.S.[3]
[1]CNRS-IPGP, Géochimie et Cosmochimie, Paris, France ([*]neuville@ipgp.jussieu.fr)
[2]LPCML, UCBL, Villeurbanne, France
[3]Dept. of Geology, University of Toronto, Canada

Structure of silicate and aluminosilicate melts is not well known at high temperature. X-ray absorption spectroscopy is a very specific and interesting way to probe the network structure and more specifically the Al and Si surrounding. Recent developments on X-ray absorption spectroscopy at light K-edges, made on the LUCIA beamline at the SOLEIL light source, enable to measured XANES spectra at high temperature on the Na, Ca, Al and Si K-edges. We have investigated mineral and melts at different K-edge and different temperature above to the liquidus temperature. The method and first results will be presented. Significant change on the XANES spectra at the Ca K-edge can be observed just after the melting point, where important changes appear in the liquid state. At Al K-edge, we observed also important modifications in the mean resonances. These first measurements are a good illustration of loss of medium range order after melting characterized by the disappearance of structural features in XANES spectra.

Elastic wave velocities and densification of silica glass at high temperatures and high pressures

Matsui, M.[1*], Yokoyama, A.[1], Higo, Y.[2], Kono, Y.[3], Irifune, T.[3] & Funakoshi, K.[2]
[1]School of Science, University of Hyogo, Japan
([*]m.matsui@sci.u-hyogo.ac.jp)
[2]Japan Synchrotron Radiation Research Institute, Hyogo, Japan
[3]Geodynamic Research Center, Ehime University, Matsuyama, Japan

The elastic P and S wave velocities of silica glass at high temperatures and high pressures were measured using a combined use of ultrasonic interferometry, in situ synchrotron X-ray diffraction and radiographic techniques in a large-volume Kawai-type multi-anvil apparatus SPEED1500 at the BL04B1 beam line of SPring-8. Details of the experimental setup were described previously [1,2].

We found no first-order amorphous-amorphous transformation throughout the temperature and pressure conditions up to 5 GPa and 1173 K, contrary to previous studies suggested by MD simulations [3] or those reported using piston cylinder experiments in which the density of silica glass increased discontinuously with pressure by about 20 % at 3.6 GPa and 953 K [4].

For both the 650 and 800 K isothermal runs, the P and S wave velocities of silica glass initially decreased with increasing pressure, reaching minimum values at around 3 – 4 GPa, followed by increases with pressure up to 6 GPa; on successive decompression, both velocities slightly increased irreversibly to ambient pressure due to permanent densification, and no minima were observed in both velocities. Such unusual behavior in the P and S wave velocities associated with densification process at high temperature and high pressure is quite similar to that which occurs in silica glass at room temperature with increasing and decreasing pressures [5,6].

We found that the measured density of recovered silica glass after a second compression-decompression cycle at 800 K, 2.52(1) g/cm^3, agrees within error with that after the first compression-decompression cycle, 2.51(1) g/cm^3, indicating the densified silica glass compressed reversibly (elastically) with decreasing and increasing pressure at 800 K. Using the measured P and S wave velocities in reversible (elastic) compression regions as a function of pressure, we calculated the densities of silica glass up to 6 GPa at three isotherms of 300, 650, and 800 K. We found the density of the glass increases with temperature at high pressures, indicating a negative thermal expansion in the temperature-pressure range studied here; e.g. the densities at 5 GPa are 2.60, 2.70, and 2.74 g/cm^3 at 300, 650, and 800 K, respectively.

Structure transition of $Fe_{3-x}Ti_xO_4$ solid solution under pressures

Yamanaka, T.[*], Kyono, A., Kharlamova, S., Ahart, M., Struskin, V., Mysen, B.O., Mao, H.-k. & Hemley, R.J.
Geophysical Laboratory, Carnegie Institution of Washington, Washington DC, USA ([*]t.yamanaka@kce.biglobe.ne.jp)

The solid solutions between Fe_3O_4 and Fe_2TiO_4 are principal magnetic substance for the rock magnetism in the crust. Fe_3O_4 is ferrimagnetic and Fe_2TiO_4 is antiferromagnetic. Several models of the cation distribution in $Fe_{3-x}Ti_xO_4$ solid solutions have been proposed. In the present study electron spin states of these solid solutions under high pressures have been investigated by X-ray powder diffraction, X-ray emission, Raman spectra and Mössbauer studies.

Powder diffraction experiments of $Fe_{3-x}Ti_xO_4$ up to 60GPa using DAC and synchrotron radiation indicates their volumes of the tetrahedral (A) and octahedral site (B) as functions of composition and pressure. High-pressure transition from cubic to orthorhombic structure is found in the whole compositional range. The transition pressure decreases from 27GPa (x=0.0) to 1 GPa (x=1.0). The solid solutions with $0.734 \leq x \leq 1.0$ show the transition from cubic to tetragonal with c/a<1. The transition pressures are 12GPa (x=0.734) and 8 GPa (x=1.0). This transition can be explained by Jahn-Teller effect of Fe^{2+} at the A site or high-low spin transition of Fe^{2+} ion in the A or B site.

Bulk modulus, bond distance and site volume of $Fe_{3-x}Ti_xO_4$ spinels are observed with increasing Ti^{4+} substitution for Fe^{3+} in the octahedral site. The bulk modulus of Fe_2TiO_4 spinel is much larger than that of Fe_3O_4.

X-ray emission study of Fe_2TiO_4 under compression at BL16-IDD APS confirms mixed spin state or intermediate spin of both ions at much lower pressure as 9GPa compared with Fe_3O_4. The ionic radii change by the high-low spin transition may induce the cubic-to-tetragonal transition and bring the first order transition. The emission spectra do not show any other spectra change up to 15GPa even in the orthorhombic phase.

Raman spectra have been observed under high pressures. Four bands were obtained at ambient conditions. These peak positions continuously shift toward the higher energy sides with increasing pressure up to 15GPa.

Boggsite under high pressure: a case of zeolite over-hydration

Quartieri, S.[1], Arletti, R.[2], Vezzalini, G.[2*] & Dmitriev, V.[3]
[1]Dept.of Earth Sciences, University of Messina, Italy
[2]Dept. of Earth Sciences, University of Modena and Reggio Emilia, Modena, Italy ([*]mariagiovanna.vezzalini@unimore.it)
[3]SNBL-ESRF, Grenoble, France

Boggsite is a rare natural zeolite [1-4]. Its crystal structure [2] is characterized by a pentasil framework and an interesting 3D channel system of 10- and 12-rings, which makes this topology potentially very suitable for industrial and environmental applications.

The elastic behavior of boggsite from Terra Victoria Land (Antarctica) is investigated by in-situ H*P* synchrotron X-ray powder diffraction, using both silicon oil (s.o.) (P_{amb}–9.3 GPa) and methanol:ethanol:water (16:3:1) mixture (m.e.w.) (P_{amb}–7.6 GPa), as non penetrating and penetrating *P*-transmitting medium, respectively. Neither X-ray amorphization nor phase transitions are observed up to the highest investigated *P*, and the original unit cell parameters are recovered upon decompression. The following decreases of *a*, *b*, *c*, and *V* are observed: 5.3, 4.2, 4.0 and 13%, in s.o. up to 5.9 GPa; 4.1, 4.1, 3.8 and 11.5%, in m.e.w up to 7.6 GPa.

The Rietveld structural refinements of the powder patterns collected in m.e.w. reveal a significant over-hydration between 0.3 and 2.9 GPa. This occurs with increasing the occupancy of 4 of the 13 extraframework sites already present in boggsite at P_{amb}. In this *P*-range, the compressibility in m.e.w. is lower than in s.o., due to the entering of the additional water molecules, which contribute to make more rigid the structure. At higher *P*, the compressibility is similar for the two media (Fig. 1). The elastic parameters were calculated from P_{amb} to 5.9 GPa for s.o., while for m.e.w. the calculation was performed after the water content stabilization, that is from 2.9 to 7.6 GPa. The following results were obtained: V_0 = 6240(6) Å³, K_0 = 31.1(4) GPa, and V_0 =6405(17) Å³, K_0 = 37(1) GPa, for s.o. and m.e.w., respectively.

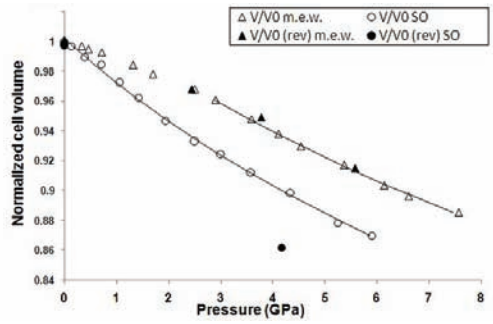

Fig. 1: Plot of ΔV vs. P for boggsite compressed in s.o. and m.e.w. Solid lines represent the EoS fits.

Rhombic-shaped nanodomains in columbite driven by contrasting cation ordering

Tarantino, S.C.[1,2*], Zema, M.[1,2], Capitani, G.[3], Scavini, M.[4], Ghigna, P.[5], Brunelli, M.[6] & Carpenter, M.A.[7]

[7]Dept. of Earth Sciences, University of Cambridge, UK

Columbites, having general formula $A^{2+}B^{5+}{}_2O_6$, are well-known for their excellent dielectric properties. Their crystal structure, orthorhombic *Pbcn*, is formed by chains of two different edge-sharing octahedral sites, named A and B, where cations can be hosted. Columbites undergo a convergent cation exchange process which is responsible for a first-order polymeric isomorphic phase transition: when the octahedral sites are randomly occupied, columbite adopts the α-PbO_2-type crystal structure; ordering of divalent cations on A sites and pentavalent cations on B sites gives rise to an …ABBABB… sites sequence along the *a* direction resulting in a tri-α-PbO_2-type structure. It has been suggested that the ordering could have a strong influence on the microwave properties of columbite [1], as also observed in PMN-PSN relaxor ferroelectrics [2].

The mechanism of the intracrystalline cation exchange reaction in a natural columbite from Kragero, with composition $(Mn_{0.85}Fe_{0.15})(Nb_{1.8}Ta_{0.2})O_6$ [3], has been characterised by means of TEM and HR synchrotron-radiation powder diffraction. The natural untreated sample is monophasic and homogeneous as revealed by previous single-crystal diffraction analyses [3] and Rietveld refinement. After few minutes of annealing at 650°C, a highly unusual distribution of ordered rhombic-shaped domains bordered by {310} planes becomes established on a nano-scale within a disordered matrix (Fig. 1).

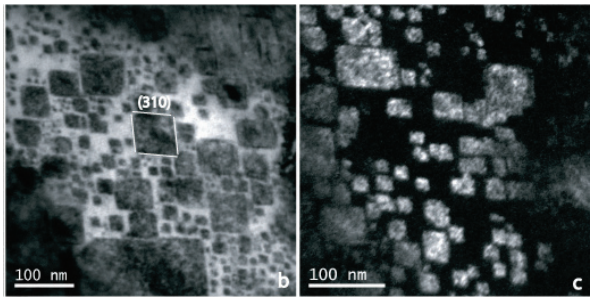

Fig. 1: Diffraction contrast images showing nanosized domains with rhombic shape.

In situ HT powder diffraction clearly evidences the separation into two discrete columbite phases having the same composition but different degrees of order. Biphasic Rietveld refinements of the diffraction patterns show that progressive ordering takes place both within the ordered domains and the disordered matrix but the domains maintain more or less constant shape and distribution over a prolonged time of annealing. In the last stages of annealing, split reflections merge into single peaks and the diffraction pattern is again that of one single columbite phase which is now almost completely ordered.

ANKA-IR2: a synchrotron infrared center for micro and nanospectroscopy

Gasharova, B., Moss, D. & Mathis Y.-L.*
Karlsruhe Institute of Technology (KIT), ANKA Synchrotron Light Source / Institute for Synchrotron Radiation, PKarlsruhe, Germany (*mathis@kit.edu)

In this presentation we will introduce the infrared (IR) facilities of ANKA, a synchrotron light source at KIT, and we will illustrate the possibilities, which they offer for cutting-edge research in Earth and Planetary sciences.

As the characterization of complex samples on the micro- and even on the nano-scale becomes increasingly important in the geosciences, this research area benefits, in general, from the development of techniques based on synchrotron radiation. Microspectroscopy is traditionally one of the key areas of application for synchrotron IR sources that is of interest for mineralogy and geochemistry. The high brilliance of synchrotron light compared to conventional sources leads to a much higher measurement beam intensity through small sample areas approaching the diffraction limit. Thus IR microscopes coupled to synchrotron beamlines can deliver spectra from a sample spot size of only a few micrometers, with data quality that could only be matched on a benchtop instrument by increasing the spot size to 0.1 mm or more.

Due to the high demand for high spatial resolution infrared equipment ANKA has constructed a second IR beamline, which will be dedicated to IR micro- and nanospectroscopy (Fig. 1).

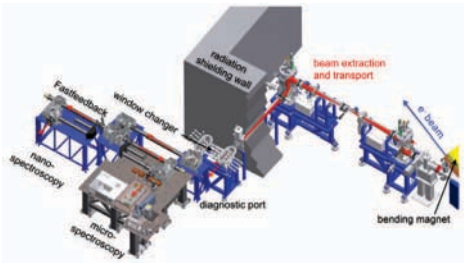

Fig. 1: ANKA-IR2 beamline layout.

Two experimental stations are planned. One is coupled to the IR microscope (formerly at ANKA-IR1), which covers the spectral range from ~100 cm^{-1} up to the NIR. It can be used for transmission, normal-incidence reflection, ATR and grazing-incidence reflection experiments under ambient, HP, HT or LT conditions. Confocal geometry and XYZ-motorized stage allow sample mapping with a micrometric precision. IR images can be taken with a FPA detector. Applications range from cement materials analysis [1,2], biominerals [3], water in nominally anhydrous minerals [4], zeolite nanoparticles [5], FIR study of phylosilicates [6] to fluid inclusions and water in terrestrial materials and meteorites [7,8]. The second station, a Scanning Near-field Infrared Microscope (SNIM) will deliver images at a spatial resolution 100-1000 times better than a conventional IR microscope [9]. The possibility to measure samples at a nano-scale spatial resolution using broadband IR radiation will be further attraction for research in Earth and Planetary sciences.

Application of micro-diffraction to characterise newly formed minerals at interfaces

Dähn, R.[1*], Popov, D.[1], Pattison, P.[2], Mäder, U.[3] & Wieland, E.[1]
[1]Paul Scherrer Institute, Villigen, Switzerland (*rainer.daehn@psi.ch)
[2]ESRF/SNBL, Grenoble, France and EPFL, Lausanne, Switzerland
[3]Institute of Geological Sciences, University of Bern, Bern, Switzerland

Synchrotron-based X-ray micro-diffraction (microXRD) is a potentially powerful method to investigate the inhomogeneity of mineral phases with micro-scale resolution; in particular in combination with micro X-ray fluorescence mappings. However, interpretation of the diffraction patterns from microXRD, which are produced by multi-component samples, is still a challenging task since they are complex images in which many crystal grains from different structures and orientations can contribute. The aim of the present study was to develop microXRD data collection and reduction techniques to study heterogeneous materials with typical features on the micro-meter scale. Exemplarily, synchrotron-based microXRD was employed to characterize the interface between argillaceous rocks and cementitious materials.

Cement-based materials play an important role in multi-barrier concepts developed worldwide for the safe disposal of radioactive waste in deep geological repositories. For example, ~95 wt% of the material of the planned Swiss disposal cavern for low and intermediate level waste consists of cementitious backfill materials. In a deep geological repository very strong chemical gradients control mineral alterations at the interface between the cementitious near field (pH >12.5) and the surrounding claystone formations (pH 7-8) due to the very different chemical conditions encountered in these matrices. While macroscopic reactive transport models are able to capture many essential features of the interaction between cementitious materials and the geosphere, such models consider no information on processes that operate at the relevant pore scale (µm - nm), and at the interface itself.

Two examples will be presented. The first from a multi-year field experiments at the Mt. Terri rock laboratory, where cement mortar was brought into boreholes in the Opalinus clay host rock. MicroXRD was used to study changes in the mineralogy across the cement – host rock interface. The study revealed that predominantly the cementitious zone was altered within two years contact time. In the second example the only known natural hyperalkaline system at Maqarin (Jordan) has been studied. There, high temperature and low pressure conditions led to the formation of clinker, and subsequent re-hydration to the formation of natural cement. U-Th disequilibrium series dating suggested an age of the cement mineralization of ~100000 years. Continuous leaching along fracture-bound groundwater flow-paths formed cementitious in-fills, interfaces to the adjacent bio-micritic and clay-bearing limestone, and diffusion-controlled wall-rock alteration. The interface consists predominatly of small (1 µm) needle-like crystals, which were identified by microXRD as 11Å-tobermorite. The studies demonstrated that crucial information on the mineralogy at interfaces can be obtained by applying synchrotron-based microXRD techniques.

Anomalous X-ray scattering study on chrysocolla

Murao, R. & Sugiyama, K.*
Institute for Materials Research, Tohoku University, Sendai, Japan (*kazumasa@imr.tohoku.ac.jp)

The anomalous X-ray scattering (AXS) technique allows us to obtain environmental structural information around a target element. Recent developement of synchrotron radiation source extensively stimurates the structural analysis of non-crystalline materials using the AXS method. Chrysocolla is a copper silicate mineral with disordered structure and it indicates only diffuse scattering pattern. Therefore, the conventional X-ray powder diffraction analysis serves no useful structural information. The purpose of the present study is to analyze the structure of chrysocolla by the ordinary radial distribution function (RDF) anlysis coupled with the AXS method.

Cu-*K* AXS of chrysocolla from Congo ($Cu_1Si_1O_{4.5}H_{2.6}$) was measured at PF-7C in IMSS, KEK. The present AXS measurement clearly indicates the energy dependence of scattering intensity at the Cu-*K* absorption edge. The observed differential intensity readily leads the environmental RDF around Cu, since only the change in the real part of the anomalous dispersion term of Cu is significant at this energy region. Fig. 1 shows the environmental RDF around Cu and the ordinary RDF of the chrysocolla sample. The Si-O correlation around 1.65 Å in the ordinary RDF indicates the overall presence of SiO_4 tetrahedra. The Cu-O correlation around 2.05 Å corresponds to nearer 4 oxygens out of distorted octahedral coordination around Cu. The Cu-Cu correlation around 3.3 Å is similar to that found in the crystalline $Cu(OH)_2$.

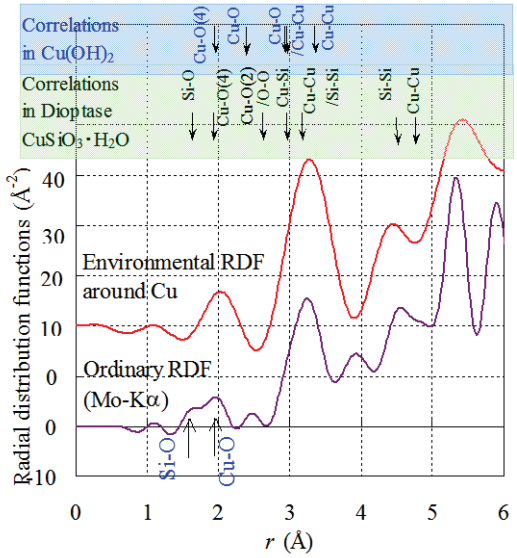

Fig. 1: (*Top*) Environmental RDF around Cu in chrysocolla by the Cu-AXS method. (*Bottom*) Ordinary RDF obtained by Mo-*Kα*. Arrows in upper part indicate correlation distances in related compounds.

Elemental nanoimaging of monazite and zircon using SR XRF

Appel, K.[1*], Appel, P.[2], Martinez-Criado, G.[3], Mocek, B.[4] & Möller, A.[4]
[1]Deutsches-Elektronen Synchrotron DESY, a Research Centre of the Helmholtz Association, Hamburg, Germany (*karen.appel@desy.de)
[2]Institute of Geosciences, CAU Kiel, Germany
[3]European Synchrotron Radiation Facility, Grenoble, France
[4]Dept. of Geology, University of Kansas, Lawrence, KS, USA

Monazite and zircon are among the most important accessory minerals used for U-Th-Pb geochronology of metamorphic and igneous rocks. Additionally, both minerals have a high potential to be used as geothermometers [1-3]. Although widely used in geochronology, the chemical stability and growth mechanisms of monazite and zircon are poorly understood. Using synchrotron radiation induced X-ray fluorescence analysis (SR XRF) at a high spatial resolution below 250 nm, we studied trace element distribution in monazite and zircon from case study localities with the aim to identify and characterize growth domains and their boundaries. This information will be correlated with age information obtained from chemical age dating by the procedure described by [4]. A similar technique is to be developed for chemical age dating of zircon with SR XRF.

Monazite and zircon from polymetamorphic terrains as well as six age reference monazite samples were selected with the Jeol electron microprobe at CAU Kiel, based on cathodoluminescence (zircon) and on back scattered electron images and results obtained from single point chemical ages following the procedure of [5] for monazite. SR XRF measurements were performed at the nano imaging beamline ID22NI at ESRF, Grenoble, with a beam size of 190 nm horizontal and 164 nm vertical. The excitation energy was set to 17.6 keV in order to allow the simultaneous detection of REE and Pb, Th and U via L-shell excitation and elements with Z between 14 and 39 via K-shell excitation, but exclude the excitation of the Zr K-edge. Fluorescence signals were recorded with an energy-dispersive SDD detector in confocal geometry.

It can been shown that the analytical settings and conditions allowed simultaneous detection of K, Mn, Fe, Rb, Ce, Dy, Er, Yb, Lu, Hf, Pb, Th and U in zircon. A correlation could be found between the elements Dy, Er, Hf, Lu, Pb, Th, U and Yb with features revealed by cathodoluminescence in a zircon with an older core and overgrowth rim (Fig. 1). The boundary between the inherited core and the overgrowth was sharp on the 250 nm scale, indicating this to be a true overgrowth with minimal or no recrystallization and scavenging of the core.

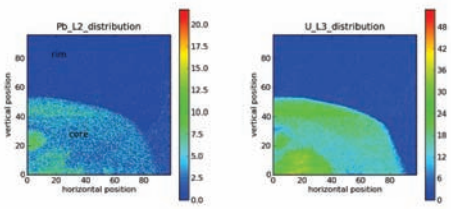

Fig. 1: Lead and U distribution maps of zircon with inherited core and metamorphic rim, axes dimensions in µm. Sample times were 0.4 sec per point, step sizes 0.25 µm in both directions.

Fast reaction kinetics in the calcium carbonate system: an *in situ* and real-time study

Rodriguez-Blanco, J.D.[1*], Bots, P.[1], Terrill, N.[2], Shaw, S.[1] & Benning, L.G.[1]
[1]School of Earth and Environment, University of Leeds, UK
([*]j.d.rodriguez@see.leeds.ac.uk)
[2]Diamond Light Source Ltd, Chilton, Didcot, UK

Calcium carbonate ($CaCO_3$) polymorphs (vaterite, calcite, aragonite) are found in a wide range of environments (e.g., oceans, lakes, soils) and are a key part of the global carbon cycles. At high supersaturation these phases form via a nanoparticulate, poorly-ordered and metastable precursor, amorphous calcium carbonate (ACC). The formation and transformation of ACC to other calcium carbonate phases can be extremely fast (nucleation in seconds and full transformation in 10s of seconds). In this study we demonstrate the use of an *in situ* time-resolved synchrotron-based Small- and Wide-angle X-ray Scattering approach (SAXS/WAXS) combined with off-line characterization to quantify the fast kinetics and crystallization mechanisms of calcium carbonate formation from ACC.

Experiments were carried out at station I22 at the Diamond Light Source, UK. The precipitation of ACC was induced by mixing equimolar solutions of $CaCl_2$ and Na_2CO_3 at different temperatures (12 to 20°C) and the crystallization was monitored via simultaneous SAXS/WAXS patterns acquisition at 1s time frames. In addition, the effects of common ions in natural aqueous environments (Mg^{2+}, SO_4^{2-} and PO_4^{3-}) on the crystallization reactions were studied, as these ions control the pathways of nucleation, growth and stabilization of carbonates.

WAXS data (Fig. 1) show that the transformation from ACC to Vaterite (Vat) in the pure system occurs within ~100s after a temperature-dependent induction time (60 and 90s at 20 and 12°C, respectively). From the SAXS data an initial radius of gyration for ACC of ~18nm was derived. These ACC nanoparticles transform to Vat nanoparticles (~10nm) via an internal reordering and dehydration process followed by Vat crystal growth via Ostwald ripening. The Vat nanoparticles eventually reach ~50nm in size (after ~3000s) and aggregate to form ~1µm clusters (Fig. 1, bottom right). The sizes for ACC and Vat are in excellent agreement with previous ACC imaging results [1] and complementary SEM observations (Fig 1, at right) from these experiments. Finally, the role and effects of Mg^{2+}, SO_4^{2-} and PO_4^{3-} on the stability of ACC and the tranformation pathways into Vat and Calcite will be discussed [see also 2].

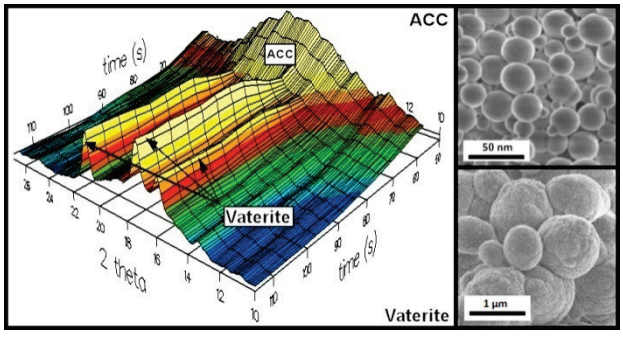

Fig. 1: 3D WAXS and SEM image showing ACC-Vat transformation.

Micro-SR-XRF and micro-PIXE studies for archaeological gold identification – the case of Transylvanian gold

Cristea-Stan, D.[1*], Constantinescu, B.[1], Vasilescu, A.[1], Radtke, M.[2], Reinholz, U.[2], Popescu, Gh.[3], Neacşu, A.[3] & Ceccato, D.[4]
[1]National Institute of Nuclear Physics and Engineering, Bucharest, Romania ([*]daniela_cristea_stan@yahoo.ca)
[2]Federal Institute for Materials Research and Testing (BAM), Berlin, Germany
[3]Dept. of Mineralogy, University of Bucharest, Romania
[4]INFN, Laboratori Nazionali di Legnaro, Italy

Romania was one of Europe's main gold-producing areas since the antiquity, especially through the ore deposits in the "Golden Quadrilateral" of the Apuseni Mountains. The Gold Museum in Brad hosts a collection consisting of about 800 samples of native gold – primary and alluvial. The geochemical investigation of Romanian gold by using micro-nuclear methods (SR-XRF and PIXE) is currently in progress. The goal is to verify if Transylvanian gold was used to manufacture Romanian archaeological objects. This is realized by using information related to trace elements: Sb, Te, Pb – recognized fingerprints for Carpathian Mountains mines and Sn characteristic for the panned river-bed (alluvial) gold. To solve these issues, samples from various Transylvanian mines and rivers and some very small (few milligrams) fragments of archaeological objects are measured. During the experiments, point spectra for 22 natural gold samples from Transylvania and 18 very small (less than 300 microns diameter) samples from Dacian "Koson" – type gold staters were acquired at 34 keV excitation SR energy, using a spatially resolved SR-XRF set-up mounted for analyses at the hard X-ray beam line – BAM-line at BESSY Synchrotron, Berlin.

A summary for the characterization of Transylvanian native gold is the following: (a) high (8 - 30%) Ag and low (0.05 – 0.5%) Cu amounts; (b) placer deposits (Valea Oltului, Stănija, Valea Pianului) contain Sn 150-300ppm – most probably from cassiterite or stanite; (c) primary deposits present Te 200-2000ppm, Sb 150-300ppm; the samples are very inhomogeneous; (d) primary deposit Săcărâmb: Te 0,25%, Sb 500ppm, Sn 200ppm; (e) primary deposit Fizeşti: Pb 1%, Sb 350ppm, Te and Sn traces.

The micro-PIXE experiment was performed using 2 MeV protons at the AN 2000 Van de Graaff accelerator of Laboratori Nazionali di Legnaro - point and map spectra. Two Roşia Montană and Musariu gold polished samples were studied. For Roşia Montană the Au/Ag ratio is very different from a point to another: 53.58/16.30, 34.60/10.78, 13.83/3.75, 34.60/10.53. On the maps a weak presence of Cu in the gold region in comparison with Ag may be observed. Au and Ag are strongly mixed. On the outlying gold grains there are Sb, Te, Zn and also Ag-rich areas. For Musariu sample the Au/Ag/Cu ratio is strongly variable from 3.24/0.42/0.0027, 6.05/1.32/0.0217 to 19.13/4.19/0.0078. In the case of Musariu, Ag and Cu are evidently mixed; a strong presence of Cu is observed. A big amount of Si (quartz) was observed surrounding the gold grains. On the distribution map, Zn-rich areas are observed, beside Au, Sb, and less Ag. There are some metallic Cu-points, Fe-points (pyrite), Pb-points (galena), Mn-points (alabandite) and native As-rich points.

As concerning the "Koson" Dacian coins, the type "with monogram" is made from refined (more than 97%) gold with no Sb, Te or Sn traces (re-melted gold) and the type "without monogram" is clearly made from alluvial gold, partially combined with primary Transylvanian gold (Sn and Sb traces detected). The Greek "Pseudolysimachus" type staters (contemporary with "Kosons") are made from refined re-melted gold (no Sn, Sb, Te presence).

Synchrotron-infrared microspectroscopy

Koch-Müller, M.[1*], Mrosko, M.[1] & Schade, U.[2]
[1]DeutschesGeoforschungsZentrum, Potsdam, Germany
([*]mkoch@gfz-potsdam.de)
[2]Helmholtz-Zentrum Berlin GmbH, Berlin, Germany

Infrared spectroscopy is a sensitive probe for information on the local microscopic structure and bonding in minerals and a powerful tool for quantification of traces of volatiles such as OH, H_2O and CO_2 in ppm range in minerals and glasses. Combined with a high brightness synchrotron source infrared microspectroscopy offers the opportunity to achieve the spatial resolution approaching the diffraction limit of the light. Thus, beside quantification of volatiles in the NIR/MIR region with a spatial resolution down to 8x8 μm, it enables us to investigate pressure-induced structural changes in the THz/FIR region of geomaterials placed in diamond-anvil-cells (DAC). In this contribution we will present two examples of applications of synchrotron IR microspectroscopy on geomaterials:

(1) *Pressure-induced phase transition in Sr-anorthite***:** Anorthite belongs to the group of feldspar minerals, which represents the most common unit within the Earth's crust. The Ca-endmember crystallises with triclinic symmetry in space group $P\bar{1}$. Increasing pressure forces the structure to turn into space group $I\bar{1}$ at 2.6 GPa [1]. Further pressure-induced structural changes take place between 9.6 and 10.3 GPa [2] but are not closer described so far. To investigate these kind of structural modifications in materials we developed a THz/FIR microscope adapted to a Bruker IFS 66/v spectrometer at the BESSY Synchrotron IR-beamline IRIS (Berlin, Adlershof). The microscope was built to conduct in situ pressure depending measurements in diamond anvil cells in the FAR-IR-region. We used the synthetic Sr-anorthite (monoclinic, I 2/c) as analogue material and measured spectra from polycrystalline thin films down to 30 cm^{-1} with pressures exceeding 15 GPa. Between 6 und 7 GPa we observed changes in the compressional behaviour of the FAR-IR-bands, indicating a phase transition. This is confirmed by high pressure XRD-measurements [3] that show a phase transition to $P2_1/c$ at 6.6 GPa.

(2) *Hydrogen zoning in zinc- and lithium-bearing staurolite*: This staurolite occurs as mm-long crystals at the marble footwall of meta-karst-bauxite on eastern Samos. H and Li concentrations were analyzed by secondary ion mass spectrometry (SIMS) with a 15 mm diameter O^{16} beam. In addition OH concentration was quantified by synchrotron-light polarized FTIR spectroscopy on oriented 3-5 mm thin FIB-prepared foils 10 x 20 mm wide and cut closely adjacent to the SIMS traverses. H concentrations are significantly higher in cores (up to 5.97 atoms H pfu) compared to rims (3.9 to 4.5 atoms H pfu). The zonation of H is interpreted as reflecting the P-T history of the growth of the mineral: in a first stage staurolite formed at low T of about 400 - 450°C and high P of > 1.5 GPa and incorporated nearly the maximum amount of H allowed by the staurolite structures. It was subsequently overgrown and marginally replaced during the second growth stage at about the same temperature but much lower pressures (0.2 - 0.4 GPa) resulting in much less hydrous staurolite rims.

The three dimensional observation of plagioclase crystal in synthetic basalt by using micro-tomography beam lines at SPring-8 (X-ray CT), is supported by two previous experimental studies realized on the same run charge [1,2]. The overall conclusion of these previous studies is that cooling rate effect on the characteristics of crystal size distribution, "CSD", (namely slope and intercept) is not markedly higher than those of i) coarsening through crystal agglomeration during the crystallization and ii) heterogeneous nucleation controlled by time and temperature spent above the liquidus. Consequently, no precise quantitative use of the CSD of plagioclase as a marker of the cooling history of volcanic rocks will be feasible until the processes of crystal agglomeration and heterogeneous nucleation can be properly understood and quantified. Accordingly, it is here proposed to highlight and to quantify crystal agglomeration during crystallization with help of 3D imaging. Micro-tomography was performed at SPring-8 by ultrahigh-resolution X-ray CT [3]. We got three-dimensional images of the run products in the resolution of 2.74 µm, allowing us to obtain information about the agglomeration of crystals, and in particular to assess connectivity (touching crystals/non touching crystals) and shape of the plagioclase crystals during cooling. Run charges were cooled from above the liquidus (~1175°C) at a rate of 1°C/h. Four samples have been quenched along a ramp with a temperature interval of 20°C. The last run charge contains ~40% crystals at the quenching temperature ~1110°C (Fig. 1).

Size and shape evolution during cooling is clearly visible and especially the lack of acicular plagioclase crystal usually described. The agglomeration process is significant, however, preferential attachment is still difficult to highlight. The connectivity between plagioclase crystals increases very rapidly with the crystallinity from 0.4 in early stages of crystallization (5% plagioclase crystals) to 1 for 20-25 % of plagioclase crystals. This suggests that viscosity of magmas crystallized without magma flow may increase at lower crystallinity than ever estimated in the previous experiments, in which preferred crystal orientation was formed by measurement with a rotational viscometer.

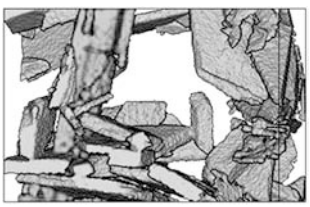

Fig. 1: 3D reconstruction of plagioclase crystals (981x674x537 µm).

A key parameter for the mobility of high field strength elements (HFSE) in the lithosphere is the alkali/alumina ratio in fluids and melts, which is determined by the interacting mineral assemblage during equilibration (e.g., [1]). However, there is only fragmentary knowledge on the solubility of HFSE in aqueous alkali silicate fluids at the P -T conditions of the lower crust and upper mantle and the effect of alumina addition to the system, and on the complexation of the HFSE in such fluids.

Using high P-T in-situ techniques, we studied fluids produced by dissolution of known amounts of $Na_2Si_3O_7$ (NS3) or $Na_2Si_3O_7$ + 10 wt% Al_2O_3 (NS3Al10) glass in water, which were equilibrated with zircon or hafnon in hydrothermal diamond-anvil cells at temperatures to 750 °C and pressures to ~1 GPa. The concentrations of Zr and Hf in the fluids were determined by synchrotron radiation micro-XRF analyses at beamline L, HASYLAB. Spectroscopic constraints on the complexation were obtained from dispersive XAFS measurements at the Hf L_3 edge at ID 24, ESRF, along with additional information on the Hf concentration from XRF data.

A consistently observed feature was the substantial decrease in the Zr concentration in the fluid with pressure at constant temperature and NS3 concentration. This indicates pronounced pressure dependent changes in the speciation in aqueous sodium silicate systems and a decreasing Zr mobility with depth in peralkaline fluids, which agrees with observations on natural samples. The Zr concentration in the fluid also showed a strong increase with $Na_2Si_3O_7$ concentration at similar P-T conditions, e.g., by one order of magnitude from 10 to 30 wt% NS3. This signifies that aqueous sodium silicate fluids are efficient means for transport of Zr and other HFSE. Addition of alumina, however, resulted in distinctly lower Zr concentrations in the solutions, e.g., at ~650 °C, ~800 MPa, it was ~200 ppm in H_2O+18 wt% NS3 compared to ~100 ppm in H_2O+20 wt% NS3Al10. Determined Hf concentrations followed similar trends, although they were mostly higher than those of Zr at comparable conditions. On the expense of hafnon, the Hf-analogue of katapleiite formed in a run with H_2O+22 wt% NS3, and probably the Hf-analogue of baddeleyite in a run with H_2O+35 wt% NaOH. In that run, the Hf content in the fluid was much lower than runs with H_2O+28 wt% NS3 or NS3Al10.

This observation, the increase in the Zr and Hf concentrations in the fluid with dissolved Na silicate and the decrease with addition of alumina point to formation of a (Zr,Hf)-O complex involving Na and/or Si. Measured Hf L_3 XANES regions in the fluid were similar for experiments with hafnon and H_2O+NS3, H_2O+NS3Al10 or H_2O+NaOH. Simulation of the XANES using FEFF8.4 for a HfO_6 octahedron at R(Hf-O)=2.07 Å (equal to that of Zr in peralkaline $Na_{3.3}AlSiO_{17}$ glass [2]) approximated these experimental Hf L_3 XANES well. Measured Hf L_3 XANES on H_2O+16 wt% HCl fluids equilibrated with hafnon were significantly different.

Determination of Mn speciation in aragonitic freshwater bivalve shells using synchrotron x-ray absorption and emission techniques

Soldati, A.L.[1,2*], Geck, J.[3], Jacob, D.E.[1], Glatzel, P.[4] & Swarbrick, J.C.[4]
[1]Dept. of Geosciences and Earth System Science Research Centre, Johannes Gutenberg-Universität, Mainz, Germany ([*]asoldati@cab.cnea.gov.ar)
[2]CONICET, Grupo Caracterización de Materiales, Centro Atómico Bariloche, S.C. de Bariloche, Argentina
[3]Leibniz Institut für Festkörper-und Werkstoffforschung, Dresden, Germany
[4]European Synchrotron Radiation Facility, Grenoble, France

We investigated shells from seven different freshwater bivalve species by means of spin-resolved x-ray absorption near edge spectroscopy (XANES) and x-ray emission spectroscopy (XES). The shells are composed of aragonite ($CaCO_3$) and less than 5 wt% of organic material. The aim of the experiments was to clarify whether Mn replaces the Ca^{2+} ion in the carbonate structure or if it is associated with the organic molecules in the shells (inter- and intra-crystalline).

Bivalve shells used here comprise specimens of *Hyriopsis cumingii*, *Margaritifera margaritifera*, *Margaritifera falcata*, *Anodonta Cygnea*, *Anodonta Anatina* and *Unio tumidus* as well as modern and archaeological specimens of *Diplodon chilensis patagonicus* from two different Patagonian lakes [1]. All XANES spectra of the different bivalve shells (independent of the bivalve type, provenance, or if modern or archaeological) show the same absorption features with identical positions of the Mn K-edge (6.548 keV), the white line (6.552 keV), as well as of the position (6.540 keV) and intensity of the pre-edge peak [2]. The Mn pre-edge feature is a result of quadrupole 1s→3d transitions and is present at the same energy in all shells as well as in Mn-bearing calcite ($CaCO_3$) and in synthetic and natural rhombohedral $MnCO_3$. In addition, the spin-resolved XANES shows that the electronic configuration of Mn in these materials is largely $3d^5$ corresponding to Mn^{2+}.

Mn-Kβ emission spectra provide detailed information regarding the chemical environment (i.e. the next neighbours). All shells show the same Kβ´ and $K\beta_{1,3}$ main, and $K\beta_{2,5}$ satellite lines. Most importantly, all spectra show the same features as the emission spectra of a Mn-bearing calcite crystal and of $MnCO_3$, while they clearly differ from Mn-bearing aragonites and reference compounds containing other Mn coordination. These data therefore reveal that: (i) Mn in the aragonitic shells resides largely in the mineral part and not in the organic material. (ii) Mn in the orthorhombic shell aragonite is present as Mn^{2+} in a calcite microenvironment with rhombohedral coordination.

Development of a new high-resolution synchrotron Gandolfi camera

Tanaka, M.[1*], Nakamura, T.[2], Noguchi, T.[3], Katsuya, Y.[4] & Matsushita, Y.[1]
[1]NIMS Beamline Station/SPring-8, National Institute for Materials Science, Hyogo, Japan ([*]masahiko@spring8.or.jp)

[3]Dept. of Materials and Biological Sciences, Ibaraki University, Mito, Ibaraki, Japan
[4]SPring-8 Service, Hyogo, Japan

A new high-resolution Gandolfi camera with a large camera radius of 955 mm has been developed for synchrotron X-ray diffraction experiments.

Gandolfi method [1] is an X-ray diffraction method that enables acquisition of pseudo-powder diffraction patterns from single crystals. Using the Gandolfi method with synchrotron we developed a non-distractive analysis method for mineral phase determination and quantitative mineral-phase analysis [2-3] of micro-amount samples. Applying the multi-phase Rietveld method to the diffraction patterns obtained by the synchrotron Gandolfi method we successfully conducted quantitative mineral-phase analysis [3]. We applied the methods to analysis of micro-amount extraterrestrial samples, but many overlapped peaks were observed in the diffraction patterns. These overlapped peaks decreased the accuracy of the Rietveld analysis. However the new Gandolfi camera can achieve higher angular resolution, which enables separation of the overlapped diffraction peaks, and more accurate quantitative-phase analysis.

The new Gandolfi camera was developed for the diffractometer of BL15XU at SPring-8, the 3rd generation synchrotron radiation facility in Japan. A Gandolfi head of Tenno Co. of Italy, set at the centre of the diffractometer was used to perform the Gandolfi motion and the imaging plate (IP) cassette developed for the Debye-Scherrer powder diffraction camera of the diffractometer [4] was applied to the detector (Fig. 1a). The IP cassette has a cylindrical surface with the radius of 955 mm and the long side of the IP is parallel to the 2θ direction. The minimum step of the 2θ is 0.003 degrees. With the new Gandolfi camera, powder diffraction images were properly collected from the trial samples; NIST-CeO_2 powder and mixtures of some mineral powders fixed in resins (Fig. 1b).

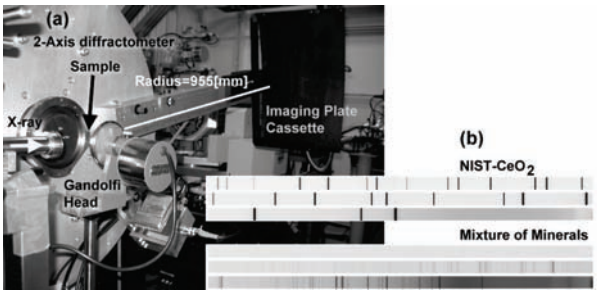

Fig. 1: (a) The photograph of the new high-resolution synchrotron Gandolfi camera. The camera radius is 955 mm and the minimum step of the 2θ angle is 0.003 degrees. (b) The powder diffraction images obtained by the new Gandolfi camera. The imgaes are separated in three sections of lower, middle and higher range of the 2θ.

Selected advances in neutron techniques for studies of Earth materials

Parise, J.B.[1*] & Tulk, C.A.[2]
[1]Dept. of Geosciences & Chemistry Dept., Stony Brook University, Stony Brook, NY, USA ([*]john.parise@sunysb.edu)
[2]Neutron Scattering Science Div., Oak Ridge National Lab., Oak Ridge, TN, USA

The characteristics of neutrons that make them a unique probe for condensed matter are well known: their electrical neutrality, possession of magnetic moments, polarizability, a scattering cross section (*b*) independent of *Q* and atomic number but dependent on isotope, and the wide range of energy and momentum transfer possible in a scattering experiment. The charge neutrality of neutrons means that they penetrate solids to depths of centimeters, thus enabling studies of bulk phenomena in situ, and ready construction of bulky sample cells capable of high pressures, temperatures and strains. The isotopic dependence and atomic number independence of *b* can be used to study light elements in the presence of heavy elements, study site-occupancies of elements neighbouring in the periodic table, and the concoction of mixed solvents (D_2O/H_2O) that match the scattering contrast of colloid suspended in them. Techniques to produce polarized beams of particles with magnetic moments makes neutrons uniquely sensitive probes of magnetic interactions; the only technique allowing simultaneously determination of arrangements of nuclei and magnetic moments in materials. Neutrons can be readily produced over a wide range of energies ranging from thermal to cold, for investigating the structure and dynamics over length scales from the atomic to the mesoscopic, 1 to 105 Å, and over energy transfers from 10^{-9} to 1 eV. Many developments and applications to Earth Science research, are summarized in a series of presentations (http://neutron.neutron-eu.net/n_nmi3/n_networking_activities/n_nese).

Several examples illustrating new information available from elastic neutron scattering will be presented, including studies of ion exchange in crystalline materials, and nuclear and magnetic structures of crystalline and geonanomaterials. Increasingly researchers seek to carry out these studies under the operating conditions of planetary surfaces and interiors.

Neutron experiments, especially those that seek to study Earth materials *in operando* and as a function of time, are "flux hungry" and this is one driving force behind the development of ever more powerful sources, such as the Spallation Neutron Source (SNS). Additional brightness gains have recently been realized at the Spallation Neutron and Pressure (SNAP) beamline used KB optics. By combining Montel-like nested focusing optics with pressure vessels considerably smaller samples should be accessible at Mantle pressures. Neutron focusing is used to improve spatial resolution and lower detection limits for neutron-based analytical methods. The SNAP beamline is the first fully optimized high pressure beamline at a neutron source, and has several features that allow adaptation of components to fit experiments as varied as studies at extreme conditions for liquids, glasses, nano- and crystalline materials. For example, until very recently, the prospects for high-pressure single crystal studies at anything approaching 50-80 GPa using neutrons seemed remote indeed. The integrated fluxes for neutron sources barely approach that for a laboratory X-ray Source. With the advent of the SNS, large area detectors and novel focusing optics, the SNAP beamline may make routine high-pressure studies on single crystals of a size approaching what is achievable with laboratory-based X-ray investigations. Recent trials suggest this is possible now.

The use of neutron diffraction in studies of planetary ice-rock analogue mixtures

Middleton, C.A.[1,2*], Wood, I.G.[1,2], Grindrod, P.M.[1,2], Fortes, A.D.[1,2], Hunt, S.A.[2], Zhang, S.Y.[3], Covey-Crump, S.J.[4] & Sammonds, P.R.[2]
[1]Centre for Planetary Sciences at UCL/Birkbeck, London, BT, UK ([*]ceri.middleton@ucl.ac.uk)
[2]Dept. of Earth Sciences, UCL, London, UK
[3]ISIS Facility, STFC Rutherford Appleton Laboratory, Harwell Science and Innovation Campus, Chilton, Didcot, UK
[4]School of Earth, Atmospheric and Environmental Sciences, The University of Manchester, UK

We have carried out rheological experiments on planetary ice-rock analogue mixtures in the ENGIN-X beamline at the pulsed neutron source ISIS in Oxfordshire, UK.

Neutron diffraction has previously been used to study the deformation of geologically relevant polyphase materials (e.g. [1]), as it allows the strain in each phase to be determined, and hence (via the elastic constants) the stress partitioning between each phase to be calculated, whereas traditional deformation tests only allow bulk properties of the whole sample to be obtained. We demonstrate for the first time the application of neutron diffraction to the deformation of icy planetary materials at conditions relevant to large icy bodies such as Europa, Ganymede and Titan.

Experiments were conducted on samples with fluorite fraction 0.09 and 0.27, at strain rates of 5×10^{-7} - $5 \times 10^{-6} s^{-1}$, temperatures of 233 and 253K, and confining pressures of 50MPa. This pressure is equivalent to depths of 30-40 km in the largest icy satellites, therefore allowing us to explore the P,T conditions throughout the thickness of Europa's icy crust [2], and much of Titan's outermost ice shell [3], however, strain rates are necessarily faster than planetary rates to allow for results on laboratory timescales.

In order to obtain these conditions, we adapted a previously used pressure vessel design [4] to allow study of cylindrical polycrystalline D_2O ice + fluorite samples of diameter 25mm, length 65mm. This vessel was designed to fit within the beamline cryogenic chamber [5].

Our preliminary results suggest that the ice phase may be experiencing localised melting during higher temperature runs, possibly due to stress increases around the fluorite grains. We suggest that this is due to the angular shape of our rock grains, and would not be seen if our grains were spherical. This would have important ramifications for planetary ice analogue experiments, as using spherical rock particles (e.g. [6]) may not well represent the actual situation in icy bodies, and it may, therefore, be important that interactions between the ice and rock grains are accounted for when considering these polyphase mixtures.

We will present these results, along with further analysis of the strain partitioning between the ice and fluorite phases.

Evaluation of zirconia anvils for use in high pressure neutron scattering

Komatsu, K.[1*], Sano-Furukawa, A.[2], Abe, J.[2], Hattori, T.[2], Arima, H.[3], Arakawa, M.[1,2] & Kagi, H.[1]
[1]Geochemical Research Center, Graduate School of Science, The University of Tokyo, Japan
([*]kom@eqchem.s.u-tokyo.ac.jp)

[3]J-PARC Center, Japan Atomic Energy Agency, Japan

Tungsten carbide(WC) and sintered diamond(SD) are widely used as anvils or pistons in any kind of high pressure apparatus because of their hardness. WC and SD anvils has also been mainly used in opposed type presses like the Paris-Edinburgh cell for neutron scattering as they are somehow transparent for neutron. For example, the attenuation (I/I_0) of WC of 10mm for neutron is 0.2~0.4 depending on the wavelength. Although SD is a bit more transparent than WC, it has strong Bragg edges which may cause a difficulty for intensity correction. Yttria-stabilized zirconia (YSZ), which is also used as anvils for diamond anvil cells [1], was successfully applied for sliding-blocks (anvils) in the mini cubic apparatus for high pressure neutron diffraction [2]. It is quite likely that YSZ has a enough potential to use as opposed anvils in high pressure neutron scattering with the merits of the neutron transparency, low thermal conductivity (for high- or low-temperature experiments) and low cost. In this study, we conducted compression test using YSZ anvils and measured its transparency and neutron diffraction from sample in it in order to evaluate YSZ anvils for use in high pressure neutron scattering experiments.

A pair of YSZ was commercially supplied and machined as single-toroidal anvils for the Paris-Edinburgh cell. A NaCl pellet without pressure medium was put into the anvils as a pressure calibrant. Duralumin (A7075) rings were used as gaskets. Energy dispersive x-ray diffraction from NaCl was obtained at elevated loads at NE7 beamline in PF-AR, Tsukuba, Japan, and each pressure was estimated using Decker's EOS [3]. The obtained load-pressure curve is shown in Fig. 1. Pressure is successfully generated along a slope of 0.1 GPa/ton from 10 to 40 tons. The YSZ anvils survived up to 5.1 GPa, and blowout at 80 tons.

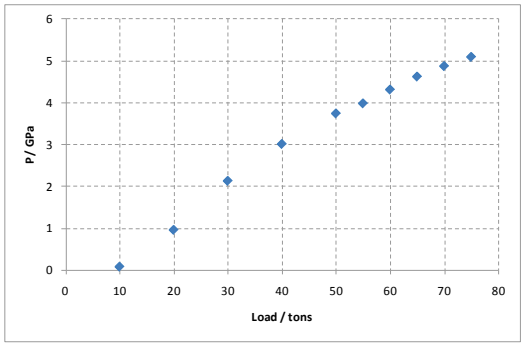

Fig. 1: Load-pressure curve of the single-toroidal zirconia anvil set on the Paris-Edinburgh cell.

Neutron transparency of YSZ as a function of wavelength and neutron diffraction of a lead palette in the YSZ anvils at ambient pressure was measured at an Engineering Materials Diffractometer "TAKUMI" in J-PARC. The results showed that an effective intensity using YSZ anvils is 1.5~6 times more intense than that using the conventional WC anvils.

Contrast variation small angle neutron scattering in biomineralization

Schwahn, D.
Institute of Solid State Research of the Helmholtz Research Center Jülich GmbH, Jülich, Germany
(d.schwahn@fz-juelich.de)

Mineralization of calcium carbonate and calcium phosphate in the presence of proteins was explored by small angle neutron scattering (SANS) using the technique of contrast variation. SANS is a rather new experimental technique in biomineralization. It allows full structural characterization of scattering particles of sizes between 10 Å and 1000 Å and delivers detailed information about mineral-protein composites. The last mentioned information is obtained from contrast variation experiments achieved by the exchange of proper isotopes such as from variation of H_2O/D_2O composition in aqueous solutions [1]

Time resolved mineralization of calcium carbonate in the presence of the protein ovalbumin was explored by gas diffusion technique [2]. The mineralization followed Oswald's law by a step-by-step formation from less stable to more stable polymorphs. The formation of the amorphous mineral polymorph occurred in parallel to denaturation and aggregation of the protein. After about 6 h from starting the mineral transformed to the more stable vaterite, and finally after about 10 h to the even more stable aragonite. Calcite as the most stable polymorph was not detected within the experimental time. No complexation of the protein ovalbumin occurs in the presence of $MgCl_2$ and $SrCl_2$.

Another explored protein was fetuin-A which acts as an inhibitor of calcium phosphate mineralization [3]. We found of the order of 1000 Å large mineral-organic particles whose structure was analyzed by contrast variation. We found an octacalcium phosphate core and a dense monolayer of the protein, which protected the mineral from further growth.

Neutron- and X-ray imaging in archaeology and geosciences in South Africa

De Beer, F.C.[1*] & Masiteng, I.N.[2]
[1]Radiation Science Dept., Necsa, Pretoria, South Africa
([*]Frikkie.debeer@necsa.co.za)
[2]National Cultural History Museum, Pretoria, South Africa

For the past 8 years, the South Africana Neutron Radiography and tomography facility (SANRAD) [1], located at the SAFARI-1 nuclear Research Reactor at Necsa, South Africa, has been exploited successfully in geosciences, palaeosciences and archaeology fields of application [2]. The facility has been also equipped with a 100kV X-ray source for complementary tomography investigations.

The 125 kV X-ray and neutron attenuation coefficients of some metals, which are of high relevance for archaeological investigations, are listed in Table-1 [3].

Table 1: Linear attenuation coefficients of some metals for thermal neutrons and 125 kV X-rays

	Material (cm^{-1})							
Probe	Au	Ag	Cu	Sn	Bronze	Pb	Zn	Fe
Neutrons	6.28	3.99	0.99	0.20	0.87	0.37	0.34	1.20
X-rays	35.9	5.67	1.97	3.98	2.5	22.8	1.64	1.57

It is evident from Table-1 that the high density materials, which are more likely to be found as base material of archaeological artefacts, are more transparent to neutrons as X-rays and therefore is capable to reveal information hidden in precious findings through tomography imaging.

Figure 1 shows a neutron tomogram, revealing the inside structure of an OSIRIS statuette showing the chaplets which indicate that the lost max method were applied during its manufacturing.

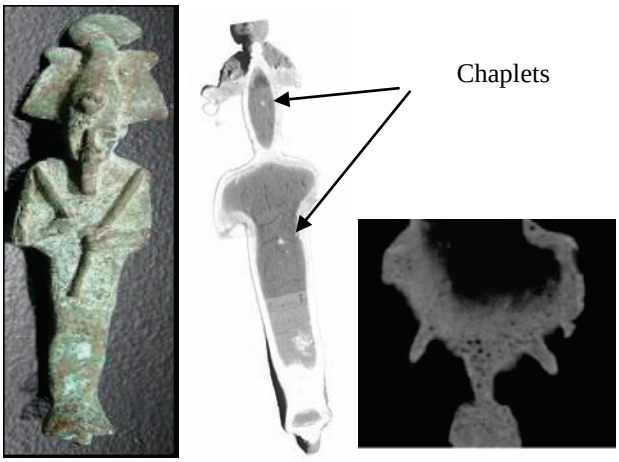

Fig. 1: Photo (left) and thermal neutron tomogram of an OSIRIS bronze artefact sliced from the front (Middle) and an axial cross section of the head area (right)

Sectioning of the neutron tomography in the head area reveals its high porosity and heavily corrosion structure which has storage, curation and conservation implications.

This contribution describes the recent neutron- and X-ray tomography investigations being performed on archaeological and geological samples through collaboration with the national museums and higher educational institutions.

H, B, N or Pb, Bi, Cd: the PGAA for multielemental analysis of light and heavy elements in geological samples

Canella, L.[1], Kudejova, P.[2*], Söllradl, S.[3] & Türler, A.[3]
[1]RCM, Technische Universität München, Garching, Germany
[2]FRM II, Technische Universität München, Garching, Germany
([*]petra.kudejova@frm2.tum.de)
[3]Paul Scherrer Institute (PSI), Villigen, Switzerland

Not only when determining light elements in a sample volume non-destructively, the PGAA technique is the method to choose. On one hand, Instrumental Neutron Activation Analysis (INAA) is a well-established method for non-destructive determination of elemental composition of geological samples. However, H, Li, Be, B, C, N, S cannot be determined by INAA and for elements like P, Cd, Gd, Pb – PGAA is a competitive method with regard to the detection limits. The next advantage of PGAA compared to INAA is its rapidity: the irradiation takes max. few hours, the data analysis can be performed on the day of measurement and the sample is not activated for a long time. Depending on the composition, the sample can be given back to the owner within one or more days. This is a great advantage, if another e.g. neutron-based analysis (e.g. rest-strain in material through neutron diffraction) should follow soon or if the researcher wants to have a fast estimation, which elements are to be expected in the object (usually on ppm level). For PGAA, the sample needs no preparation, which also speeds the process of deriving the general composition.

We want to present some of our performed PGAA experiments with the elements named in the title. For example, we have measured hydrogen in clathrates and nitrogen in correlation with sulphur in carbonaceous shales and coals. Next, light elements together with Pb, Cd or Va were measured in air pollution samples. Dynamic range for boron was determined as well as the detection limit and used for measurements of boron in alloys. Distribution of bismuth in lead crystals was determined with very good statistics. Cadmium was analysed also in biological samples for medical research [1,2].

The effect of SEM imaging on the Ar/Ar system in alkali feldspars

Flude, S.[1*], Sherlock, S.C.[1], Lee, M.R.[2] & Kelley, S.P.[1]
[1]Dept. of Earth and Environmental Sciences, Centre for Earth, Planetary, Space & Astronomical Research (CEPSAR), Open University, Milton Keynes, UK ([*]s.flude@open.ac.uk)
[2]Dept. of Geographical & Earth Sciences, University of Glasgow, UK

Alkali feldspars from a range of tectonic environments have been used to reconstruct thermochronological histories by employing the multi domain diffusion (MDD) model of Ar/Ar dating [1]. MDD is based on the notion that, as feldspars cool, they may undergo various processes of exsolution, phase transformation and fluid-mediated recrystallisation that split the crystal into a number of smaller diffusional subgrains However, substantial controversy remains regarding which microtextures and micro structures control Ar-diffusion [2]. A number of studies have addressed these issues using coupled SEM imaging and Ar/Ar UV laser ablation microprobe (UV-LAMP) analysis on the same samples, to enable direct comparison of microtextures with Ar/Ar age data [3].

Here we have tested the idea that SEM work may affect Ar/Ar systematics, leading to inaccurate results in subsequent Ar/Ar analyses. Alkali (Na, K) redistribution due to ionisation and electro-migration during electron microprobe analysis of alkali feldspars is a common problem [4] and radiogenic Ar (^{40}Ar*) is not bonded in the crystal lattice, so is likely to be more mobile than K during electron irradiation. Electron irradiation can also cause hydrocarbon molecules (present on the sample surface or in the sample chamber) to become immobilised on the sample surface [4]. This may be a problem during subsequent Ar-analysis as hydrocarbon fragments can cause mass interferences with Ar isotopes. This is a particular problem for ^{36}Ar, which is used to correct for atmospheric ^{40}Ar by assuming ^{40}Ar/^{36}Ar=295.5, as few mass spectrometers are able to resolve the difference between ^{36}Ar and contaminants. Some SEM techniques require chemical-mechanical polishing with colloidal silica, which may rapidly dissolve some alkali feldspars [5] potentially resulting in differential loss of K and Ar. Similarly, feldspar microtextures may be studied by etching cleavage fragments with HF vapour [6], which again may affect K and Ar within the sample to different degrees.

We are empirically testing the possible effects of these processes on the Ar-system in alkali feldspars. Three feldspars have been selected, with microtextures ranging from simple to complex. The distribution of Ar-isotopes and K (in the form of neutron-induced ^{39}Ar) has been characterised for each sample by UV-LAMP Ar-analysis of thick sections that have not been studied in the SEM. Ar/Ar analysis was carried out using a Nu Instruments Noblesse mass spectrometer, which can distinguish ^{36}Ar from hydrocarbon contaminants. Further thick sections were polished with colloidal silica and imaged in the SEM (60 Pa vacuum, 20 kV and high beam current). Selected areas were irradiated at high magnification for eight minutes to maximise sample damage. UV-LAMP Ar/Ar dating was subsequently carried out on these samples to determine the distribution of Ar-isotopes and K within the sample after SEM imaging. Here two sets of data are compared, facilitating debate on the validity of Ar/Ar ages from alkali feldspars that have been imaged with the SEM.

Loss of ^{40}Ar(rad) from leucite-bearing basanite at low temperature: implications on K/Ar dating

Balogh, K.[1*], Németh, K.[2], Itaya, T.[3], Molnár, F.[4], Stewart, R.[2], Thanh, N.X.[5], Hyodo, H.[3] & Daróczi, L.[6]
[1]Inst. of Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary ([*]balogh@atomki.hu)

[5]Dept of Geology, Hanoi University of Mining and Geology, Hanoi, Vietnam
[6]Dept. of Solid State Physics, University of Debrecen, Hungary

Ar/Ar ages have been determined [1] on alkali basalts from the Balaton Highland Volcanic Field, Hungary. Some Ar/Ar ages were conflicting with K/Ar data reported earlier [2]. The leucite-bearing basanite of Hegyestű hill has been selected for a detailed study in order to explain why K/Ar ages are too young. It has been found that K/Ar and Ar/Ar ages are similar, if (1) K/Ar dating is performed on samples treated with HCl, or (2) the argon extraction line was baked only at 150°C.

Olivine, augite, plagioclase, magnetite leucite, nepheline and analcime (in one sample) have been identified by XRD investigations. After HCl treatment plagioclase and augite remained in all samples, implying that dissolved minerals are responsible for the loss of ^{40}Ar(rad). Microscopic and EMP investigations have shown that K is concentrated in patches of < 200 μm size. A TEM analysis failed to detect leucite. HCl treatment of 6 samples dissolved 28.0 – 63.5 % of K contents and 4.02 – 6.42 % K have been calculated for the dissolved part of carbonate-free basalts. On the basis of these results leucite is regarded to be responsible for the Ar(rad) loss, but a subordinate role of nepheline can not be excluded. This observation refers only to Hegyestű hill, since it conflicts with the experiences of Ar chronological studies on leucite. Ar may be released at low temperature from (1) very fine-grained leucite without change of the crystalline structure, or (2) due to a change of crystalline structure during baking the argon extraction line.

A set of the same sample has been dated after a stepwise raising of the baking temperature from 55°C to 295°C and the ^{40}Ar(rad) loss and diffusion parameters (D/a^2) have been calculated. In case (1) the diffusion parameters should have arranged along a straight line in the Arrhenius diagram. In contrast, the arrangement of points suggests a structural change in the 145°C–295°C temperature range. XRD investigations did not identify structural change up to now.

K content of the variably altered rocks varies from 2.1 to 0.3 %. The groundmass is not uniform: a coarser- and a finer-grained type can be distinguished, which are well separable in the quarry. Minerals from the basement rock have been recognized: this may influence the K/Ar age too.

K-Ca ages of authigenic sediments: examples from Paleozoic glauconite and potassium-rich evaporites and applications to low temperature thermochronometry

Cecil, M.R.[1] & Ducea, M.[2*]
[1]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, USA
[2]Dept. of Geosciences, University of Arizona, Tucson, AZ, USA ([*]ducea@email.arizona.edu)

K-Ca ages of Cambrian glauconites from the Llano uplift, central Texas, and Permian K-rich evaporites from the Delaware Basin, New Mexico, were determined in order to re-evaluate the ability of the K-Ca system to constrain the timing of deposition of sedimentary packages. All but one of the K-Ca ages presented here were found to be younger than their stratigraphic ages. In addition to being too young, the K-Ca ages are also highly variable, ranging in age from Silurian to Permian in the case of glauconites and from Permian to Cretaceous in the case of the evaporites. The oldest subset of glauconite ages are in agreement with previously published Rb-Sr ages from the same outcrop and provide further evidence for there having been a postdepositional thermal or recrystallization event that reset both the Rb-Sr and K-Ca systems. The range of younger glauconite K-Ca ages are not seen in the Rb-Sr data, but are similar to the distribution of available apatite fission track ages for the Llano basement. K-Ca ages are interpreted as thermochronologic data reflecting partial retention of Ca in thermally fluctuating basin conditions. Estimates of the closure temperature of Ca in glauconite are found to be 75 - 90°C for cooling rates of 0.3 - 1°C/My. Sylvites and langbeinites from the Delaware Basin give K-Ca ages ranging from the timing of primary mineralization (~ 250 Ma) to 100 Ma. The random distribution and wide spread of K-Ca ages is unlike previously published K-Ar and Ar-Ar from the same potash zone, which cluster distinctively and apparently record discrete geologic events. K-Ca ages argue for ongoing recrystallization of the K-salts throughout most of the Mesozoic. The lack of any ages younger than ~ 94 Ma implies that a significant tectonic or paleoenvironmental change occurred at that time, stabilizing the salts and effectively closing even the most sensitive K-Ca system. The K-Ca system is potentially useful as a low temperature thermochronometer with closure temperatures <100°C for glauconite.

The Dej Tuff of Transylvania (Romania): how old, what flavour and where from?

Nicolescu, S.[1,2*] & Mârza, I.[3]
[1]Dept. of Geosciences, University of Arizona, Tucson, USA
[2]*now at*: Peabody Museum of Natural History, Yale University, New Haven, USA ([*]stefan.nicolescu@yale.edu)
[3]36 Bd. 1 Decembrie 1918, Cluj-Napoca, Romania

The Transylvanian Basin of Romania, one of the important sedimentary basins and natural gas producing provinces of SE Europe, belongs to the Central Paratethys stratigraphic domain.

The many kilometres thick basin fill consists of a monotonous, mainly Tertiary, sedimentary sequence of alternating marl, sand/sandstone and clay layers. The only breaks in its stratigraphic monotony are several Miocene to Pleistocene volcanic tuff layers, accounting for about 10 % of the basin fill volume. The most important of these is the Dej Tuff. Because of its regional extent and easily recognisable petrography, the Dej Tuff is an excellent stratigraphic marker. Its biostratigraphic age, based on micro- and nannofossil marker species in adjacent sediments, is Lower Badenian [1]. In spite of repeated radio-isotope and fission track dating attempts, no conclusive eruption age of the tuff has been established so far [2].

Here we present robust zircon (U-Th)/He ages obtained on two zircon populations collected from the Pâglişa (NE Transylvania; 47°00'34.45" N, 23°38'35.41" E; 450 m a.s.l.) Dej Tuff outcrop. The two ages on samples collected about 30 m stratigraphic thickness apart, are identical within error: 14.9 ± 0.7 Ma and 15.6 ± 0.9 Ma respectively. Their weighted average of 15.1 ± 0.5 Ma constrains the eruption of the investigated Dej Tuff occurrence to the Middle Badenian.

Besides the accurate and precise age of the Dej Tuff, other intensely debated points of contention in the literature are its petrographic classification (rhyolite *vs.* rhyodacite/dacite) and eruption source(s). Petrographic classification attempts have been based so far on the rock's major element composition. The problem with this is that the Dej Tuff has undergone pervasive post-deposition alteration and thus its present major element chemistry has changed significantly since emplacement. Therefore, a classification based on "immobile" trace elements, e.g., Zr/TiO_2 *vs.* Nb/Y [3], seems more appropriate. Based on such criteria, the Dej Tuff at Pâglişa falls within the rhyodacite/dacite field.

As already pointed out by many previous studies, identifying the eruption centre(s) of the Dej Tuff is a difficult task. The Transylvanian Basin is bordered to the north, east and west by significant volcanic chains contemporaneous with the Dej Tuff and a systematic study of all possible candidate sources is lacking so far. However, the geotectonic environment of magma generation can be estimated based on trace element abundances. The Rb *vs.* (Y + Nb) discrimination diagram [4] places the Pâglişa occurrence in the volcanic arc post-collision field. When compared to various magma generating environments (MORB/N-MORB, Upper-, Lower- or Average Crust) "the best fit" for the Pâglişa outcrop is with an Upper Crust magmatic source. These data, together with other published geochemical characteristics and combined with its He eruption/cooling age should narrow the field of potential eruption centre candidates of the Dej Tuff.

U-Pb ages of detrital zircons from Ielova Metamorphic Sequence - constraints on tectonic affiliation within South Carpathians (Romania)

Zaharia, L.[1*] & Jeffries, T.[2]
[1]Dept. of Geology, "Babes Bolyai" University, Cluj Napoca, Romania ([*]luminita.zaharia@ubbcluj.ro)
[2]Dept. of Mineralogy, Natural History Museum, London, UK

The basement of the Romanian Carpathians consists of pre-Variscan metasedimentary and metaigneous units. In the South Carpathians, these units are grouped in two large Alpine domains with different features, namely Getic domain and Danubian domain, and one small domain, Severin, with rift-originated tectonic units.

Situated in south-eastern part of Romania, in Banat area, Ielova Metamorphic Sequence (IMS) is a metasedimentary sequence, with orthogneiss bodies, metamorphosed up to amphibolite facies. It represents a "disputed" area between the two large domains, and more precisely between Sebeş-Lotru (Getic) and Drăgşan (Danubian) terranes, being situated at the tectonic border between the two.

These two terranes have a different paleogeographic origin. Sebeş-Lotru was interpreted as a fragment of the Cadomian Gondwana eastern extension [1,2], while for Drăgşan a northern Gondwanan, Pan-African origin, thus an Avalonian affinity was shown [3,4].

To constrain the tectonic affiliation of IMS to one of the two discussed terranes, based on their different paleotectonic affinities, zircons from four metasedimentary rocks of IMS were extracted and U-Pb izotopic ages were determined by LA-ICP-MS.

Zircon crystals are mostly transparent. Prismatic shapes, with very rounded termination, as well as almost spherical grains were found. Internal structures are complicated. The elongated grains have an internal structure oscillatory-zoned, sometimes with recrystallised areas, or with fine rims due to dissolution. Spherical grains have either no inherited cores and sector zoning, or large inherited cores, represented by irregular fragments of older grains, with narrow dark metamorphic overgrowths.

Most detrital zircon ages are mid-Neoproterozoic-Early Cambrian, specific for the Cadomian interval (650-530 Ma), while older ages are Paleoproterozoic (1.9-2.5 Ga) and Archean (2.5-2.9 Ga). Variscan overprints are also registered. Major age peaks are at 0.55-0.65 Ga, 2.00-2.01 Ga and 2.6-2.7 Ga.

One of the characteristics of IMS detrital ages is the almost complete absence of Mesoproterozoic (Grenvillian) zircons. Only two grains yielded concordant ages of 1.2 and 1.5 Ga. Another feature is the large number of ages falling in the 2.4-1.95 Ga interval. This interval is specific for Cadomian-related terranes, while for the Avalon terrane (sensu lato, [5]) it represent a "minimum zone" with few or no ages.

The IMS detrital age spectrum reveals a strong Cadomian affinity. This supports a tectonic affiliation of IMS at Sebeş-Lotru (Getic) which shows the same affinity. Drăgşan terrane (Danubian) is characterized by an Avalonian inheritance, which cannot be supported by the IMS age.

The Annandagstoppane granite, East Antarctica: evidence for Archean intracrustal recycling in the Kaapvaal-Grunehogna Craton from zircon O and Hf isotopes

Marschall, H.R.[1*], Hawkesworth, C.J.[2], Storey, C.D.[3], Dhuime, B.[1] & Leat, Ph.T.[4]
[1]University of Bristol, UK ([*]Horst.Marschall@bristol.ac.uk)
[2]University of St Andrews, UK
[3]University of Portsmouth, UK;
[4]British Antarctic Survey, Cambridge, UK

The Grunehogna Craton (GC, East Antarctica) is interpreted as part of the Archean Kaapvaal Craton of southern Africa prior to Gondwana breakup. The basement of the GC is only exposed within a small area comprising the dominantly leucocratic Annandagstoppane (ADT) granite. The granite (and hence the craton) has been dated previously only by Rb-Sr and Pb-Pb mica and whole-rock methods. Here, the crystallisation age of the granite was determined to 3,068 ± 4 Ma by U-Pb dating of zircon. This age is coeval with granitoids and volcanics in the Swaziland and Witwatersrand blocks of the Kaapvaal Craton.

Inherited grains in the ADT granite were discovered with ages of up to 3,433 ±7 Ma, and are the first evidence of Palaeoarchean basement in Dronning-Maud Land. The age spectrum of the inherited grains reflects well-known tectono-magmatic events in the Kaapvaal Craton and form important pieces of evidence for the connection of the GC to the Kaapvaal Craton for at least three billion years and probably longer. Whole-rock chemistry and zircon O isotopes demonstrate a supracrustal sedimentary source for the granite, and Hf model ages show that at least two or three different crustal sources were contributing to the magma with model ages of ~3.50, ~3.75 and possibly ~3.90 Ga, respectively.

3.1 Ga granites covering ~60 % of the outcrop area of the Kaapvaal-Grunehogna Craton played a major role in the mechanical stabilisation of the continental crust during the establishment of the craton in the Mesoarchean. Combined zircon Hf-O isotope data and the lack of juvenile additions to the crust in the Mesoarchean strongly suggest that crustal melting and granite formation was caused by the deep burial of clastic sediments and subsequent incubational heating of the crust. Intracrustal recycling of this type may be an important process during cratonisation and the long-term stabilisation of continental crust.

Imaging and spectroscopy of ion-beam luminescence (IBL) and X-ray excited optical luminescence (XEOL) of framework silicates

Finch, A.A.*, King, G., Taylor, R.P. & Friis, H.
Division of Earth Sciences, University of St. Andrews, UK
(*Adrian.finch@st-and.ac.uk)

Luminescence contains information about the structural state of metals and defects at ultradilute concentrations. Furthermore, minerals have geological timescales over which to perfect states of defect order, making them ideal materials in which to study luminescence. In principle, light emission is a powerful tool for determining defect structure, but interpreting such data is challenging since we have an incomplete understanding of luminescence in many minerals, and how features such as coordination state and symmetry are encoded within it. Here we present data on two spectroscopic methods in quartz and feldspar. We have measured the light emitted during implantation by ions, known as ion beam luminescence (IBL) or ionoluminescence (IL). We model closely the implantation using Monte-Carlo simulations and, by changing acceleration potential, current and nature of the ions (i.e. H^+, He^+, N^+), we change implantation depth (i.e. bulk vs. surface responses) and the relative proportions of ionisation, vacancy and phonon formation. Comparing ions (H^+) and molecules (H_2^+) contrasts luminescence from excitation of ground states with excitation of excited states, i.e. double excitation. We also monitor the change in luminescence as a function of implantation dose. This allows us to determine whether the changes are consistent with the proposed nature of the luminescence centres. Since most natural minerals have significant radiation damage, we also gain insights into how luminescence of real minerals differs from synthetic mineral analogues.

The development of synchrotrons allows advances in x-ray excited optical luminescence (XEOL, also known as radioluminescence, RL). X-irradiation results in ionisation but not atomic displacements, in contrast to IBL. By comparing IBL and XEOL we deconvolute responses that derive from vacancy formation and atomic recoils. By varying x-ray energy over the absorption edges of particular elements (e.g. Fe), we combine XEOL with x-ray absorption spectroscopy (XAS), used widely to determine local coordination in solids. Initial optically determined (OD-)XAS experiments studies of Fe in feldspar show little variation in light intensity as a function of x-ray energy across the Fe edge. We infer that the long (ms) lifetime of that decay effectively divorces light emission from the XAS and we hypothesise that OD-XAS will be most effective on very fast (e.g. ns) lifetime decays. Experiments to develop time-resolved OD-XAS are underway. Since the spot in XEOL is only a few microns across, there are a whole family of hyperspectral imaging methods which can access structural state within crystals. We briefly review such methods in determining structural state variations in individual crystals.

Advantages of combined cathodoluminescence and Nomarski DIC microscopy in the Earth sciences

Götze, J.
Inst. of Mineralogy, TU Bergakademie Freiberg, Germany
(goetze@mineral.tu-freiberg.de)

Microscopic methods play an important role in modern investigations of minerals and materials. Besides conventional light and electron microscopy, cathodoluminescence (CL) microscopy has developed into a powerful analytical method in the geosciences and materials sciences [1]. The principle of CL is based on the detection of an electron-excited luminescence signal, which is generated by electron transitions at certain point defects within the solid. Accordingly, CL is an excellent method to characterize defects in materials, to distinguish different phases and to reveal information about the chemical composition down to the trace-element level (Fig. 1).

Nomarski interference contrast imaging was developed by G. Nomarski [2] and has routinely been applied especially in reflected light microscopy in metallurgy and materials sciences. Applications in geosciences are rare [3-7]. Nomarski DIC microscopy can visualize different phases and/or surface reliefs in the scale of several nm. The treatment with natural and artificial etching agents can significantly enhance this effect [6]. The method is based on the principle of beam splitting by a double-crystal prism split, resulting in the superposition of laterally shifted wave fronts. Using this effect, micro-textural features can be revealed, which are not discernable using conventional polarizing microscopy (Fig. 1).

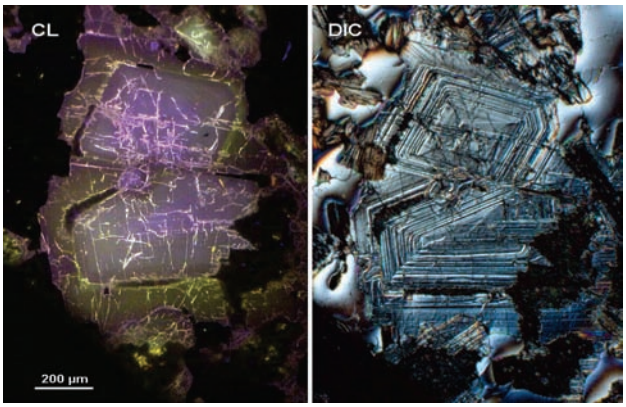

Fig. 1: Altered plagioclase from a granite imaged with CL microscopy (left) and Nomarski DIC (right); CL reveals chemical heterogeneity and cracks, whereas DIC clearly shows oscillatory zoning.

The present study discusses the potential of an integrated application of CL and Nomarski DIC microscopy for the investigation of minerals and rocks in the Earth sciences. By combining these two microscopic techniques, chemical, crystallographic and textural information can be obtained from the same sample area in a polished thin section.

Self-affine pattern of crystal growth from heterogeneous magmas – 3D depiction of LA-ICP-MS data

Słaby, E.[1*], Śmigielski, M.[2] & Domonik, A.[3]
[1]Inst. of Geological Sciences, Polish Academy of Sciences, Research Centre in Warsaw, Poland ([*]e.slaby@twarda.pan.pl)
[2]Inst. of Geology, University of Warsaw, Poland
[3]Inst. of Hydrogeology and Ingineering Geology, University of Warsaw, Poland

Growth textures and the trace element composition of alkali feldspars from the Karkonosze pluton, an igneous body of mixed magma origin have been investigated. Each crystal was analyzed (Ba, Rb, Sr) along several transects, in constant step, from margin to margin. 3D depiction combined with fractal statistics allow us to gain an insight into the mechanism of crystal growth in a system showing non-linear dynamics.

The LA ICP MS spots are located along a traverse (X axis). Each laser ablation pulse (60-120μm in diameter) gives data collected from a 5 μm thick layer of feldspar. About 70-100 impulses were used within one spot; the number of laser impulses and the depth reflects the duration of each LA ICP MS analysis (Y axes). Natural neighbor interpolation [1] was applied to the data. The 3D depiction of the data as a contour map and surface model of element distribution involved the use of Surfer 8.0 (Golden Software), classical izoline maps and 3D models merged with shaded-relief images [2]. Depiction of the three-dimensional models was preceded by a spline smooth procedure without any recalculation of the model. To further improve the resolution of the data depiction and to best display the spatial distribution of an element concentration, the vertical scale on the plots was arbitrarily chosen and usually magnified 2-5 times.

A self-similarity parameter, the Hurst exponent, was used to show the long-range dependence of element behaviour during the growth process. The expected values of H lie between 0 and 1. For H = 0.5, element behaviour shows a random walk and the process produces uncorrelated white noise. For values either higher or lower than 0.5, the system shows non-linear dynamics. H < 0.5 represents anti-persistent (more chaotic) behaviour, whereas H > 0.5 corresponds to increasing persistence (less chaotic).

The magmatic system responsible for the formation of the investigated feldspars shows different, non-linear dynamics. The crystals grew from mixed magmas characterized by different degree of homogenization. Feldspars grown in more chaotic, active regions of mingled magmas are strongly zoned. The Hurst exponent ranges from H=0.06 to H=0.47 reflecting intensive chemical mixing and underlying strong non-linear dynamics of the system. The 3D depiction shows particularly complicated pattern of compositionally heterogeneous domains within each zone, being products of intensive, chaotic magma steering. Feldspars grown from mixed and homogenized magmas are almost homogeneous. Relatively small variation in trace element contents can be still recognized due to 3D depiction. Despite homogenization, the fractal statistics reveal that trace elements were incorporated chaotically into the growing crystals. The anti-persistent, chaotic behaviour of elements during growth of these feldspars is preserved. It appears that 3D depiction combined with fractal statistics is an ideal tool for the identification of the growth mechanism and any subsequent changes occuring due to chaotic processes in on open system.

[1] Sibson, R. (1981) in Barnett V. (ed.) *Interpreting Multivariate Data*. John Wiley and Sons, New York. [2] Yoeli, P. (1965) *Surv. Mapp.*, **25**, 573-579.

From EDS microanalysis towards nanoanalysis: hyperspectral imaging for mineralogical applications using silicon drift detectors (SDD) and EBSD analysis

Salge, T.[*] & Goran, D.
Bruker Nano GmbH, Berlin, Germany
([*]Tobias.Salge@bruker-nano.de)

Within the last decade, SDD systems have become state of the art technology in the field of energy-dispersive spectroscopy (EDS). The main characteristic of the SDDs is their extremely high pulse load capacity of up to 750,000 counts per second at good or reasonable energy resolution (<123 eV Mn-Kα, <46 eV C-Kα at 100,000 counts per seconds). These properties in conjunction with electron backscatter diffraction (EBSD) technique, modern data processing and automated stage control opens a range of innovative analysis options, not only high speed mapping but also hyperspectral imaging techniques.

This paper presents mineralogical applications with the QUANTAX system with EDS SDD and EBSD detector using the options described above: (1) Fast detection and discrimination of minerals within impact-induced accretionary lapilli [1]. (2) Drill core analysis of a Chicxulub impact ejecta sequence from the K/Pg boundary at ODP leg 207 [2] using fast, high resolution element maps. (3) Detection of monazite in granite by the *Maximum Pixel Spectrum* function [3]. (4) Distribution of elements with overlapping peaks by deconvolution at the example of rare earth elements (REE) in zoned monazite. (5) Spectroscopic phase analysis of a sulfate-carbonate-dominated impact matrix at borehole UNAM-7 from the Chicxulub impact crater [1]. (6) Automated baddeleyite particle search within lunar meteorite Dhofar 287 [4] by feature analysis. (7) EBSD studies with examples of iron meteorites and impact-induced, recrystallized carbonate melts [1].

In addition, continuing technological advances require the elemental analysis of increasingly smaller structures in many fields, including mineralogy and nanotechnology in general. It will be demonstrated that using low accelerating voltages, the element distribution of nanometer-sized structures in bulk samples can be displayed in a short time due to optimized signal processing and solid angle. Peaks composed of contributions from several overlapping elements (e.g. Co-L, Ni-L and Fe-L or N-K and Ti-L) can be deconvolved using an improved atomic database with 250 additional L, M and N lines below 4 keV.

Quantitative estimation of radiation-induced effect on cathodoluminescence of plagioclase

Kayama, M.[1*], Nishido, H.[1], Toyoda, S.[2], Komuro, K.[3] & Ninagawa, K.[2]
[1]Research Institute of Natural Sciences, Okayama University of Science, Okayama, Japan ([*]kayama@rins.ous.ac.jp)
[2]Dept. of Applied Physics, Okayama University of Science, Okayama, Japan
[3]Earth Evolution Sciences, University of Tsukuba, Japan

Cathodoluminescence (CL) halo in quartz caused by alpha-radiation has been investigated for the application to geodosimetry. The halo in feldspar minerals, however, has not been studied from the perspective of CL spectroscopy. In this study, albite, andesine and anorthite implanted by He^+ ion have been characterized by CL spectral analysis to clarify the emission mechanism for the applications to geodosimetry and geochronology.

Single crystals of albite (Or_2Ab_{98}) from Minas Gerais, Brazil, andesine ($Or_2Ab_{51}An_{47}$) from Bekily, Madagascar and anorthite ($Or_0Ab_5An_{95}$) from Yoichi, Hokkaido, Japan were selected for CL measurements. He^+ ion implantation (dose density: $1.23 \times 10^{-4} \sim 7.38 \times 10^{-4}$ C/cm^2) on the samples was performed using a 3M-tandem ion accelerator at 4 MeV corresponding to the energy of alpha-particles from ^{238}U.

CL imaging of the albite shows CL halo on the surface of He^+ ion implanted sample. Approximately 15 μm width of CL halo in the section is consistent with theoretical range of alpha-particles from disintegration of ^{238}U in albite. CL line analysis along the halo section of the albite reveals that an increase in the CL intensity along depth direction substantially corresponds to the Bragg's curve, suggesting an energy loss process of specific ionization along the track of a changed particle. CL intensities of the andesine and anorthite, however, gradually decrease from the implantation surface to approximately 15 micron meters in depth, over which they jump up to the bulk emission level of non-implanted areas.

The spectra of CL halos in albite, andesine and anorthite consist of emission bands at around 400, 580 and 730 nm. Furthermore, a CL emission at around 660 nm is detected in only albite. These emission spectra in energy units can be deconvoluted by Gaussian curves, resulting in four components centred at 3.05, 2.10, 1.86 and 1.56 eV. An integral intensity of the component at 1.86 eV (666 nm) positively correlates with radiation dose of He^+ implantation in the halo area of individual albite. It suggests that the CL emission corresponding to the component at 1.86 eV might be assigned to a radiation-induced defect centre formed by He^+ ion implantation. Therefore, the CL halo of albite caused by alpha-particle radiation can be used to quantitatively estimate the radiation dose of alpha-particles induced on feldspar minerals as an indicator applied for a geodosimeter.

Micro-computed tomography applied to mineralogical samples: towards quantification

Abel, R., Armstrong, R., Hezel, D.C., Elangovan, P. & Williams, C.T.[*]
Dept. of Mineralogy, Natural History Museum, London, UK
([*]t.williams@nhm.ac.uk)

The aim is to present some recent developments in mineralogy using a high-resolution (ca. 5–125 μm) micro-Computed Tomography system (micro-CT Scanner) at the Natural History Museum, London.

The principles of this non-destructive technique will be outlined, and brief (30-second) video clips will illustrate the potential for 3-dimensional representations of mineral specimens, drill core and rock slices. Samples shown will include the 3-D distribution of silicates and metal in meteorite samples; silicates, oxides and sulphides from an ultrabasic sample (rock slice from Rum, Scotland); gold in smectite (drill core from Patagonia), and gold in calcite (Fig. 1, hand specimen from Hope's Nose, UK).

Quantification of 3-D images from multi-phase and variable density materials (i.e. rock and mineral samples) poses significant challenges. We will outline how we are addressing these challenges, and in addition present work in progress on refining the scanning and threshold parameters for different matrices; investigate possible mineralogical applications; establish limitations of the technique and suggest future directions for instrument and software development.

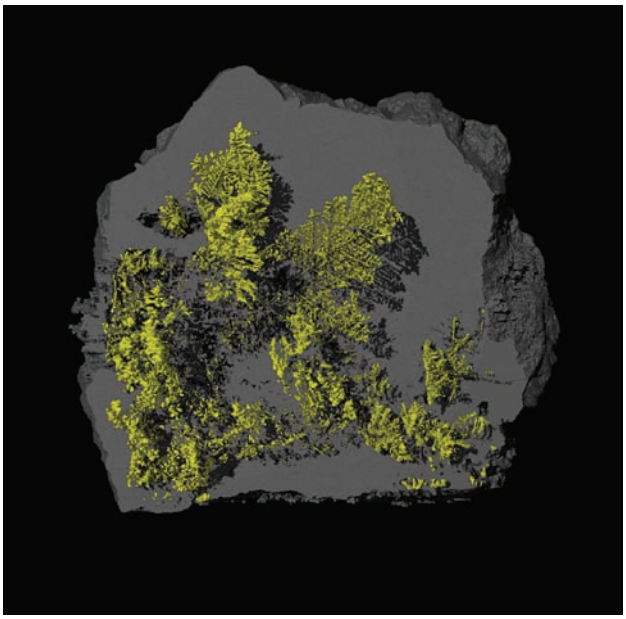

Fig. 1: Perspective rendered cut-away of Au-bearing calcite from Hope's Nose, UK) to reveal frond-like crystals of gold (false-coloured yellow) sitting in calcite matrix (false-coloured grey). Field-of-view approximately 8 cm.

Imaging diamond: using birefringence & infrared to map strain and impurities

Howell, D.[1,2*], Griffin, W.L.[1], O'Reilly, S.Y.[1], O'Neill, C.[1], Wood, I.[2], Dobson, D.[2] & Jones, A.P.[2]
[1]GEMOC, ARC National Key Centre, Macquarie University, Sydney, Australia ([*]dhowell@science.mq.edu.au)
[2]Earth & Planetary Sciences Department, University College London, UK

Birefringence is an anomalous optical property that has commonly been observed in diamond, but until recently has rarely been quantified. With the development of the MetriPol system [1] an automated microscope technique is now available that allows rapid quantitative birefringence analysis of diamond. This technique has some advantages over 2D Raman mapping of diamond's pressure sensitive 1332 cm^{-1} band [2] (Fig. 1). This method of imaging diamond can be used to investigate all of the documented causes of stress and strain within diamond [3].

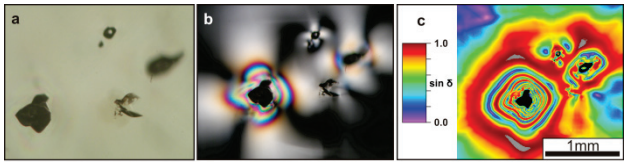

Fig. 1: Series of images of four coesite inclusions in a diamond from Finsch mine (South Africa): (a) plane-polarised transmitted light; (b) cross-polarised light; (c) MetriPol $|\sin(\delta)|$ false colour image.

Since the original classification of diamonds based on their absorption in the one-phonon region of the mid-infrared (IR) range was first introduced, IR analysis has become the principle tool for classifying diamonds based upon the concentration and aggregation state of nitrogen.

Recent technological developments in the field of spectroscopy allow detailed μ-FTIR analysis to be automated and performed rapidly. The Nicolet iN10 microscope allows spectra to be collected with greater efficiency than is possible with conventional μ-FTIR spectrometer-microscope systems. Combining this with a computer controlled *x-y* stage allows the automated measuring of several thousand spectra in only a few hours. IR maps of diamond plates can now be recorded with minimal effort, but this has created the need for an automated technique to process the large datasets of IR spectra and to obtain quantitative data from them. A new computational method achieving this has been accomplished which generates false colour images that can define nitrogen concentrations, aggregation states, as well as hydrogen and platelet defects.

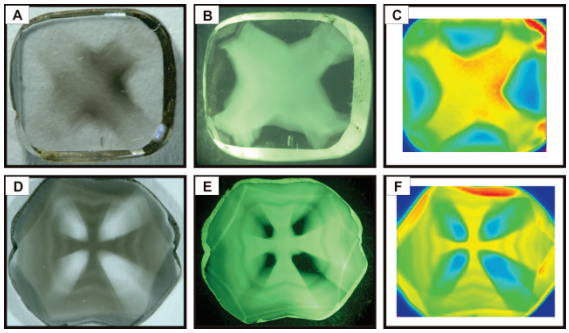

Fig. 2: Images of two diamond crystals showing 'maltese-cross' style growth zonations. Images A and D are under plane-polarised light, B and E are taken under UV, and C and E are false-colour images of the relative intensity of the 3107cm^{-1} (hydrogen) peak taken from IR maps.

Revealing cryptic alkali feldspar microtextures by SEM charge contrast imaging

Flude, S.[1*], Lee, M.R.[2], Sherlock, S.C.[1] & Kelley, S.P.[1]
[1]Dept. of Earth and Environmental Sciences, Centre for Earth, Planetary, Space & Astronomical Research (CEPSAR), Open University, Milton Keynes, UK ([*]s.flude@open.ac.uk)
[2]Dept. of Geographical & Earth Sciences, University of Glasgow, UK

Understanding the coherency, interconnectivity and microporosity of alkali feldspar microtextures is crucial if their host grains are to be used for Ar/Ar thermochronology, owing to potential of these microtextures to act as fast-diffusion pathways for ^{40}Ar. In this first application of Charge Contrast Imaging (CCI) to alkali feldspars we show that the technique can reveal microtextures that are difficult to image by any other technique but have very important implications for Ar isotope work and determination of geological histories.

CCI work was undertaken on polished but uncoated thin sections using a FEI Quanta 200F SEM operated at ~60 Pa and with water vapour in the chamber. Contrast in CCI comes from differences over grain surfaces in the intensity of secondary electron emission, which relates to the populations of charge traps immediately beneath the surface. CCI enables high contrast and high resolution imaging of crypto- and micro-perthites, but crucially also highlights micrometre-sized patches and veins of deuterically formed 'irregular' microcline within orthoclase. These fine-scale perthites and near-isochemical intergrowths cannot be resolved by Z contrast SEM, but TEM imaging of foils cut from them using the focused ion beam (FIB) technique shows that they are real and not charging artefacts. We speculate that the magnitude and distribution of elastic strain energy within albite exsolution lamellae, and the strained interiors of irregular microcline subgrains, plays a major role in charge trapping and so CCI in feldspars.

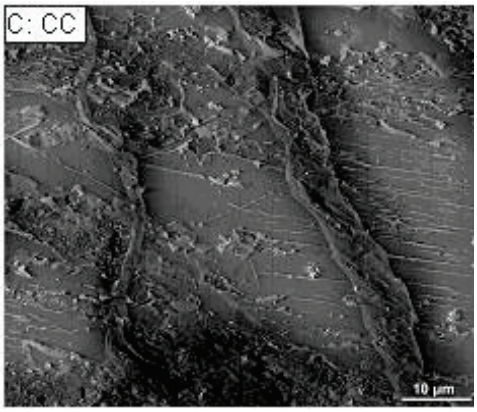

Fig. 1: CCI of alkali feldspar showing veins of irregular microcline.

Using CCI we have examined alkali feldspars from the Dartmoor Granite (UK) and results have provided new insights into its geological evolution. For example, CCI shows that veins of Or-rich feldspar ('irregular microcline') cross-cut orthoclase and are far more abundant than indicated by Z contrast SEM. Importantly this microcline divides volumes of pristine feldspar into tens of micrometre-sized subgrains, which may have a major impact on Ar diffusion rates. As it enhances considerably our ability to characterise and measure microtextures that must be taken into account in Ar isotope work, CCI is thus is of great importance in understanding and refining Ar/Ar thermochronology.

Distribution of bubbles in moldavites

Franz, A., Rantzsch, U.[*] & Kloess, G.
Inst. of Mineralogy, Crystallography and Materials Science, Leipzig University, Leipzig, Germany
([*]rantzsch@uni-leipzig.de**)**

Moldavites occur in several shapes corresponding to their strewn- and sub-strewn fields. Suess [1] published the first extensive work about moldavites. A detailed petrographical and geochemical investigation on Lusatian moldavites was carried out by Lange [2].

Bubbles occur in all tektites. Their origin within moldavites has been studied extensively in previous investigations [3,4]. A correlation of bubble- size, -shape and -alignment has not been done yet.

In the present study 3D µ-CT measurements on moldavites were conducted to gain further information about the bubble shape and their distribution within the samples. The most important advantage of 3D µ-CT measurements is the non destructive process and the higher statistic compared to other methods. Additionally the measurements yield 3D information of the samples and their inclusions.

For interpretation of the data sets the graphic program VGStudio Max 2.0 (Volume Graphics) was used. The 3D µ-CT measurements display significant differences of bubble distribution and elongation within each moldavite (Fig. 1). Different sizes (pore volume) and shapes with spherical or elongated alignment could be determined.

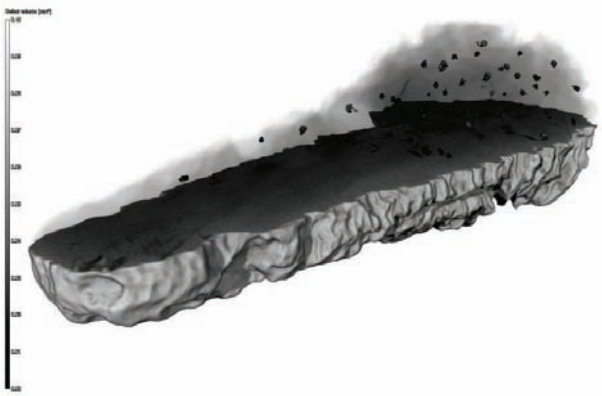

Fig. 1: 3D µ-CT measurement of a moldavite from southern Bohemia with bubble distribution.

Within this study a new method of estimating the pore volume, their shape and distribution will be presented. Especially their alignments indicate findings about the direction of flow of the tektite melts. The non-sphericity is increasing with bubble size. The obtained data will reveal further information about moldavite origin of their aerodynamic morphology.

[4]Dept. of Applied Geology, Curtin University of Technology, Perth, Australia
[5]Fachbereich Materialforschung und Physik, Universität Salzburg, Austria
[6]Inst. für Geowissenschaften, Universität Mainz, Germany

Over a century ago there was discussion of whether Th may be present in monazite as a separate Th silicate phase, rather than substituting for Ce^{3+} in the monazite lattice [1]. Our study, addressing chemical alteration textures in large pegmatitic monazite–(Ce) crystals from the Dillingøya island, Moss area, Norway, seems to support, at least partly, the above hypothesis.

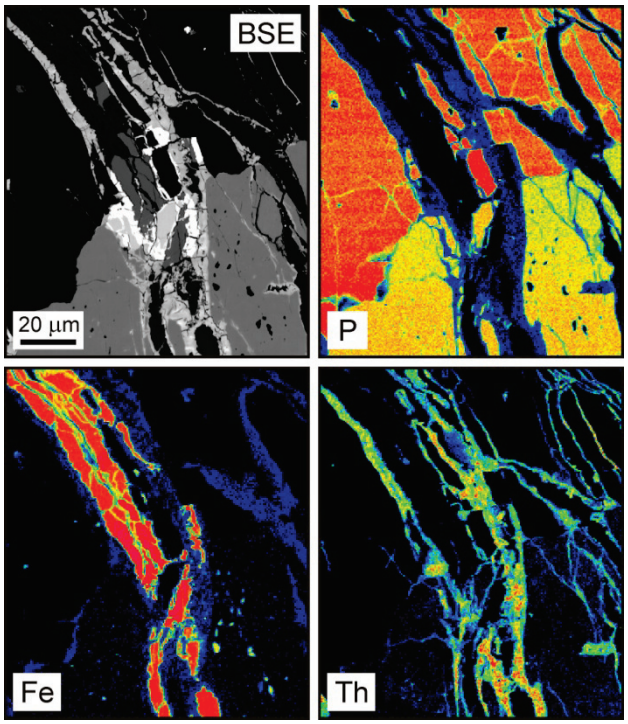

Fig. 1: BSE image and three colour-coded EPMA element distribution maps showing a multitude of Fe sulphide and Th silicate veins pervading apatite (upper left) and monazite–(Ce) (lower right).

The bulk monazite–(Ce), which contains ca. 8 wt% ThO_2, is intergrown with Ca apatite. These two phosphate phases are pervaded by several generations of veins of sulphide phases and thorium silicate (> 50 wt% ThO_2). Both well-crystallised thorite and amorphous $ThSiO_4$ were found in the TEM.

No chemical alteration haloes were observed within the bulk phosphates, emanating from the veins. This suggests that the phosphates cannot represent unaltered remnants of the primary monazite. Rather, the chemical alteration has resulted in virtually complete phase decomposition of the primary crystals, with potentially uncontrolled elemental changes.

LRGB colour imaging of panchromatic SEM-CL images

Shimobayashi, N.[1*], Takaya, M.[1], Nomoto, T.[1] & Notoya, S.[2]
[1]Dept. of Geology & Mineralogy, Graduate School of Science, Kyoto University, Kyoto, Japan ([*]shimo@kueps.kyoto-u.ac.jp)
[2]Electron Optics Division, JEOL Ltd., Akishima Tokyo, Japan

The SEM-CL system, composed of a detector for cathodoluminescence (CL) attached to a SEM or EPMA, is capable of producing high-resolution digital CL images of luminescent materials. In most conventional SEM-CL, a photomultiplier tube (PMT) is used as a detector for a weak CL signal and then only monochromatic CL images can be obtained directly. In contrast, the colour CL images contain much more valuable information than the monochromatic images. We attempt a colour imaging of the monochromatic SEM-CL images by adopting an LRGB composite technique instead of a traditional RGB method.

The SEM-CL system used is based on an EPMA (JEOL: JXA-8105) and the emitted CL is detected by PMT (Hamamatsu Photonics: R955) through a special light guide. Introduction of a photon-counting method enables us to obtain the high sensitive CL images. Either RGB or LRBG technique requires three monochromatic images, each of which should be obtained by the separate R-G-B component colours. The separate R-G-B images can be obtained by placing bandpass red (R), green (G) and blue (B) filters (Astronomik: LRBG Type-2c) in front of the PMT. Then, these separate R-G-B images are recombined digitally using the conventional photo-retouch software (*e.g.*, Photoshop) to produce a full colour image. The traditional RGB technique, however, has an inconvenience that it takes very long exposure times to acquire the three R-G-B separate images in a high-resolution mode. It takes over three times as long as capturing a monochromatic CL image in the same resolution. The long exposure time is a serious problem for the specimen that is easily irradiation damaged and/or the specimen whose CL emission is short-lived.

In contrast, LRGB combination technique (the "L" referring to "luminance" or "lightness") allows us to shorten the total exposure time. This compositing technique has been developed independently by two amateur astrophotographers, R. Dalby (U.K.) and K. Okano (Japan; plasma physicist). The LRGB technique involves capturing separate R-G-B images to compose the colour as well as the RGB technique, and also a high-quality monochrome image [L image] to act as the luminance (brightness) of the final image. The quality of the final composite image strongly depends on the luminance image. The lower resolution in the colour images does not degrade the final composite. If only the luminance image should be photographed in a fully high resolution mode, the resolution of the three R-G-B colour images produces little effect on a quality of the final composite colour image. The quicker acquisition of the separate R-G-B colour images in a lower resolution makes possible to shorten the total exposure time (Table 1), during which the specimen is exposed by the electron irradiation. Therefore, the introduction of the LRGB technique to the SEM-CL system is useful particularly to the short-lived CL emission or the specimen which is easily subjected to irradiation damage.

Table 1: Comparison of the total exposure times between two composite techniques (*example*)

	(1) RGB	(2) LRGB
L	---	7 min.
R,G,B	12 min. each	2 min. each
Total	36 min.	13 min.

(1) [R,G,B]: 512 x 512 pixels, dwell time: 2 msec/pixel,
(2) [R,G,B]: 128 x 128 pixels, dwell time: 2 msec/pixel,
[L]: 512 x 512 pixels, dwell time: 1 msec/pixel.

Infra-red mapping of defects in diamonds using a focal plane array (FPA) detector

Shiryaev, A.A.[1*], Johner, N.[2] & Zedgenizov, D.A.[3]
[1]Institute of Crystallography, Moscow, Russia
([*]a_shiryaev@mail.ru)
[2]Bruker Optics, Ettlingen, Germany
[3]Institute of Geology and Mineralogy, Novosibirsk, Russia

Nitrogen is the main elemental impurity in diamond. It substitutes carbon in the lattice and forms different defect centres, which determine spectroscopic and some physical properties of diamond crystals. For geosciences nitrogen is an important tracer of growth conditions and of post-growth annealing regime. Infra-red (IR) absorption spectroscopy provides quantitative information about N content of the diamond in almost all cases, since its majority is present as IR-active defects. Hydrogen is another important impurity and its total concentration may be comparable to that of N, but only a fraction of H is IR-active. The models of H-defects are not yet firmly established even for the very common defect manifested as a sharp absorption peak at 3107 cm^{-1}.

Diamonds are notoriously heterogeneous making IR microscopy indispensable in many cases for reliable conclusions. We have studied the N and H spatial distribution in plates cut from natural diamonds from different localities. A FTIR imaging microscope (HYPERION 3000) including modern Focal Plane Array (FPA) detector technology was employed for this study. The used FPA consists of an array of 64×64 elements, allowing simultaneous acquisition of 4096 IR spectra. Using the 15x objective the field of view is 170x170 µm with a pixel resolution of 2.7 µm. To achieve a reasonable signal/noise ratio at very short acquisition times, 4×4 pixel binning was applied. Spectral resolution was 4 cm^{-1}. The OPUS 6.5 software was used for data acquisition and evaluation.

Figure 1 shows the distribution of the A-defect (N pairs), and of the H-related defect (3107 cm^{-1}) in an area of 340x510 μm^2 of a natural diamond from Brazil. For this sample the concentration of the A-defect is a close proxy of the total N content. Positive correlation between these two defects is obvious. Similar trends are observed also for other diamonds with variable concentration and speciation of N-defects.

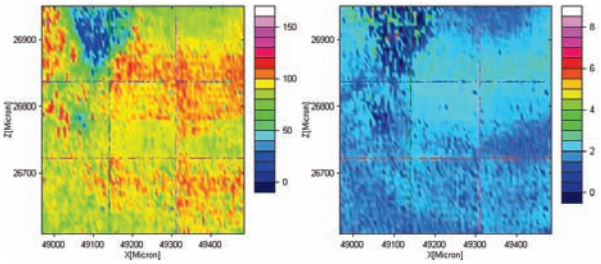

Fig. 1: Spatial distribution of nitrogen (left panel) and of IR-active hydrogen in a natural diamond.

Earlier, the N-H correlation was observed on the basis of IR spectra of individual diamonds. In this work we show that such correlation holds also for individual diamonds and statistics (number of spectra) is substantial. The most likely explanation of the observed behaviour is that nitrogen diffusion during thermal annealing forces redistribution of hydrogen, converting a fraction of it into the IR-active form. Mapping of the spatial distribution of other N-related defects will be also presented.

Characterization of wet clays in TEM

Chiou, W.-A.[1*], Ishikawa, A.[2] & Fukushima, K.[3]
[1]NISP Lab, NanoCenter, University of Maryland, College Park, USA ([*]wachiou@umd.edu)
[2]Dept. of Physics, Nihon University, Tokyo, Japan
[3]JEOL Ltd., 3-Chome, Akishima, Tokyo, Japan

Characterization of particle size and shape, including surface morphology, is an important step in clay research. Despite previously reported techniques, the precise measurement of clay particle size remains difficult due to the minuscule size and diversity of shapes, surface activities, and sample preparation methods. The key to successful size analysis lies within the ability to keep the particles well dispersed in their natural (wet or specific liquid) environment. This paper presents novel methods and technologies of studying clay minerals in a fully wet (water) environment using different transmission electron microscopy (TEM) techniques.

Special techniques have been developed to overcome the difficulty of clay specimen preparation in their natural state. The wet environmental-cell TEM (WETEM) technique provides a special wet environment chamber at atmospheric pressure in TEM that allows for examination of individual clay particles at high resolution. The cryo-method involved creates a thin vitrified film of suspensions using a specially designed cryo-plunge device. Two spray methods, EFFA spray system and special atomizer, are also applied to disperse clay particles on carbon coated copper grids for TEM observation. Finally, clay nanocomposite samples are dispersed and embedded in epoxy, and ultra-thin sectioned for TEM study.

Large agglomerates with scattered overlapped clay particles are the typical TEM image obtained from conventional specimen preparation techniques. However, with the fore-mentioned techniques, clay particles can be fully or partially dispersed. The wet environmental-cell TEM technique allows *in-situ* observation of individual particles in wet environment, and thus the size and shape of individual clay particles can be analyzed in high resolution. Clay particles of different shapes (e.g., spherical-like, platy, elongated rod-like, needle, triangular, and polygon) of nano-size are observed in WETEM. The fast quench of clay suspensions in Cryo-TEM is capable of preserving different clay orientation before settling occurs. The spray technique using the atomizer offers relatively good dispersion of clay particles whereas the conventional spray system often produces small aggregates.

Experiments utilizing these techniques demonstrate that the fundamental (the thinnest) individual smectitic clay particles appeared to have a very similar measurement of 5 to 10 nm in thickness, with the majority around 5 nm. This thickness is unique and may be universal. Excellent high resolution characterization of clay particles has also recently been achieved by other techniques such as TEM tomography.

Physical interpretation of Scherrer crystallite size for parallel-layered crystallite aggregate

Wang Chunyun[*] & Xie Xiande
Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, P. R. China ([*]chunyun@gig.ac.cn)

Scherrer equation was first developed in describing the contribution of the small crystallite size in metallurgy to the peak broadening of X-ray diffraction pattern in the form of full width at half maximum (FWHM) [1], and was hence extensively utilized by chemical physicists, material scientists, applied crystallographers and clay mineralogists to determine the thicknesses of coherently scattering domains (CSD) perpendicular to the diffracting planes for parallel-layer groups of carbon black [1], illite, chlorite [2-6] and other crystallites from the obviously broadened (00l) peak profiles. The Scherrer crystallite size thus derived is called “effective length” [7], “apparent crystallite size” [1,7], “effective crystallite size”[3-4], or “realistic mean thickness” [8], etc., and is simply interpreted as CSD mode of thickness distribution [3,5,6], or as mean weighted by number [4,9-11], by area [12,13] or by volume [14,15], when it is compared with TEM-measured crystallite sizes. Here we show by using interference function for one-dimensional X-ray diffraction [9-11,16] that Scherrer crystallite size as frequently used for parallel-layered crystallite aggregate, in particular clay minerals, is actually the mean thickness weighted by number, rather than by area or by volume, and the Scherrer constant is variable, rather than fixed, with the number of layers in each crystallite.

As the interference function depends on the thickness and the thickness distribution of CSDs, an idealized one-dimensional diffraction pattern from perfectly oriented illite or chlorite clay sample was studied and we found by modeling that Scherrer crystallite size is the average thickness weighted by number perpendicular to the diffraction direction c.

A new approach to the extraction of illite crystal thickness distribution from XRD data

Szczerba, M.* & Środoń, J.
Institute of Geological Sciences, Polish Academy of Sciences, Kraków, Poland (*ndszczer@cyf-kr.edu.pl)

The classic approach to the calculation of the illite crystal thickness distribution from X-ray diffraction patterns is based on the Bertaut-Warren-Averbach analysis. Before registering the XRD patterns illite and illite-smectite samples are treated with polymer polyvinylpyrrolidone (PVP) in order to split mixed-layer crystals into free fundamental particles. The presence of PVP on the particle surfaces influences XRD patterns. This problem was approximatelly solved by [1].

The alternative approach is based on modeling the structure of PVP on smectite surface and on assumption that the structure of PVP is similar on smectites and on illites [2]. The X-ray diffraction pattern of illite is calculated as a weighted sum of diffraction patterns of illite fundamental particles of particular thicknesses with PVP on their surfaces.

For the purpose of this study a computer program, which employs Genetic Algorithms as the minimization paradigm, was written and tested. It was found that this approach works best if the mean thickness of illite fundamental particles is relatively small.

Thermal analysis of synthetic hydrotalcite and bauxite refinery hydrotalcites

Palmer, S.J. & Frost, R.L.*
Chemistry Discipline, Faculty of Science and Technology, Queensland University of Technology, Brisbane, Australia (*r.frost@qut.edu.au)

Hydrotalcites have the useful ability of removing anionic species from solution either by anion exchange or through the initial formation process of the layered double hydroxide structure. This investigation has looked at removing arsenate and vanadate using hydrotalcites prepared in two different ways: 1) co-precipitation and 2) thermal activation. The thermal activation method has been clearly shown to increase the number of anions removed from solution. This increase in effectiveness is due to the increased chemical reactivity of the hydrotalcite structure after dehydration. Hydrotalcites were prepared using synthetic materials, Bayer liquor, and seawater neutralised bauxite refinery residues.

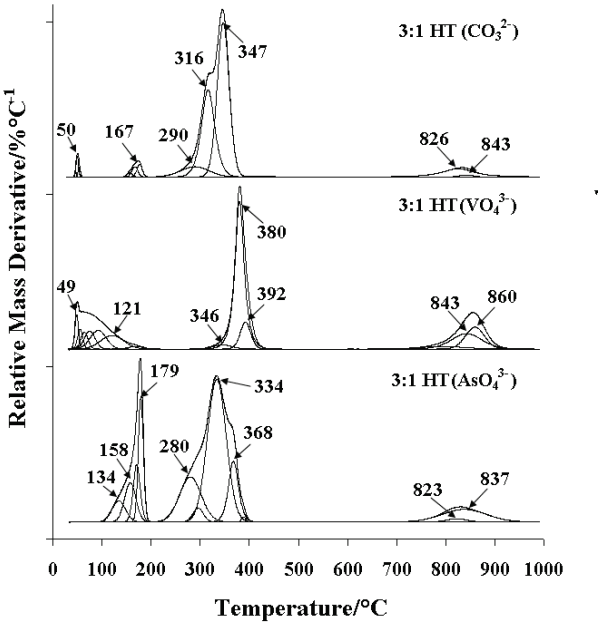

Fig. 1: Thermal analysis patterns of hydrotalcite with intercalated carbonate, vanadate and arsenate.

This work has shown that the intercalation of arsenate and vanadate increases the thermal stability of the hydrotalcite structure compared to carbonate hydrotalcites (Fig. 1). The Mg:Al ratio used for the removal of the toxic anions has been found to be dependent on the method used. For the co-precipitation method the formation of hydrotalcite in solution with a Mg:Al ratio of 3:1 is favoured over the 2:1 and 4:1, whereas for thermally activated hydrotalcites with a Mg:Al ratio of 4:1 is most favourable. Using a variety of techniques the mechanism for the inclusion of arsenate and vanadate has been determined. It has also been established that the removal of toxic anions in highly alkaline solutions is diminished.

This investigation has also shown that Bayer refinery residues may be used for the treatment of solutions containing toxic anions. Thermally activated Bayer hydrotalcite has been shown to be highly effective in the removal of arsenate and vanadate, with 100 % removal being observed. The formation of hydrotalcite during the seawater neutralisation process removes anions via two mechanisms rather than one observed for thermally activated red mud.

Investigation of layered structures using terahertz time-domain spectroscopy

Janek, M.[1,2*], Matejdes, M.[2], Zich, D.[2], Bugár, I.[3], Szöcs, V.[4], Vincze, A.[3], Danielik, V.[5], Velič, D.[2,3] & Darmo, J.[6]

[2]Dept. of Physical and Theoretical Chemistry, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
[3]International Laser Center, Bratislava, Slovakia
[4]Inst. of Chemistry Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia
[5]Dept. of Inorganic Technology, Slovak University of Technology, Bratislava, Slovakia
[6]Inst. of Photonics, Technical University Wien, Vienna, Austria

Model inorganic layered structures based on selected layered minerals from the micas group and boron (aluminium) nitride were investigated in the far infrared region using terahertz time-domain spectroscopy (THz-TDS). This technique allows determination of the complex index of refraction – refractive index and absorption index, including sample thickness determination from single sample and background measurement in the frequency region from 0.1 to ~6.0 THz (3.3 to ~200.0 cm^{-1}). The main advantage for utilization of the THz-TDS is the coherent nature of measured transmitted electric field, providing high sensitivity and resolving phase information [1]. Therefore, this technique is able to deliver frequency dependence of material complex dielectric permittivity related to the refractive properties through Maxwell´s relationships.

The samples were characterised also by X-ray diffraction, Fourier transform infrared spectroscopy and other conventional techniques. Micas were selected in such manner that differed significantly in chemical composition e.g. in structural cations and ratios of interlayer cations. For instance the structural iron content as determined by EDS differed significantly. The results of frequency dependent complex index of refraction ($\tilde{n}_s = n_s - i\kappa_s$) of used layered materials were determined.

The benefits of the near-infrared spectroscopy in the characterization of organoclays

Madejová, J.[*], Jankovič, Ľ. & Komadel, P.
Institute of Inorganic Chemistry SAS Bratislava, Slovakia
([*]jana.madejova@savba.sk)

Near infrared (NIR) spectroscopy belongs to spectroscopic methods with dynamic development and spreading into many areas of science and technology, however, its utilization in the organoclays studies is rather rare [1-4]. Detailed analysis of the NIR spectra of montmorillonite-based organoclays was performed to show the advantages of this spectral region in their characterization and in identification of specific bonds "not visible" in the middle infrared (MIR) region. Na-saturated <2 μm fraction of bentonite from Jelšový Potok (Slovakia) was used for organomontmorillonites preparation. Different alkylammonium cations were selected to allow more ways of comparisons of the spectral features within the series. Four samples contained various amounts of octylammonium chains: monooctyl- (1C8), dioctyl- (2C8), trioctyl- (3C8), and tetraoctyl- (4C8) ammonium, while two others had chains of double length, hexadecyl- (1C16) and dihexadecyldimethyl- (2C16) ammonium. Last two cations were of different structure containing aromatic benzene, either without double bonds benzyltrimethylammonium (C10) or with a reactive double bond present in 4-vinylbenzyl-trimethylammonium (C12).

Similar shape of the MIR patterns of CH_3 and CH_2 stretching (3000-2800 cm^{-1}) and bending (1500-1300 cm^{-1}) vibrations was observed within 1C8-4C8 and 1C16-2C16 series. However, the spectra of the samples with 16 C atoms - 2C8 and 1C16, and 32 C atoms - 4C8 and 2C16, were significantly different due to altered ratios of CH_3 and CH_2 groups in the cations. Only weak bands corresponding to stretching NH_3^+ and NH_2^+ vibrations (~3270-3190 cm^{-1}) were resolved in the MIR spectra of 2C8, 3C8 and 1C16, the NH^+ band was overlapped with the CH and/or H_2O vibrations. Only vibrations of trimethylammonium cations were clearly identified in the MIR spectra of C10 and C12, weak bands near 3100 cm^{-1} should correspond to Ar-CH (Ar = aryl). Vibrational modes of Ar-C-C, or H_2C=C (vinyl) group were overlapped with more intense vibrations of aliphatic CH groups.

Based on the vibrations observed in the MIR region the first overtone ($2\nu_{XH}$) and combination $(\nu+\delta)_{XH}$ bands of XH groups (X = O, C, N) were identified in the NIR spectra of organo-montmorillonites. The complex band near 7070 cm^{-1} was assigned to overlapping $2\nu_{OH}$ of the structural OH groups and bound H_2O molecules, the combination modes of H_2O and structural OH groups were found near 5250 cm^{-1} and 4523 cm^{-1} respectively. The intensity and the position of the $(\nu+\delta)_{H2O}$ band was strongly affected by the type of the organic cation used. While the presence of CH_3 and CH_2 groups in 1C8-4C8 and 1C16-2C16 samples was recognized in the 6000-5500 cm^{-1} ($2\nu_{CH}$) and 4450-4100 cm^{-1} $(\nu+\delta)_{CH}$ regions, the overtone and combination bands of Ar-CH (C10 and C12 sample) were clearly shifted to higher wavenumbers. The NIR spectra were found to be extremely useful to identify NH and vinyl groups, which were difficult to recognize in the MIR region. The intensive bands of the first overtone and combination modes of NH_3^+ and NH_2^+ were found in the 6600-6050 cm^{-1} and 5000-4600 cm^{-1} regions, respectively. Though no NH^+ overtone was observed in the NIR spectrum of 3C8, the intensity of the $(\nu+\delta)_{NH+}$ near 4750 cm^{-1} was high enough to unambiguously identify this bond. The characteristic band assigned to $2\nu_{CH2}$ in H_2C=C at 6130 cm^{-1} was detected in the spectrum of C12.

FTIR and UV-Vis spectroscopic investigation of illite-smectite minerals from Dolná Ves (Slovakia)

Komadel, P.*, Pentrák, M., Czímerová, A. & Madejová, J.
Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia (*peter.komadel@savba.sk)

Information available from the most common spectroscopies, infrared and UV-Vis, on illite-smectite (I-S) mixed layer minerals is discussed. Figure 1 shows the IR spectra of samples containing a montmorillonite (JP, Jelšový Potok, Slovakia), an I-S (DVS, Dolná Ves, Slovakia) and an illite (Mo, Morris, Illinois, USA). XRD analyses prove 30 and 9 % of swelling interlayers, respectively, in I-S and illite [1]. The IR spectra of JP and DVS suggest similar chemical composition with AlMgOH bending vibrations near 845 cm^{-1}. Higher Al^{IV} for Si substitution in illitic layers generates the Al^{IV}-O (~830 cm^{-1}) and Al^{IV}-O-Si (755 cm^{-1}) vibrations.

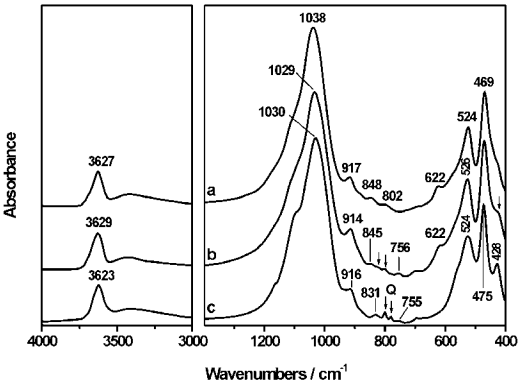

Fig. 1: IR spectra of < 2 μm fractions of a) JP montmorillonite, b) DVS illite-smectite and c) Mo illite; (Q = quartz).

The presence of illitic layers in DVS and Mo modifies the shape of the IR pattern near 620 and 420 cm^{-1}. The well developed band at 622 cm^{-1} in the JP spectrum corresponds to coupled Al^{VI}-O and Si-O vibrations. The intensity of this band is lower for DVS and it is absent from the Mo spectrum. The reverse sequence is found for the Si-O band at 428 cm^{-1}. A well developed band appears for Mo, a shoulder for DVS, and no absorption for JP. A similar dependence was found for a set of DVS samples with different expendability. These IR features may help to differentiate illitic layers in clay samples but not to distinguish between a mixture of individual minerals and an I-S.

Cationic dyes, such as methylene blue or Rhodamine 6G (R6G), form molecular aggregates on clay surface and change their colour. Dye cation agglomeration is a good tool for testing layer charge density on smectites which affects the distance between the dye species. Formation of aggregates results in creation of different forms of the dye, absorbing visible light at different wavelengths. Second-derivative of UV-Vis spectra (SDS) of a series of I-S from DVS deposit with R6G show a direct relationship between the SDS amplitude for the band assigned to the H-aggregates and the expandability. I-S interact with R6G more intensely than do smectites [2].

Structure elucidation of organoclay-polymer composites by instrumental techniques

Horváth, E.[1], Khunová, V.[2], Kristóf, J.[1*] & Makó, É.[3]
[1]Institute of Environmental Engineering, University of Pannonia, Veszprém, Hungary (*kristof@almos.vein.hu)
[2]Dept. of Plastics and Rubber, Faculty of Chemical and Food Technology, The Slovak University of Technology, Bratislava, Slovak Republic
[3]Institute of Materials Engineering, University of Pannonia, Veszprém, Hungary

The industrial application of layer-structured minerals depends on their surface reactivity. In addition to the common applications (e.g. paper, plastics, rubber, pharmaceutical and ceramic industries) they can improve the physical and/or chemical properties of polymers as additives in an amount of 2-5 %. The requested properties can be achieved by the addition of highly dispersed (micro- or nanoscaled) minerals (kaolinite, halloysite and montmorillonite) embedded in the polymer (e.g. polypropylene, polyethylene and polycaprolactone) matrix. The use of reactive modifiers is also necessary to ensure compatibility between the mineral particles and the polymer.

Organoclay nanocomposites can be obtained either by ion exchange (in the case of montmorillonites) or by intercalation (in the case of halloysites and kaolinites in solution or with mechanochemical treatment). Since property improvement is proportional with increased dispersity and reduced particle size of the mineral additive, delamination and the formation of nanotubes is the main goal of this research. The structure of the nanocomplexes formed and that of the clay-polymer composites prepared can be investigated by instrumental techniques such as FTIR (DRIFT) spectroscopy, Raman microscopy, thermal analysis combined with mass spectroscopy, XRD, etc.

Delamination of different kaolinites and halloysites was made by multiple intercalation using urea and triethanol amine. With an electrophilic agent tetraalkyl ammonium cations have been synthetized between the layers reacting with a polyacryl sodium salt added to the system.

Polymer nanocomposites have been prepared by melt mixing in a twin-screw extruder at temperatures of 130 (PCL), 200 (PP) and 250°C (PA).

The addition of 1,3-phenylenedimaleimide (BMI) as reactive modifier further increased the expansion of montmorillonite and improved all of the end-use properties of the polymer. The most significant effect (some 80%) was the improvement in gas permeability. Dissimilarly to montmorillonite-based nanocomposites, no further expansion was observed with 1:1 type minerals with the addition of BMI. In this case improvement in mechanical properties was due to BMI forming an interphase between the clay particles and the polymer matrix.

The effect of dry grinding on the structure of sepiolite from Turkey

Dikmen, S.[1*], Özçelik, H.[1], Yılmaz, G.[2] & Yörükoğulları, E.[1]
[1]Physics Dept., Science Faculty, Anadolu University, Eskisehir, Turkey ([*]sdikmen@anadolu.edu.tr)
[2]Porsuk Vocational School, Anadolu University, Eskisehir, Turkey

The effects of grinding on clay minerals are investigated with great interest because this process produces changes in the textural and structural properties of powdered material.

Sepiolite is a fibrous hydrated magnesium silicate and a natural clay with a unit cell formula $(Si_{12})(Mg_8)(O_{30})(OH)_4(OH)_2 \cdot 8H_2O$ [1]. This mineral is 2:1 layer silicate, which means that the octahedral layer is bound above and below by a silica tetrahedral sheet. The tetrahedral sheets are linked infinitely in two dimensions. It is structurally different from other clay minerals in that the octahedral sheets extend in only one dimension and the tetrahedral sheets are divided into ribbons by a periodic inversion of rows of tetrahedrons [2].

The sepiolite powder sample supplied from Element Mining Co., Eskişehir. The raw mineral was subjected to dry grinding by ball milling, for periods ranging from 0 (smaller than 40 μm) to 120 min, using a planetary ball mill (Fritsch Pulverisette 6).

The physico-chemical and structural alterations are determined by particle size distribution (PSD), specific surface area (BET method), density, porosity, color (L, a, b), X-ray diffraction (XRD), scanning electron microscopy (SEM), FT-IR analyses were carried out. According to the mineralogical and chemical analysis results, the raw mineral can be accepted pure sepiolite ore (Table 1). With grinding, the rate of size reduction decreases with time, but reduction continues up to about 30 min. At this time of grinding, particle size reduction decreases with time, but reduction continues up to about 30 min. Grinding of sepiolite produces an increase of the starting BET surface area value progressively up to a maximum of 364 m^2g^{-1} at 30 min. A subsequent decrease of surface area with increasing grinding time was observed. A breakdown of the initial particles due to grinding effect observed more rounded particles, aggregates and agglomerates, as proved SEM images.

Table 1. Chemical, mineralogical composition and some physical properties sepiolite

AFM study of vermiculite particles

Barabaszová, K.* & Valášková, M.
Nanotechnology Centre, VŠB-TU of Ostrava, Czech Republic
(*karla.barabaszova@vsb.cz)

Atomic force microscopy (AFM) has been evolved as a promising device to explore the mineral surface, determine morphology, visualize the sorption of organic substances, measure size and thickness of clay-size particles and also measure growth, dissolution, heterogenous nucleation and redox processes [1]. AFM is a powerful technique for the characterization of particles with the size ranging from 1 nm to 10 μm and therefore it can be used for exploration of clay minerals [2,3].

Vermiculite small particles were prepared using two milling procedures. Each sample was milled for 15 minutes in jet mill (Sturtevant Micronizer®) parallel with 15 min of milling in planetary ball mill (wolfram carbide mill chamber and balls). Jet milling was realized with the pressure of compressed air (as the grinding energy) 350 kPa and constant feed rate of grinding material (1.5 g/min) to obtain particles of size approximately 2 μm. Both vermiculite powder fractions showed uniform mean particles size of 3 μm, as it was determined using the laser method (Fritsch Particle Sizer Analysette 22). Morphology of vermiculite particles was examined using the scanning electron microscope (SEM).

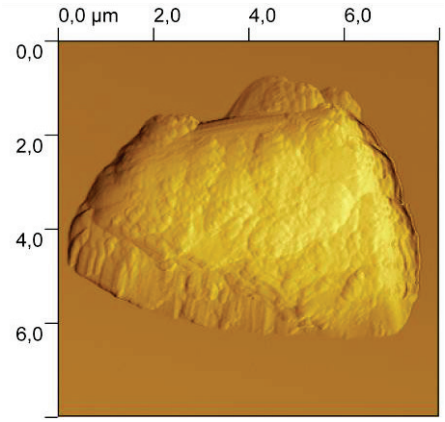

Fig. 1: The 2D AFM image of jet milled vermiculite particle.

In comparison to the traditional technique (SEM), AFM can give 3D and 2D images with Z information through color intensity, providing the opportunity to obtain quantitative measurements of particles using GWYDDION software.

The morphology of the milled vermiculite particles was studied with atomic force microscopy AFM-Explorer™. The suspension of the vermiculite powder in anhydrous ethanol was placed on mica plate and then dried at 60°C for 10 minutes. The AFM scanning was performed with the silicon probe 1650-00 in non-contact mode with 8 μm Z-linearized dry scanner.

The particle size distribution, orientation and the aspect ratio of vermiculite particles after different mechanical disintegration procedures were by the help of AFM with non-contact mode successfully studied.

Gas barrier properties of natural rubber/mechanochemical treatment coal bearing strata kaolinite nanocomposites prepared by melt blending

Frost, R.L.* & Cheng, H.
Chemistry Discipline, Faculty of Science and Technology, Queensland University of Technology, Brisbane, Australia
(*r.frost@qut.edu.au)

Nanocomposites materials are two-phase systems that consist of a polymeric matrix and dispersed inorganic particles of nanometer scale [1]. The use of organic clays as precursors to nanocomposite formation have been extended into various polymer systems including epoxys, polyurethanes, nitrile rubber, styrene-butadiene rubber, isobutylene–isoprene rubber and ethylene propylene diene monomer [2,3]. Kaolinite-rich rocks are very abundant in the Permo-Carboniferous coal-bearing strata of North China and are widely used [4]. Thereafter, coal bearing strata has been applied to incorporate the layered silicates in polymer hosts by in situ polymerization, solution intercalation or simple melt mixing. Recently, much of the work clay application in the rubber has been done to improve the barrier performance of rubbery materials with organic montmorillonite particles [5], and there are relatively few reports on organic kaolinite in this application.

The X-ray diffraction pattern at room temperature indicated that the intercalation of potassium acetate into kaolinite causes an increase of the basal spacing from 0.718 to 1.42 nm, and with the particle size reduction, the surface area increased sharply with the intercalation and exfoliation by ball-milling. the particulates have high aspect ratio according SEM images.

It is also shown coal bearing strata kaolinite layers are finely dispersed into the natural rubber matrix and orientationally arranged in parallel. These highly filled natural rubber/mechanochemical coal bearing strata kaolinite (NR/MCBK) nanocomposites exhibit outstanding mechanical properties, excellent gas barrier properties and much higher thermal stability compared to the pure natural rubber. The significant improvements in the mechanical properties (Table1), thermal stability and gas barrier properties may be attributed to the restriction of the parallel kaolinite platelets to the free movement of rubber molecule chains and the retardation of the impermeable kaolinite layers to the progress of gas molecules through the rubber composites.

Table 1: Mechanical properties of NR composites filled with various MCBK loadings

MCBK content /phr	Hardness (HA)	Stress /MPa		Tensile strength /MPa	Elongation at break /%	Permanent set /%
		300%	500%			
0	37	1.89	5.49	23.2	745	25
70	55	4.35	14.2	25.2	663	68

Thermal analysis of China kaolin –kaolinite, coal-bearing strata kaolinite and halloysite

Frost, R.L.* & Cheng, H.
Chemistry Discipline, Faculty of Science and Technology, Queensland University of Technology, Brisbane, Australia (*r.frost@qut.edu.au)

Kaolinite and its polytype, halloysite have a wide variety of applications in industry [1]. These applications include their use in the fabrication of paper, paints and inks, rubber and plastic, ceramic raw material, medicines, etc. [2-4]. Most of the industrial kaolin in china which generally contain a certain amount of organic carbon need to be calcined to improve whiteness [5]. Thermal stability and whiteness are very important properties of calcined kaolin particularly for industrial applications [6]. Therefore, the thermal analysis of kaolin also gives new insights not only about improvement of the properties but also protection of the environment.

Comparing the temperature of dehydroxyl, it is established that kaolinite with lower Hinckley crystallinity index dehydroxylates easilier than those whoes Hincley index are high. The comparison of kaolinite and hallosite is shown that the thermal decomposition of kaolin is determined by different factors, such as degree of the structural ordering, mineral impurities and adsorbed and substituted ions. The mass gain in the MS curves corresponds precisely with the mass loss in the TG curves.

The thermal decomposition of kaolin occurs in main three main steps (a) desorption of water blow 100 °C, (b) dehydration at about 225°C, (c) well defined dehydroxylation at around 450°C (Fig. 1).

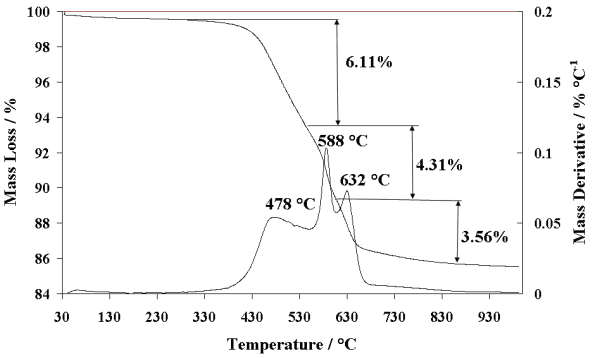

Fig. 1: TG and DTG curves of coal bearing strata kaolinite.

The temperature of dehydroxylation of kaolinite is found to be influenced by the degree of disorder of the kaolinite structure and the gases evolved in the decomposition process can be various because of the different amount and kind of impurities. It is evident by the mass spectra that the interlayer carbonate from impurity of calcite is released as CO_2 around 225, 350 and 710°C in the kaolin samples. TGA-MS show the coal bearing kaolinite released CO_2 about 450°C. Thus for geosequestration decarbonization and purification before industry application of kaolin is necessary.

Characterization of bleaching phenomena in German red bed sediments by directly coupled evolved gas analysis (DEGAS).

Hilse, U.*, Goepel, A., Pudlo, D., Heide, K. & Gaupp, R.
Institute of Earth Sciences, Friedrich-Schiller-University Jena, Germany (*ulrike.hilse@uni-jena.de)

In this study varied coloured Buntsandstein sandstones in Central Germany (Thuringian Vorderrhön) were investigated by a thermo-gravimetric/pyrolytic method (DEGAS – directly coupled evolved gas analysis) to analyse the degassing behaviour of red bed sediments and their bleached modifications. Often such bleaching of primary red bed sandstones is contributed to fluid-rock interactions. Therefore the investigations were focused on geochemical/mineralogical features of such sediments to validate the causes of such bleaching processes. The pyrolytic experiments were performed using a commercial, slightly modified NETZSCH TG-MS system (thermobalance coupled directly to quadrupole mass spectro meter). All gaseous species were analysed in multiple ion detection mode and correlated with the total pressure change in the sample chamber during heating (temperature range: from room temperature (22°C) to 1200°C and 1450°C, respectively) [1]. The ion current for different mass/charge ratios (e.g. m/z 18, 44 & 78, Tab. 1) was recorded as a function of time. Depending on the amount of volatiles in the sample about 10 mg of sample material were used. The samples were taken from core plugs and carefully prepared without using cooling additives to avoid any contamination.

Table 1: Detected element species during MS analysis

Mass number	Fragment ions	Geogene source
1	H^+	sheet silicates,
2	H_2^+, D^+	hydroxides,
17	OH^+, NH_3^+	hydrates
18	H_2O^+	& organic material
28	N_2^+, $C_2H_4^+$, CO^+	carbonates
44	CO_2^+, $C_3H_8^+$, N_2O^+	& organic material
78	$C_6H_6^+$	organic material

Degassing patterns of sample M44 indicate a preferential breakdown of sheet silicates, hydroxides, hydrates and carbonates [2]. Its two red subsamples M44-R1 and -R2 are dominated by the release of H_2O and CO_2, whereas in the two bleached subsamples M44-B1 and -B2 an additionally H^+ source without any correlation with m/z 17 and 18 occurred, probably due to the presence of hydrocarbon species. Another Buntsandstein sample M49 was separated into 12 subsamples representing a profile from unbleached to bleached rock portions. The increase of m/z 44 in subsamples M49-1, -3 and -9 are attributed to small carbonate domains in the sample. A prominent signal of m/z 78 in the transition zone between bleached and unbleached areas implies the presence of a further hydrocarbon species.

The performed mass spectrometric gas analysis sustain geochemical differences in red and bleached sandstone rock composition, sometimes only weakly maintained by conventional geochemical methods (XRF, ICP). The results constrain that DEGAS might serve as an efficient and complementary analytical tool in sedimentary research in evaluating the involvement of specific gaseous species during fluid-rock processes.

X-Ray Diffraction and lithologico-mineralogical studying of Kazakhstan clay minerals

Kudaikulova, G.A.* & Aitugulova, B.A.
Geology Prospecting Inst., Kazakh National Technical University, Almaty, Kazakhstan (*kgulzhanabd@mail.ru)

Among all existing methods of studying the mineral structure of clay minerals, the X-Ray method is the most authentic. More over, the X-Ray method can state a quantitative estimation whereas other methods are qualitative. From X-Ray methods it is most effective diffractometrical.

In the present work, roentgenograms of clay minerals have been obtained on X-Ray Diffraction type DRON – 3 with CuK_α – radiation, monochromatized by graphite monochroma-tor installed in the front of the counter. Interpretation of diffractograms has been carried out with the help of the ASTM Powder diffraction card file datas and diffractograms purefied from impurities of minerals. The Kazakhstan samples of clays Taukentsky, Akkalkinsky (2 samples) and Akzharsky deposits have been investigated.

Results of X-ray and also lithologico – mineralogical analyses have shown that Taukentsky clay concerns clays of hydromicas-mont-morillonite group with prevalence of montmorillonite component of alkaline-earth calcium–magnesian form. In the investigated sample crystallites of blended-layer formations are formed which decrease exchange capacity of a clay. Estimated content of a hydromicaceous component is 10–15 % and montmorillonite component – 60 – 65 %. The total content of a clay component is approximately 80 %.

An assay of Akkalkinsky clay (the sample № 1) consists of 79.4 % of pelite fractions (<0.01 mm); 15.8 % of aleurite fractions (0.01–0.1 mm); 4.8 % of sandy fraction (> 0,1мм). The sample № 2 of Akkalkinsky clay consists of 91. 0 % pelite fractions, 8.8 % aleurite fractions and 0.2 % – sandy. By the prevalence of montmorillonite clay (both samples) concerns to bentonite type.

By the results of the mineralogical analysis Akzharsky clay concerns to adjournment bottom Eocene and is combined bentonite clays of is light – grey to dark – grey colour, fat, high-plastic, as soap with the raised maintenances montmorillonite. On the figure diffractogram of Akzharsky clay is shown.

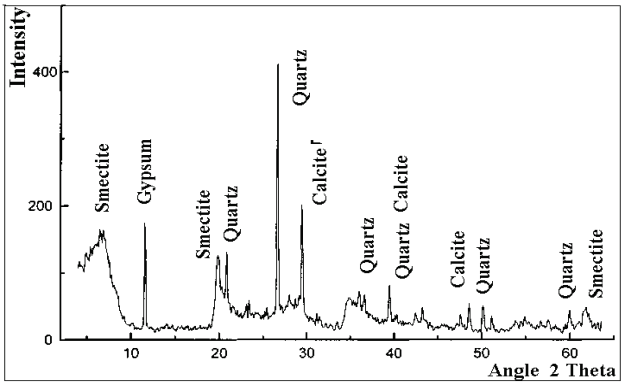

Fig. 1: Diffractogram of Akzharsky clay.

Thus, X-Ray diffraction and lithologo-mineralogical studying of clay minerals of the Kazakhstan deposits has allowed to draw a conclusion that montmorillonite component of the studied minerals allow successfully use them as raw materials for preparation drilling muds in geology-prospecting and oil-gas industries.

Study of dispersions and thin films based on montmorillonite and fluorescent dyes

Matejdes, M.[1*]& Janek, M.[1,2]
[1]Dept. of Physical and Theoretical Chemistry, Faculty of Natural Sciences, Comenius University, Bratislava, Slovak Republic (*matejdes@fns.uniba.sk)
[2]Institute of Technology, Slovak Academy of Sciences, Bratislava, Slovak Republic

Preparation of novel organic-inorganic nanocomposites reflects their significant potential for its possible utilization as novel materials e.g. shown in the recent years in combinations with polymers and semiconducting polymers [1] with electroluminiscent properties. These nanocomposites are forward-looking not only for improved mechanical properties, but in the case of luminiscent materials, they could also provide broadening of spectral field compared with conventional semiconductors. Properties of these nanocomposites are dependent not only on the properties of individual components, but also on their morphological properties, the character of the phase interface, charge characteristics of clay lamellas, etc.

In our study we are trying to shed more light on the preparation conditions of the fluorescent dyes based nanocomposites, while the functional skeleton is based on the organized structure of the sodium montmorillonite particles. The sense of its preparation rests on the fact that this material may be used as narrow frequency response on the exciting radiation, polarisation component in optical devices, or as a part of the solar panels or devices, where the energy transfer with high effectiveness is necessary.

In most studies related to the nanocomposite materials preparation based on clay minerals with negative layer charge and organic cation molecules, the production of the aggregates of organic molecules [2] occurs on the surface of clay mineral. The disadvantage of the production of the aggregates is that their optical and other properties are different from the properties of their monomer form. In the report related to this issue, we assume that the arised problem can be solved by additing the appropriate spacer (β-cyclodextrin), which is able to interact with one organic molecule for purpose of the supramolecular complex formation. The outcome is that we suppose the prevention of the molecular aggregates creation.

Preparation of nano-spherical smectite particles by hybrid atomization

Minagawa, K.[1*], Yamada, H.[1], Tamura, K.[1], Morimoto, K.[1] & Watanabe, Y.[2]
[1]National Institute for Materials Science, Tsukuba, Japan (MINAGAWA.Kazumi@nims.go.jp)
[2]Kanazawa Institute of Technology, Hakusan, Japan

Nano-particles of smectites have various applications related to catalysis, catalytic support, adsorption and development of new functional nanomaterials. We present a novel process called hybrid atomization in the production of nano-spherical particles of smectites. Hybrid atomization is new technique that combines gas atomization with centrifugal atomization [1,2]. Such process has been successfully applied in the production of fine, spherical metal powders at lower costs. The average sizes of the powders are 20 μm in diameter with a homogenous size distribution.

In its use for molten metals, the melt is broken into several tens to several hundreds μm droplets by gas atomization and subsequently sprayed on a high speed rotating disk. A thin film of liquid less than 10μm is formed on the disk and the fine droplets are scattered from the edge of the disk. For the case of aqueous suspensions and organic solvents, the atomization modes can be used to control a homogenous size distribution and a desired shape for nano-particles of smectites. The products were characterized by XRD, SEM and TEM. The results will be compared further with those from conventional methods such as spin-coating and spray-dry methods.

These results confirmed that the nano-spherical particles with narrow size distribution from smectites were formed following the same atomization mode, that is, ligament formation in the case of the aqueous solutions and organic solvent. A new process, hybrid atomization method, would effectively produce the inorganic nano-spherical particle for any chemical compositional system.

Short Wavelength InfraRed petrology: a new laboratory and remote sensing method in low to very low-grade pelites

Potel, S.[1*], Doublier, M.P.[2] & Roache, T.[3]
[1]Dépt. Géosciences, Institut Polytechnique LaSalle Beauvais, Beauvais, France ([*]sebastien.potel@lasalle-beauvais.fr)
[2]Geological Survey of Western Australia, Kalgoorlie, Australia
[3]CSIRO, Earth Science and Resource Engineering Perth, Australia

Since Kübler (1967) [1], X-ray diffraction has become a standard method to characterize the metamorphic grade of metapelites metamorphosed under very low- and low temperature conditions. This method is based on the full width measurement of the first illite/muscovite peak at middle height (FWHM).

The few attempts that have been made to quantitatively apply spectroscopy methods to K-white mica in the field of very low-grade petrology focused on the infrared wavelength area ('Flehmig index' [2]) and have gained little application [3].

The new illite spectral maturity (ISM) method uses Short Wavelength InfraRed Reflectance spectroscopy (SWIR) to measure K-white mica mineral physicochemistry within very low grade metamorphic pelites. The three ISM measures used in this study parameterize the absorption features at 1900 nm and 2200 nm in terms of their area, depth and asymmetry. Through comparison with the powder XRD-derived Kübler index it is demonstrated that ISM allows the differentiation of anchizonal from diagenetic domains in very low-grade pelites (Fig. 1).

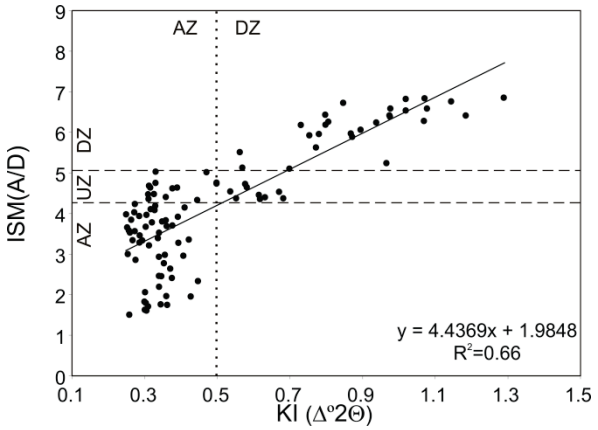

Fig. 1: Correlation between KI (in Δ°2Θ) and ISM measures determined by SWIR. The black dotted line corresponds to the anchizone/diagenetic zone boundary after Kisch et al. (2004), and the stippled lines define the 'unassignable zone' (UZ) for the ISM measures based on that boundary. AZ – anchizone; DZ – diagenetic zone.

The wavelength of the 2200 nm absorption feature provides a measure of the celadonite substitution. It shows a linear correlation (R^2=0.85) with K-white mica *b* cell dimension (powder XRD), and can be used to differentiate the metamorphic pressure facies and related geothermal gradients in pelites of greenschist facies and anchizonal metamorphic grade. The boundaries between LP/MP and MP/HP facies series can be defined at 2204 and 2220 nm, respectively.

Magnesium sulfate trihydrate: an elusive mineral on Earth and Mars?

Fortes, A.D.[1,2*], Lemée-Cailleau, M.-H.[3], Knight, K.S.[4,5] & Jura, M.[4]
[1]Centre for Planetary Sciences at UCL/Birkbeck, London, UK
([*]andrew.fortes@ucl.ac.uk)

[3]Institut Laue-Langevin, Grenoble, France
[4]ISIS Facility, STFC Rutherford Appleton Laboratory, Harwell Science and Innovation Campus, Chilton, Didcot, Oxfordshire, UK
[5]The Natural History Museum, London, UK

Magnesium sulfate trihydrate was, hitherto, one of the last $MgSO_4$ hydrates with an unknown structure. Amongst the $M^{2+}SO_4$ hydrates, only two other trihydrates are known, the mineral bonattite ($CuSO_4{\cdot}3H_2O$) and $CrSO_4{\cdot}3H_2O$, which are isostructural in space-group Cc. We have grown large (order 1 mm^3) single crystals, with a flat bladed morphology [forms {100}, {010}, {102}], which are comparatively stable in air at room temperature for periods of at least several days. Our synthesis method suggests to us that $MgSO_4$-trihydrate may be formed commonly in low-T hydrothermal systems, but will transform over time to pseudomorphs composed of hexahydrite ($MgSO_4{\cdot}6H_2O$) and/or epsomite ($MgSO_4{\cdot}7H_2O$). However, on Mars, the hydration process may be inhibited by the low atmospheric water abundance and the low temperatures.

We report the crystal structure of $MgSO_4{\cdot}3D_2O$, determined from neutron single-crystal diffraction measurements made using the VIVALDI diffractometer at the Institut Laue Langevin, and X-ray single-crystal measurements. We also report complementary measurements of the thermal expansion of $MgSO_4{\cdot}3D_2O$ powder in the range $8 < T < 295$ K made using the High Resolution Powder Diffractometer (HRPD) at the ISIS neutron spallation source, as well as C_p and TGA data. $MgSO_4{\cdot}3D_2O$ undergoes a first-order phase transition at 245 K from the high-T Pbca structure to a low-T monoclinic structure ($P2_1/c$ after permutation of the axes into a standard monoclinic setting); the transition is apparently caused by orientational ordering of the disordered hydrogen bonds in the structure. Unit-cell dimensions are a = 8.1925(2) Å, b = 10.9210(2) Å, c = 12.3866(4) Å at 295 K, and a = 12.3616(5) Å, b = 8.1414(3) Å, c = 10.8324(2) Å, β = 91.131(3)° at 8 K.

The axial thermal expansion is highly anisotropic, being largest along the b-axis (the direction perpendicular to the plane of the h-bonded sheets in the structure) and smallest along the c-axis. The volume thermal expansion at room temperature is comparable to that of hexahydrite, and much larger than that of epsomite, suggesting that $MgSO_4$-trihydrate may exert large (i.e., damaging) pore pressures in natural or manmade materials wherever hot aqueous fluids are able to precipitate.

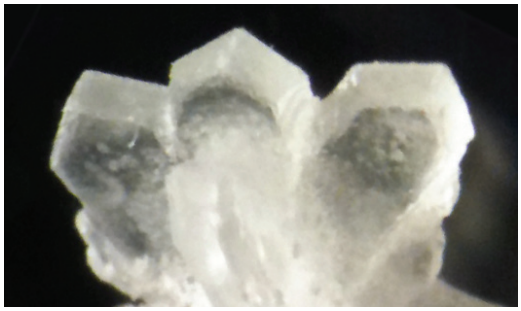

Fig. 1: Synthetic $MgSO_4{\cdot}3D_2O$ typically forms small clusters of blades (each shown here is ~ 1mm across the 010 face). These may occur in nature as hexahydrite or epsomite pseudomorphs.

Structure, thermodynamics and redox flexibility of Fe^{II-III} oxyhydroxycarbonate green rust homologous to fougerite mineral in gleysols as monitored by Mössbauer spectroscopy

Génin, J.-M.R.[1*], Morin, G.[2], Ona-Nguema, G.[2] & Ruby, C.[1]
[1]Institut Jean Barriol, CNRS-Université Henri Poincaré, Vandoeuvre-lès-Nancy, France
([*]jean-marie-genin@esstin.uhp-nancy.fr)
[2]Institut de Minéralogie et de Physique des Milieux Condensés Université Paris 6 et 7, Paris, France

Speciation of iron was monitored by Mössbauer spectroscopy during corrosion of iron. Intermediate compounds belonging to the layered double hydroxide family have been observed, where cations were Fe^{II} and Fe^{III}. Commonly called green rusts, many GRs have been synthesized and their structure determined by XRD and Mössbauer spectroscopy revealing long range order for Fe and anions, e.g. Cl^-, SO_4^{2-}, CO_3^{2-}, $HCOO^-$, $C_2O_4^{2-}$, SeO_4^{2-}.

GRs get usually oxidized by dissolving before precipitating into several types of orange ferric oxyhydroxides FeOOH rusts, such as ferrihydrite, lepidocrocite, goethite or even akaganeite depending upon the dissolved anion species and pH of aqueous solution. But, *in situ* oxidation may also occur by deprotonation of OH^- ions within the GR without any structural change as shown by Mössbauer spectroscopy, XRD and TEM. For CO_3^{2-} ions, $[Fe^{II}_4Fe^{III}_2(OH)_{12}]^{2+} \bullet [CO_3^{2-} \bullet 3H_2O]^{2-}$, the Fe^{II-III} hydroxy-carbonate GR(CO_3^{2-}), becomes Fe^{II-III} oxyhydroxycarbonate GR*(x), $[Fe^{II}_{6(1-x)}Fe^{III}_{6x}O_{12}H_{2(7-3x)}]^{2+} \bullet [CO_3^{2-} \bullet 3H_2O]^{2-}$ where ferric molar ratio $x = [Fe^{III}/Fe_{total}]$ belongs to the [0, 1] interval. It ends into ferric green rust, $[Fe^{III}_6O_{12}H_8]^{2+} \bullet [CO_3^{2-} \bullet 3H_2O]^{2-}$, GR($CO_3^{2-}$)*, which is in fact orange. Mössbauer spectra of GR and GR*(x) display a continuous change *in situ* when x varies as prepared by adding a controlled amount of H_2O_2 to the initial GR precipitate.

The major interest of this type of oxidation process concerns an outstanding redox flexibility of GR(CO_3^{2-})* which is the chemical compound equivalent to the "fougerite" mineral (IMA 2003-057) found in waterlogged areas [1] and responsible for the bluish-green color of gley sols This identification was confirmed by XRD patterns of samples found in ground water at Bornholm and Äspo where d_{003} distances in $R\bar{3}m$ space group structure were measured at 7.594 and 7.605 Å [2] in excellent agreement with those of synthetic samples (Table 1).

Table 1: Interplanar distances d_{hkl} and cell parameters of $R\bar{3}m$ space group GR*(x) computed from XRD data versus $x = [Fe^{III}/Fe_{total}]$

x	0.33	0.50	0.67	0.83	1
d_{003} (Å)	7.632	7.569	7.565	7.54	~ 7.34
d_{012} (Å)	2.679	2.669	2.672	-	-
c (Å)	22.896	22.707	22.695		
a (Å)	3.182	3.169	3.173		

Detailed structure of GR*(x) was obtained from XRD patterns and Mössbauer results that led to magnetic ordering based on the structure of GR(CO_3^{2-}). Occurrences of fougerite mineral are limited for values of x in the [0.33, 0.67] interval. *E*-pH diagram of GR(x)* is drawn from chemical potential data with parallel lines for reduction: $GR^*(x)+dx\ H^+ + dx\ e^- \rightarrow GR^*(x)$.

Simulation of GR(CO_3^{2-})* formation by bacterial reduction of ferric oxyhydroxides explained the existence of fougerite in anoxic zones of groundwater [3]. Then, evidences showing the reduction of pollutants such as nitrates by GR(CO_3^{2-})* and consequently fougerite will be presented. A friendly process for water purification simulating natural conditions is developed.

Crystallographic orientation relationship between SFCA and hematite

Monkawa, A.[1*], Mikouchi, T.[2] & Sugiyama, K.[3]
[1]Tokyo Metropolitan Industrial Technology Research Institute, Tokio, Japan ([*]monkawa.akira@iri-tokyo.jp)
[2]Dept. of Earth and Planetary Science, Graduate School of Science, University of Tokyo, Japan
[3]Inst. for Materials Research, Tohoku University, Sendai, Japan

The quality of iron ore sinter has effects on blast furnace performance. It is well known that the iron ore with higher amount of alumina decreases the strength of sinter. The main phases of the sinter are hematite, magnetite, silica-ferrite of calcium and aluminum (SFCA) and silicates. SFCA is the most voluminously produced mineral in fluxed iron-ore sintering and has long been regarded as an important bounding phase industrial sinters. The strength of sinter is closely related to the boundary structure between SFCA and other minerals. The SFCA is iso-structural with aenigmatite-rhönite group [1]. Rhönite, which belongs to aenigmatite-rhönite group, was found among natural amphibole reaction rim together with ilmenite, Ti-augite, and olivine. Fig 1 shows SEM image for the amphibole reaction rim. It must be helped very much to understand the boundary structure between SFCA and other minerals if the crystallographic orientation relationship between rhönite and other minerals can be clarified. Electron backscatter diffraction (EBSD) pattern (Kikuchi diffraction pattern) analysis is used to provide crystallographic and phase information on micro sized crystalline materials with little or no difficult sample preparation [2]. In this study, the crystallographic orientation relationship between rhönite and other minerals was clarified by EBSD analysis. EBSD analysis shows that all rhönite minerals in the reaction rim possess the same crystallographic orientation. The crystal structure of rhönite is well demonstrated by an alternating stacking of the tetrahedral and octahedral layers. The octahedral layer of rhönite is parallel with that of pyroxene based on the crystallographic analysis of EBSD pattern. This result suggest that the crystallographic orientation relationship exists between SFCA and the mineral having octahedral layers. The hematite in iron ore sinter is composed of gibbsite-type octahedral layers stacked six-high normal to the c-axis. Therefore, it can be assumed that the crystallographic orientation relationship exists between SFCA and hematite in the same manner as the relationship between rhönite and pyroxene. The crystallographic orientation relationship was investigated in sinter samples prepared by a solid state reaction technique. The sinter sample mainly contains un-reacted hematite nuclei in a matrix consisting of SFCA. This study adopted EBSD analysis to clarify the crystallographic orientation relationship between hematite nuclei and SFCA.

What really determines coordination numbers in mineral structures - can a two-radius model for atoms help?

Christy, A.G.
Research School of Earth Sciences, Australian National University, Canberra, Australia ([*]andrew.christy@anu.edu.au)

Compatibility of trace element in minerals, as well as the extent of solid solution of major components and the activity models appropriate for describing thermodynamics of mixing, are all determined by the preferences of specific cations for specific coordination environments. The majority of textbooks still rationalise coordination behaviour in terms of radius ratios of "billiard ball" ions, despite the fact that this model gives wrong predictions more than 50% of the time for even simple classes of chemical compound such as the alkali halides. Much more success in understanding and predicting structures and their stability has been achieved over the last 30 years through a combination of the bond valence model for bond length-bond strength relationships (cf. [1] and references therein) and a Lewis acid/base strength model generating preferred bond valences between specific species, which has demonstrated considerable ability to explain the polymerisation, stoichiometry and water content of hydrated oxysalt minerals [2].

The Lewis acid/base strength paradigm, with species showing innate preference for a particular range of bond valences, can be understood as a consequence of nonlinear bond valence-bond energy relationships. However, it is likely that this is a strong controlling factor on bond valence and coordination number in only a few cases. In general, Madelung energies show that it is energetically feasible to maximise coordination number in so far as this is not counteracted by crowding of ligands. Hence, the major determinant of coordination number is actually a ratio of distances, but these are not "ionic radii"; they are the centre-ligand bonded distance and the ligand-ligand nonbonded distance. A model is proposed for predicting coordination numbers, and hence broad structure types, using these two distance parameters. Observed distances are consistent with the idea that to a first approximation, atoms in a structure have a "bonded radius" and a "nonbonded radius" which are approximately additive, subject to corrections for bond valence, and maybe bond polarity and topology. The concept of a well-defined non-bonded radius is not new [3] but has seen little exploration since its introduction.

Consideration of nearest-neighbour bonded and next-nearest neighbour nonbonded distances around both cations and anions rationalises observed structure types far better than other approaches, and can distinguish between stability fields of some topologically different structures with the same coordination numbers. The effects of pressure and temperature on coordination number depend on the relative sensitivity of these lengths to the state variables. For instance, the usually assumed increase in coordination with pressure arises since the nonbonded polyhedra edges are more compressible than the bonded centre-ligand distances. Scenarios can be predicted where the converse would be true.

Optimization of site occupancies in mineral structure analysis: a call for user input

Wright, S.E.[1*], Hughes, J.M.[2] & Foley, J.A.[1]
[1]Miami University, Oxford, USA ([*]wrightse@muohio.edu)
[2]University of Vermont, Burlington, USA

The crystal structure analysis of minerals is unique because of the multiple components that occupy sites in minerals. Mineralogists face unique challenges in analyzing the atomic arrangement of natural phases: substituents must be assigned to particular sites to best fit the observed site scattering, site bond valence, bond lengths and chemical analysis. However, the assignments are rarely made with mathematical rigor.

Wright et al. [1] proffered a quadratic programming methodology to optimize the occupants of each site on the basis of site scattering, chemical analysis, and bond-valence sums, with an additional option for bond lengths. The methodology was implemented as a program, *OCCQP*, in the *MATLAB* numerical computing environment. *OCCQP* has proven very effective in assigning occupants to various crystallographic sites and provides crystallographers with a mathematically robust starting point for the determination of site occupancies.

However, use of *OCCQP* has not been as widespread as anticipated or desired, reportedly because of the inertia of using the *MATLAB* environment, which is not widely used in mineralogy, and because of the lack of seamless creation of input files. We thus are preparing to make the optimization method compatible and seamless with the most commonly used refinement program, and independent of the *MATLAB* computing environment. We seek input from mineral structure analysts for their desired attributes of input and output. Examples of the power of the optimization method will be given.

Structural and electronic transformations in transition-metal sesquioxides and sesquisulfides at high pressures and temperatures

Prewitt, C.T.
Dept. of Geosciences, University of Arizona, Tucson, Arizona, USA (prewitt@email.arizona.edu)

When studied as a group of related structures, the sesquioxides and sesquisulfides present many different crystal-chemical features that are of interest to mineralogy and mineral physics. Although most of these phases are not considered to be major constituents of Earth's mantle, knowing their high-pressure behavior is important for understanding overall mantle character and, in particular, its oxidation state. In addition, recent developments in x-ray emission spectroscopy that provide a powerful new tool in detecting spin crossover in iron-containing materials at high pressure have created wide interest in phase transitions in Fe-containing sesquioxides. Also, there is much to be learned from high-pressure experiments on other compositions having a range of different structures under varying conditions, i.e., Al_2O_3, Sc_2O_3, Ti_2O_3, V_2O_3, Cr_2O_3, Mn_2O_3, Fe_2O_3, Co_2O_3, Ga_2O_3, In_2O_3, Tl_2O_3 and Rh_2O_3.

Sesquisulfides have become of interest recently because the structure of U_2S_3 is proposed to be closely-related to that of a possible post-postperovskite structure of Al_2O_3 [1]. Sleight and Prewitt [2] explored the crystal chemistry of rare-earth sesquisulfides a number of years ago and this work is being reviewed here to explore other possible analogies with phase transitions in sesquioxides at high pressures.

Full analysis of feldspar texture and crystal structure by combined X-ray and electron techniques

Balic-Zunic, T.[1*], Piazolo, S.[2], Katerinopoulou, A.[1] & Schmith, J.H.[1]
[1]Natural History Museum, University of Copenhagen, Denmark ([*]tonci@geo.ku.dk)
[2]Dept. of Geology and Geochemistry, Stockholm University, Stockholm, Sweden

Feldspar crystals typically show a range of exsolution and polysynthetic twinning textures which can present problems for their full characterization, but at the same time give important information about the history of geological processes. Recent improvements in the instrumentation and calculation procedures in diffraction methods allow a full and direct characterization of finely intergrown feldspars. An integrated procedure was applied to the analysis of perthitic intergrowths in large pegmatite feldspar grains from the Larvik plutonic complex in the southern part of the Oslo region, Norway. X-ray powder diffraction was used for a preliminary identification of the mineral components and determination of their crystal lattice parameters. Electron Microprobe analysis was used to bracket the chemical compositions of the constituents. Electron Back-Scatter Diffraction was used to reveal the textural characteristics of the samples and spatial distribution and crystallographic orientation of the homogeneous crystal domains. Single-grain X-ray diffraction recorded by an area detector was applied for a simultaneous integration of reflection intensities for all orientationally different constituents. Based on this, their crystal structures were simultaneously refined using the program JANA2006. Finally, a Rietveld refinement of the powder diffraction data based on the determined crystal structure parameters was applied for the quantitative determination of phase proportions in perthites and the calculation of the chemical composition of the equivalent high-temperature homogeneous alkaline feldspar. The results show that the samples from two different pegmatites have similar global compositions, but different cooling histories, with closing temperatures differing by about 200K.

The combination of methods presented here is widely applicable in mineralogy. Its advantage is in the mutual support which makes each analysis simpler and more accurate, providing in the end reliable and full information of complex mineral intergrowths.

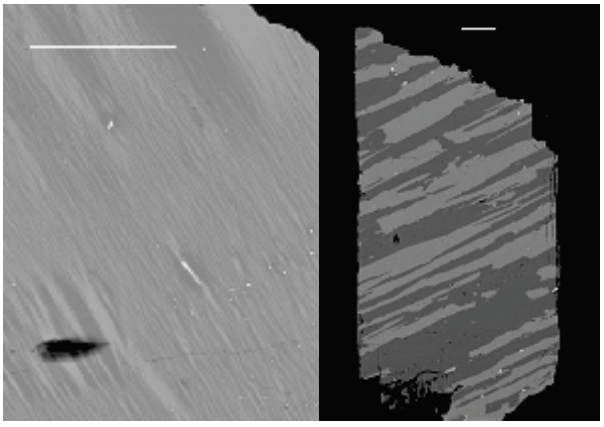

Fig. 1: Back-scatter electron images of the two investigated samples. Lighter regions belong to K-feldspar, darker to Na-feldspar. Horizontal bars in each case correspond to 100 μm.

Principles of feldspar thermal expansion

Hovis, G.[*], Medford, A., Conlon, M., Romanoski, A. & Tether, A.
Dept. of Geology and Environmental Geosciences, Lafayette College, Easton, PA, USA ([*]hovisguy@lafayette.edu)

Following the recent thermal expansion work of Hovis et al. [1] on $AlSi_3$ feldspars, we have investigated the thermal expansion of plagioclase, Ba-K, and Ca-K feldspar crystalline solutions [2]. X-ray powder diffraction data were collected between room temperature and 925°C on six natural plagioclase specimens ranging in composition from anorthite to oligoclase (and as well on their K-exchanged equivalents) and five synthetic Ba-K feldspars with compositions from 25 to 99 mol% $BaAl_2Si_2O_8$. The resulting thermal expansion coefficients for volume (α_V) have been combined with earlier results for end-member Na- and K-feldspars. Unlike $AlSi_3$ feldspars, Al_2Si_2 feldspars, including anorthite and celsian from the present study plus Sr- and Pb-feldspar from other workers [3,4], show essentially constant, and relatively limited, thermal expansion. In the context of structures where the Lowenstein rule requires Al and Si to alternate among tetrahedra, the proximity of bridging Al-O-Si oxygen atoms to divalent neighbours (ranging from 0 to 2) results in Ca-O (or Ba-O) bonds that are especially short. It is suggested that short bonds such as these have a partly covalent character resulting from the requirement for local charge balance. This in turn stiffens the structure. For feldspar series with coupled substitution, the change away from a purely divalent M-site occupant gives the substituting (less strongly bonded) monovalent cations increasingly greater influence on thermal expansion. Overall, thermal expansion in the feldspar system is well represented on a plot (Fig. 1) of α_V against room-temperature volume (V_{RT}), where one sees a quadrilateral bounded by data for (a) $AlSi_3$ feldspars whose expansion behaviour is governed largely by the size of the monovalent alkali-site occupant, (b) Al_2Si_2 feldspars whose expansion is uniformly limited by divalent cations having stronger, partially-covalent, bonds to bridging Al-O-Si oxygens, and (c,d) plagioclase and Ba-K feldspars where expansion behaviour across the series transitions from one control to the other. Overall, the coefficient of thermal expansion in any binary feldspar series is a linear function of V_{RT} between the pertinent end members. This makes it possible to predict the thermal expansion behaviour of any feldspar simply from knowledge of its chemical system and room-temperature volume.

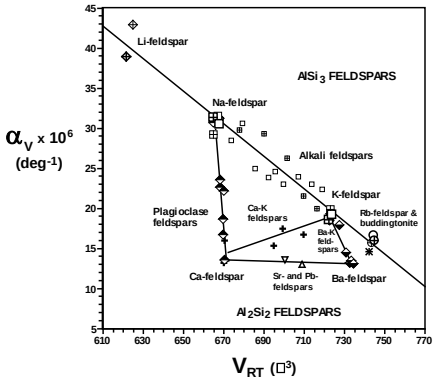

Fig. 1: Coefficient of thermal expansion (α_V) plotted against room-temperature unit-cell volume (V_{RT}) for members of the feldspar system.

Ardennite, tiragalloite and medaite: structural control of (As^{5+}, V^{5+}, Si^{4+})O_4 tetrahedra in silicates

Nagashima, M.[1,2*] & Armbruster, T.[1]
[1]Mineralogical Crystallography, Institute of Geological Sciences, University of Bern, Switzerland
[2]Dept. of Earth Science, Graduate School of Science and Engineering, Yamaguchi University, Yamaguchi, Japan
([*]piemontite@gmail.com)

Several silicate-minerals have (V^{5+}, As^{5+}, P^{5+})O_4-tetrahedra, such as ardennite ($Mn^{2+}{}_4MgAl_5[Si_5(As^{5+}, V^{5+})O_{22}](OH)_6$, Z = 2), tiragalloite ($Mn^{2+}{}_4[Si_3As^{5+}O_{12}(OH)]$, Z = 4), and medaite ($Mn^{2+}{}_6[Si_5(V^{5+}, As^{5+})O_{18}(OH)]$, Z = 4). Using electron-microprobe analysis (EMPA) and single-crystal X-ray diffraction methods, the crystal chemistry of ardennite (Salam-Château, Belgium and the Vernetto mine, Italy), tiragalloite (Gambatesa mine, Italy), and medaite (the Molinello mine, Italy and the Fianel mine, Switzerland), were studied.

Structure refinements converged to R_1 values of 2.10-5.67 %. According to chemical analysis, Σ(As + V + P) content increases with decreasing Si content. Thus, Si replaces pentavalent cations in tetrahedral coordination. The (As^{5+}, V^{5+}, P^{5+}, Si^{4+})O_4-tetrahedra are categorized by their connections to SiO_4 tetrahedra. The (As^{5+}, V^{5+}, P^{5+}, Si^{4+})O_4-tetrahedron of ardennite is isolated (0-bridging) and those of tiragalloite and medaite terminate a tetrahedral chain (1-bridging) (Fig. 1)

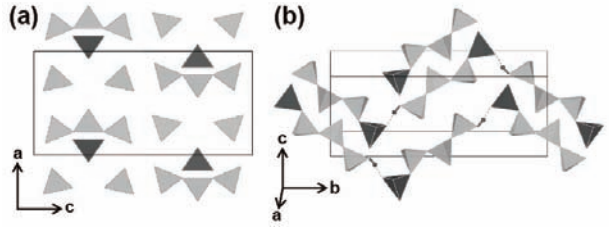

Fig. 1: Topology of tetrahedra in ardennite (a) and tiragalloite (b). (As, V)O_4-tetrahedra are represented as dark gray.

<T-O> of the isolated (As, V, P, Si)O_4-tetrahedron shows a positive correlation versus mean ionic-radius (Fig. 2). For (As, V, P, Si)O_4-tetrahedra with one T-O-T link, <T-O> and mean ionic-radius are also correlated. In addition, the longest bridging T-O bond occurs between (As, V, P, Si)O_4 and the adjacent SiO_4-tetrahedron. The bridging O atom is over-bonded to satisfy the charge requirement of Σ(As + V + Si).

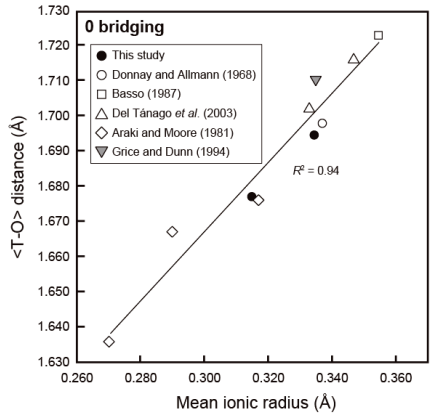

Fig. 2: Variation of <T–O> distances for 0-bridging (As^{5+}, V^{5+}, P^{5+}, Si^{4+})O_4-tetrahedra (Å).

Boron occupation of aluminium site in spinel- and olivine-related structures under high-pressure

Yoshiasa, A.[1*], Sakai, S.[2], Sugiyama, K.[2], Okube, M.[3], Wang, L.[1] & Nakatsuka, A.[4]

[4]Dept. of Advanced Materials Science and Engineering, Yamaguchi University, Ube, Japan

It is important to know pressure effect on solubility of boron in materials as solid solutions and crystal chemical behaviour of boron in the Earth's interior. Boron is the same group element as Al and its ionic radius is considerably small. The phase equilibrium and boron occupation of Al-site in spinel- and olivine-related structures in the Mg-Al-B-O system has been studied under high-pressure and high-temperature. Crystals of spinel- and olivine-related structure were synthesized under pressure of ~15 GPa at 1900 K using large volume multi-anvil-type apparatus. To determine the site occupancy of Mg, Al and B in crystal phases, the structure refinements of single-crystal diffraction method were carried out using a laboratory diffractometer with a imaging plate detector and using a four-circle diffractometer with synchrotron radiation at Photon Factory, Japan.

The olivine-type $MgAlBO_4$ sinhalite transforms to pseudosinhalite at 8.2 GPa and 1900 K. Pseudosinhalite is stable even at 12.0 GPa 1900 K. $MgAl_2O_4$ spinel decomposed to MgO and Al_2O_3 under the pressure of 14.5 GPa at 1273 K. Detailed structure of sinhalite and pseudosinhalite determined under pressure and temperature. B^{3+} ion can not occupy the octahedral Al site and it occupies only tetrahedral B site in sinhalite and pseudosinhalite. The B-Al substitution could not detect even at high pressure and high temperature. Site preferences of ions in olivine-type $MgAlBO_4$ sinhalite and pseudo-sinhalite obey the Pauling's first principle. $MgAl_2O_4$ spinel would prefer inverse spinel, if we considered Pauling's first principle. On the other hands, it is well known that $MgAl_2O_4$ spinel has a normal spinel and a peculiar site preference with higher symmetry, i.e. the octahedral sites are preferred by smaller Al ion than larger Mg ion.

The $MgAl_2O_4$ spinel can solve the much amount of boron. The maximum content of boron in $MgAl_{2-x}B_xO_4$ ($0<x<1$) spinel was about x=0.13 at 1273K and 11GPa. The small B ions do not occupy the small tetrahedral site and interstitial sites, but it occupies largely the octahedral site in $MgAl_2O_4$ spinel crystal [1]. We have estimated the cation distribution of each site from the reproduction of the observed average distance using the observed local bond distances for Mg-O and Al-O [2] and the normal B-O distance. The chemical formula of B-bearing spinel is estimated such as $(Mg_{0.50},Al_{0.50})[Al_{1.37},Mg_{0.50},B_{0.13}]O_4$. These spinel solid-solutions are largely disordered crystals and the inversion parameter grow up to 0.5 in the tetrahedral site. The site preference of boron depends greatly on the structure of host crystal. More ever, the smallest B^{3+} ion gives priority to the octahedral Al site most in Mg-Al-B spinel structure. The B^{3+} ions can replace considerably bigger Al^{3+} ion under pressure.

Crystal chemistry and the nomenclature of chromium-bearing tourmalines

Vereshchagin, O.S.*, Rozhdestvenskaya, I.V. Frank-Kamenetskaya, O.V. & Zolotarev, A.A.
Saint-Petersburg State University, Saint-Petersburg, Russia
(*oleg-vereschagin@yandex.ru)

Some aspects of crystal chemistry and nomenclature of chromium-bearing tourmalines on the basis of the original and published crystal structural refinements (Table 1) are considered.

All examined tourmalines were found in ultramafic and basic rocks. They belong to oksydravite - chromdravite series. The degree of the order of the Cr^{3+} cation distribution between Y and Z octahedral sites is distinguished.

Table 1: Characteristic of examined samples

Sub-group	Cr_2O_3 (wt. %)	Site population (apfu)		Deposit	Ref.
		Y	Z		
Order	1.48-5.90	0.19	0	Silver Knob, California, USA	[1]
		0.75	0	Middle Ural, Russia	Our data
		0.54 - 0.75	0	Middle Ural, Russia	
Dis-order	9,8-35.6	1.17	0.12	Outokumpu, Finland*	[2]
		1.29	0.89	Nausahi, India	[3]
		1.74 - 2.30	0.97 - 2.20	Sludyanka, Russia	[4]
		1.80	3.35	Onegsky progib, Centralnaya Kareliya, Russia	Our data
		1.56	3.60		[5]

Note: Cr^{+3} distribution was determined from the unit cell parameters and element composition [6].

Order subgroup. Cr^{3+}-ions occupy the Y-site. The compensating for an arising charge disbalance occurs according to the scheme: $^{Y}Cr^{3+}+^{W}O^{2-}\rightarrow{}^{Y}Mg^{2+}+^{W}OH^{-}$. Simultaneously the redistribution of Mg^{2+} and Al^{3+} ions begins: $^{Y}Mg^{2+}+^{Z}Al^{3+}\rightarrow{}^{Z}Mg^{2+}+^{Y}Al^{3+}$. The difference between <Y-O> and <Z-O> decreases from 0.116 (dravite [7]) to 0.065 Å (Cr-dravite); between the cation charge in Z and Y sites - from 0.9 to 0.4 ē, accordingly.

Disorder subgroup. Chrome ions occupy the Y and Z-sites. The incorporation of Cr^{3+} ions in Z- octahedra begins in the interval of 5.90-9.80 of Cr_2O_3 (wt. %). As a result of the $^{Z}Cr^{3+}\rightarrow{}^{Z}Al^{3+}$ substitution the <Z-O> bond distance increase; the difference between the <Y-O> and <Z-O> and the cation charges in Y and Z site decrease. In Al-free chromdravite from Kareliya with statistical distribution Cr^{3+} ions over octahedral sites this difference is 0.013 Å only. The cation charge Y site is more then Z site for 0.02 ē. Approved earlier the formula of chromdravite [8] demands revision. We suggest the ideal formula of this species $Na(Cr_2Mg)(Cr_4Mg_2)(BO_3)_3(Si_6O_{18})(OH)_4$. The increase of Cr^{3+} - ion content in tourmaline structure results in commensuraty of Y and Z octahedra.

The relationships of bulk structure, surface structure, chemistry, and physical properties of mineral phases with six- and eight-membered silicate rings

Elmi, C.[1*], Brigatti, M.F.[1], Pasquali, L.[2,3], Montecchi, M.[2,3], Nannarone, S.[2,3], Laurora, A.[1] & Malferrari, D.[1]
[1]Dipto. di Scienze della Terra, Università di Modena e Reggio Emilia, Modena, Italy (*chiara.elmi@unimore.it)
[2]Dipto. di Ingegneria dei Materiali e dell'Ambiente, Università di Modena e Reggio Emilia, Modena, Italy
[3]TASC INFM-CNR Area Science Park, Basovizza (TS), Italy

The goal of this research is to better understand the relationship between chemical composition and atomic structure (both bulk and surface structure) of minerals having six-membered silicate rings, such as osumilite and eight-membered silicate rings, such as vesuvianite. Osumilite under investigation occurs in thin fissures within a rhyolite from the volcanic massif of Mt. Arci, Sardinia (Italy). Vesuvianite sample is from skarns of Somma-Vesuvius volcano (Italy) instead.

The osumilite and vesuvianite bulk structures were refined via single crystal X-ray diffraction. Osumilite sample is hexagonal, with symmetry *P*6/*mcc* and unit cell parameters a = 10.1550(6) c = 14.306(1) (Å). The structural formula is $(K_{0.729})_C(Na_{0.029})_{B'}(Si_{10.498}\ Al_{1.502})_{T1}(Al_{2.706}\ Fe^{2+}_{0.219}\ Mg_{0.075})_{T2}(Mg_{0.660}\ Mn_{0.091}\ Fe^{2+}_{1.258})_A O_{30}$. When compared to literature data [1], osumilite sample from Mt. Arci is characterized by a significantly high Fe^{2+} content (1.478 apfu) [2].

X-ray photoelectron spectroscopy (XPS) enabled the crystal chemical characterization of osumilite surface, where iron was still observed in its divalent state, thus confirming a similarity in osumilite surface and bulk chemical composition [2]. A further evidence of Fe oxidation state at osumilite surface is provided from X-ray absorption spectroscopy (XAS) at Fe-$L_{2,3}$ edge.

Vesuvianite is a complex tetragonal silicate. Vesuvianite ideal formula is $Ca_{19}(Al,Mg)_{13}(B, Si)_{18}O_{68}(OH, O, F)_{10}$ and crystallizes, generally, in the space group *P*4/*nnc* [3]. Vesuvianite presents in nature two different structural type: a high temperature type (at about 1000°C) and a low temperature type (at about 900°C) [3]. To recognize which type of vesuvianite our sample belongs to, we studied its thermal decomposition via X-ray powder diffraction method by using a Philips X'Pert PRO diffractometer equipped with X'Celerator area detector. Finally we could assure that our sample is a high temperature vesuvianite with high symmetry *P*4/*nnc*.

Unlike osumilite, vesuvianite surface is very complex to study because of its roughness on given faces of the crystal. However we could obtain preliminary information on the chemical composition of the surface via XPS and subsequently compare these data to bulk chemical composition. Moreover, unlike osumilite sample, vesuvianite presents Fe in octahedral site both in divalent and trivalent state, as confirmed by XAS experiments performed at the $L_{2,3}$ edge of iron [2,4].

Crystallochemical aspects of potassium-calcium silicates

Arroyabe, E.* & Kahlenberg, V.
Institute of Mineralogy and Petrography, University of Innsbruck, Austria (*Erik.Arroyabe@uibk.ac.at)

Although the phase relationships among main group element silicates are of fundamental importance for geosciences and materials engineering, it is a simple matter of fact that in a large number of binary and ternary systems there are still many fundamental problems to be solved. In this respect, the system K_2O-CaO-SiO_2 can serve as an excellent example. To be precise, the only comprehensive study, focussing on the more SiO_2-rich part of the system dates back to 1930 [1]. The authors explored the melting relations and reported the existence of seven different potassium calcium silicates. Only few more subsequent surveys dealt with the phases of the system. All these investigations were restricted to the presentation of basic crystallographic data. This general lack in structural knowledge is surprising since the ternary system is of definite interest for several technologically seminal processes that are related to applied mineralogy including, for example, production of inorganic membrane filters, adsorbents or concrete additives.

The presented results are part of an ongoing investigation on compound formation, sub-solidus equilibria and crystal chemistry of the ternary phases in the system K_2O-CaO-SiO_2. Before its start, there has been only one detailed structural consideration of a potassium calcium silicate [2]. In the meantime several "white spots" on the crystal structure map could be charted. The aim of this contribution is to give a systematic outline of the achieved findings and to discuss them on the basis of crystallochemical considerations.

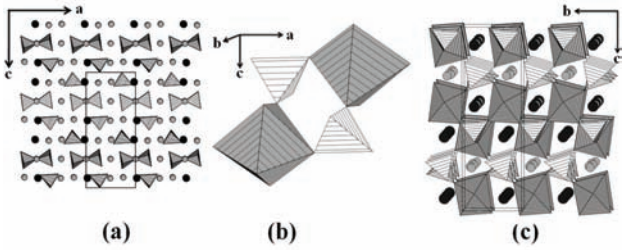

Fig. 1: Possible considerations of $K_2Ca_6Si_4O_{15}$ [3]: the compound can be described solely as **(a)** a mixed anion silicate, built of $[SiO_4]$ as well as $[Si_2O_7]$-units or as **(c)** a mixed polyhedral framework with Kroehnkite-type basic building chains **(b)**.

Outstanding structural complexity of layered Pb oxyhalides induced by the presence of stereochemically active lone-electron pairs

Siidra, O.I.* & Krivovichev, S.V.
Dept. of Crystallography, Saint-Petersburg State University, Saint-Petersburg, Russia (*siidra@mail.ru)

In the course of our ongoing research in Pb(Il) oxyhalide structural chemistry [1], new layered lead oxyhalides have been prepared by different technique [2]. The crystal structures of synthetic compounds and minerals [3] were solved by direct methods. In all studied layered Pb(II) oxyhalides with so-called "additional" O atoms, lone electron pairs on the Pb^{2+} cations are stereochemical active. All of the studied crystal structures are based upon OPb_4 oxocentered tetrahedra.

Natural and synthetic layered lead oxyhalides are important phases that occur under variety of natural and technological conditions. They were found as secondary minerals in oxidation zones of mineral deposits: kombatite, sahlinite, parkinsonite, symesite, blixite, schwartzembergite etc.

All known layers of OPb_4 tetrahedra can be derived from the [OPb] tetrahedral layer that has been observed in the structure of litharge, PbO. To transform the [OPb] layer into any layer type observed in OPb_4 inorganic compounds and minerals, one has to excise certain blocks of OPb_4 tetrahedra from the former. Lead oxychlorides with layered PbO-derived blocks have first been described as synthetic compounds by Aurivillius [4]. Structural investigations revealed that the structures of these phases consist of PbO-like blocks [3] alternating with tetragonal sheets of halide ions. Recently investigated crystal structure of mereheadite $Pb_{47}O_{24}(OH)_{13}Cl_{25}(BO_3)_2(CO_3)$ [3] is another example of layered lead oxyhalides consisting of PbO blocks. Generally, there are three basic mechanisms associated with transition of the crystal structure from idealized version (ideal PbO blocks alternating with tetragonal sheets of halogen atoms): 1.replacement of PbO_4 groups by coordination groups of highly-charged cations, 2.$O^{2-} \leftrightarrow OH^-$ substitution, 3. insertion of additional Pb^{2+} cations into the halogen sheet.

A method of square lattices for the description of topologies of PbO-derivative layered structures is proposed [5]. The method is based upon reconstruction of an abstract model of 2D layer with black and white squares symbolizing tetrahedral positions and vacancies respectively.

Lead-gold inclusions together with gold and platinum traces within olivine: evidences from a TEM-AEM study

Ferraris, C.* & Lorand, J.P.
Laboratoire de Minéralogie et Cosmochimie, Muséum National d'Histoire Naturelle and CNRS (UMR 7202) Paris, France
(*ferraris@mnhn.fr)

Precious metals commonly form their own, discrete phases in mantle-derived rocks [1]. Although of sub-micrometric size, these phases may account for a non-trivial percentage of the whole-rock budget for gold. How do these gold micro-phases occur is not fully understood. Transmission and Analytical Electron Microscopy (TEM-AEM) analyses show the presence of sparse inclusions of a both a lead-gold intermetallic compound and evidences of gold traces within the plastic deformation microstructure of olivine crystals matrix from a lherzolite (Lherz massif - Eastern French Pyrenees). Otherwise, SEM investigation of the polished thin section of this lherzolite revealed one tiny native gold inclusion, 1 micrometer across, inside a serpentinized grain boundary.

The lead-gold phase appears as isolated platy crystals few hundred nano meters in length. Crystals appear generally irregularly shaped and less commonly as rectangular flat inclusions. AEM analyses clearly show that, besides signals coming from the surrounding olivine matrix, the inclusions are precipitates of Pb and Au in about 2:1 ratio. Selected Area Electron Diffraction (SAED) attempts on the biggest crystals indicated that very likely the Pb-Au intermetallic compound has crystallographic characteristic identifying it as possible anyuiite (Tetragonal, s.g. *I4*/*mcm*, a = 7.338 Å, c = 5.658).

More difficult, and at the moment without any specific evidence, is the almost constant presence of the Au chemical signal in AEM analyses from apparently pure olivine matrix. The signal is not homogeneously distributed excluding any kind of instrumental artefacts; the Au amount is within the range of 0.1 up to 0.5 wt%. SAED investigations give no evidences about the presence of nano inclusions and/or precipitates or exsolutions of a gold phase. In correspondence of volumes where the gold signal is stronger, low magnification TEM images show the presence of randomly distributed rectangular shaped areas about 100 nm long and 20 nm width. These areas are characterized by an extremely ordered alternation of dark and bright bands about 5 nm widths. TEM high resolution images show that in correspondence of such band alternations the olivine crystal structure is affected by extremely regular waved deformation, but again no evidences of Au are referable.

In our opinion, the coincidence of high Au signal within olivine showing the described deformation, are strong evidences about the presence of gold precipitates within the olivine plastic deformation microstructures. In which form and/or geometry the gold is present is not yet clear. Hopefully, ongoing investigations using high angular annular dark field (HAADF) detectors will allow discover of such isolated gold clusters within the olivine structure as it was the case for Ir-bearing rutile exsolutions within a Cr-rich spinel from a harzburgite from the same Pyrenean peridotite occurrence [2].

X-ray and neutron Rietveld study of synthetic $Ca_2Al_{3-p}Mn^{3+}{}_pSi_3O_{12}(OD)$-piemontite

Akasaka, M.[1*], Nagashima, M.[2], Hamada, M.[1], Sano, A.[3] & Ejima, T.[1]
[1]Dept. of Geoscience, Shimane University, Matsue, Japan
([*]akasaka@riko.shimane-u.ac.jp)
[2]Dept. of Geosphere Sciences, Yamaguchi University, Yamaguchi, Japan
[3]Japan Atomic Energy Agency, Japan

Crystal structures of synthetic $Ca_2Al_{3-p}Mn^{3+}{}_pSi_3O_{12}(OD)$-piemontites were refined using X-ray and neutron powder diffraction method for the determination of hydrogen positions in epidote structure. The starting materials (s.m.s) of oxide mixture of stoichiometric compositions with p = 0.75, 1.0 and 1.1 and D_2O were used for hydrothermal synthesis experiments at 0.3-0.4 GPa and 500 ˚C. The products from s.m.s of p = 0.75 (0.3 GPa), 1.0 (0.3 GPa), 1.1 (0.3 GPa) and 1.1 (0.4 GPa) were piemontite (Pm) + anorthite + bixbyite (Bx), Pm + Bx + parawollastonite (Pwo) (Pm>>Bx,Pwo), Pm, and Pm + Bx + Wo (Pm>>Bx,Pwo), respectively. Average Al:Fe-ratio of piemontite synthesized from the p = 1.1 s.m. at 0.4 GPa was 2.12:0.83 (EPMA data), indicating decrease of Mn contents by crystallization of bixbyite.

The crystal structures of piemontite synthesized from p = 1.0 and 1.1 s.m.s at pressures of 0.3 and 0.4 GPa, respectively, and temperature of 500 ˚C, were refined using X-ray powder diffraction data, and the structure of the former was also refined using a neutron powder diffraction data. The X-ray and neutron diffraction data were obtained using an X-ray powder diffractometer with Cu$K\alpha$-radiation and JRR3-HRPD, respectively. The crystal structures were refined using RIETAN-FP program [1].

The R-factors for X-ray powder diffraction data of the piemontite from p = 1.0 s.m. were R_{wp} = 9.75, R_e = 6.01, and S = 1.62; the unit-cell parameters were given as a 8.8455(5), b 5.6676(2), c 10.1483(7) Å, and β 115.499(4)°; the site occupancies at M1 and M3 were refined as Al0.86Mn0.14(1) and Al0.55Mn0.45(1), respectively; thus, total Mn was 0.59 atoms per formula unit (apfu). The results of the refinements of the piemontite from p = 1.1 s.m. were R_{wp} = 10.66, R_e = 5.23, and S = 2.03; a 8.9154(7), b 5.7063(3), c 10.2285(9) Å, and β 115.543(5)°; the site occupancies at M1 and M3 of Al0.88Mn0.12(1) and Al0.30Mn0.70(1), respectively; total Mn was 0.82 atoms per formula unit (apfu) which is consistent with EPMA data. The refined unit-cell parameters, site occupancies and atomic positions are consistent with those after [2]. The structure refinement of the piemontite from p = 1.0 starting material using the neutron diffraction data resulted in the unit-cell parameters of a 8.854(2), b 5.6751(4), c 10.159(2) Å, and β 115.54(1)°, where the site occupancies at M1 and M3 were fixed to those refined using X-ray diffraction data. The O10-D distance derived from the refined positions of O10 and D without any constraint is 0.31 Å is considerably shorter than the published values.

Scheelite- and molybdenite-bearing andradite skarn from Mraconia Valley, Romania

Anason, A.[*], Marincea, Ş., Ghineţ, C. & Iancu, A.
Geological Institute of Romania, Bucharest, Romania
([*]angela.anason@yahoo.com)

This contribution aims to provide new X-ray powder and scanning electron microscopy data on the main minerals from the skarn in the upper basin of Mraconia Valley, Almăj Mountains, Romania, as well as on the associated mineralization. The skarn develops at the very contact between crystalline limestones of the Neamţu Series and a porphyric granodiorite of unknown age, probably Triassic.

The skarn is mainly andraditic, but, beside andradite, plagioclase, potassic feldspar, feroactinolite, magnetite, epidote, apatite, vesuvianite and wollastonite can occur in significant proportions. Four stages of mineralization overprint the primary skarn: (1) a first stage, of high temperature, consists in the deposition of scheelite as impregnations in the mass of the andradite-bearing skarn; (2) a new hydrothermal stage overprints the first event, conducing to deposition of pyrite, chalcopyrite and calcite on the cracks and to impregnations of pyrite and chalcopyrite in the skarn mass; (3) a third hydrothermal stage conduced to massive deposits of chalcopyrite, pyrite, sphalerite, galena, scarce pyrrhotite and tertahedrite, which forms veins and lenses in the skarn mass; (4) a low temperature hydrothermal stage yields the formation of bornite and covellite on chalcopyrite but also of hematite (specularite) on magnetite.

Andradite is the main skarn mineral, accounting for up to 80% of the rock volume. The mineral is generally isotropic, but optically anomalous garnet can occur; both sectorial and lamellar "twinning" was described by Marincea [1]. The X-ray powder data recorded for six representative samples were used for the least-squares refinement of the unit-cell parameters. The obtained values [a = 12.006(4) Å – 12.066(3) Å] compare well with the values reported by [1] *i.e.* a = 11.984(3) Å – 12.041(3) Å, being indicative for andradite.

Scheelite is the mean exponent of the high-temperature hydrothermal phase, occurring as isolated crystals or clusters of crystals, generally included in the andradite mass. The individual crystals are up to 2 mm in length and up to 1 mm thick, and have a prismatic-bipiramidal, tetragonal habit. All the samples fluoresce in short wave UV light (λ = 254 nm). As observed by Marincea [1] the UV response colour is characteristic for two different generations of scheelite, as follows: (1) a first generation, with yellow fluorescence, characteristic for a Mo-bearing scheelite, associates only with andradite, and (2) a second generation, that fluoresces in blue-violet tints, contains minor powellite and associates with sulphides, pistacite, quartz and calcite. The cell parameters obtained as mean of those obtained for 4 scheelite samples, as refined by least-squares analysis of the X-ray powder data, are: a = 5.242(3) Å, c = 11.370(7) Å and V = 312.5(4) Å^3.

Molybdenite is widespread in the association from Mraconia. The mineral occurs on fissures affecting the granodiorite mass, near the contact, where it associates with quartz, pyrite and chalcopyrite, and as impregnations in the andradite-bearing skarn. Individual crystals, up to 1 mm across, have lamellar hexagonal habit and generally form sheave-like, rosette-like or scaly aggregates. The unit-cell parameters, obtained by least-squares refinement of the X-ray powder datasets obtained for eight representative samples are a = 3.151(6) Å, c = 12.292(9) Å and V = 105.7(2) Å^3.

Chabournéite from Monte Arsiccio mine (Apuan Alps, Tuscany, Italy): occurrence and crystal structure

Bonaccorsi, E.[1*], Biagioni, C.[1], Moëlo, Y.[2] & Orlandi, P.[1]
[1]Dipto. di Scienze della Terra, Università di Pisa, Italy
([*]elena@dst.unipi.it)
[2]Institut des Matériaux Jean Rouxel (IMN), Université de Nantes, France

Chabournéite is a very rare Tl-Pb-Sb sulfosalt found only in the hydrothermal deposit of Jas Roux (Hautes-Alpes, France) [1], at the Toya-Takarada mine (Okkaido, Japan) [2], and as an unnamed mineral at Hemlo gold mine [3]. The crystal structure of a Pb-rich chabournéite was determined by [4]. The As-rich isotype of chabournéite, dalnegroite, was discovered recently [5]. The new finding of chabournéite at the baryte-pyrite-iron oxides deposit of Monte Arsiccio allowed a new crystallographic study. At this locality, chabournéite is associated with baryte, pyrite, realgar, sphalerite, stibnite, and zinkenite.

Electron microprobe analyses collected on two different grains give (wt.%): Tl 16.81(27), Pb 10.65(17), Sb 41.75(17), As 6.59(4), S 23.43(11), total 99.24(36) and Tl 15.05(26), Pb 13.04(32), Sb 45.49(29), As 3.07(4), S 22.77(14), total 99.42(39). On the basis of Σ*Me* = 26 *apfu*, the formula of the chabournéite grains are $Tl_{3.79}Pb_{2.37}Sb_{15.79}As_{4.05}S_{33.65}$ and $Tl_{3.47}Pb_{2.97}Sb_{17.63}As_{1.93}S_{33.50}$, in agreement with the structural formula $Tl_{5-x}Pb_{2x}(Sb,As)_{21-x}S_{34}$. Crystal structure determination shows that this chabournéite is triclinic, space group *P*–1, with unit cell parameters *a* 8.150(2), *b* 8.716(2), *c* 21.579(4) Å, α 85.18(1)°, β 96.94(1)°, γ 88.60(1)°, *V* = 1515(1) Å^3. Due to the very small crystal size, intensity data were collected at the XRD beamline of the Elettra synchrotron facility (Basovizza, Trieste, Italy). The crystal structure was solved by direct methods and refined to $R = 0.048$ for all 3392 reflections with $F_o > 4\sigma(F_o)$.

The new crystal structure solution confirms the general features given by [4], but on the basis of a simpler, more symmetric unit cell, without any visible superstructure. While in [4] all cation positions correspond to pure sites (Tl, Pb, Sb or As), the new structure presents mixed (Tl,Pb), (Pb,Sb) and (Sb,As) sites, together with pure Tl, Pb and Sb sites. According to [6], it is built up on the basis of two kinds of layer. The first one, derived from the SnS archetype, is closely related to sartorite [7] and parapierrotite [8], and is here enriched with As, while the second one, of the PbS archetype, is As-poor. Weak bonding in the middle plane of this last layer may act as a cleavage plane.

The high Sb/As ratio of chabournéite from Monte Arsiccio appears as the main factor precluding the 2*a* superstructure visible in As-rich chabournéite from Jas Roux as well as in dalnegroite.

Occurrence of a new oxy-hydroxy iron(III) sulphate from Fornovolasco (Apuan Alps, Italy)

Bonaccorsi, E.[*], Biagioni, C. & Orlandi, P.
Dipto. di Scienze della Terra, Università di Pisa, Italy
([*]elena@dst.unipi.it)

A new oxy-hydroxy iron(III) sulphate from the small magnetite-pyrite ore body at Fornovolasco (Apuan Alps, Tuscany, Italy) was identified. The origin of this mineral is related to the action of strongly acid solutions derived from the alteration of pyrite in the old tunnels of Fornovolasco mines. It is strictly associated with other sulphates, like alum-(K), copiapite, halotrichite, melanterite, römerite, and voltaite. The new mineral occurs as bladed crystals, elongated on [010], up to 50 μm long and less than 5 μm across.

XRPD showed that this mineral is the natural analogous of the synthetic compound $Fe_4(SO_4)(OH)_{10}$. This new sulphate is monoclinic, with cell parameters *a* 16.085(2), *b* 3.054(1), *c* 10.929(2) Å, β 93.78(1)°, space group *C*2/*m*. Electron microprobe analyses give Fe_2O_3 63.33, SO_3 14.07, H_2O 17.18, sum 94.58. The sum of the wt% of oxides is low even after the addition of the calculated water content. This may be a consequence of the very small crystal size, which have a thickness of less than 5 μm.

Owing to the very small size, intensity data were collected at the XRD beamline of the Elettra synchrotron facility (Basovizza, Trieste, Italy). The crystal structure was solved and refined to $R = 0.078$ for all 259 reflections with $F_o > 4\sigma(F_o)$. Figure 1 shows the crystal structure of this oxy-hydroxy iron(III) sulphate.

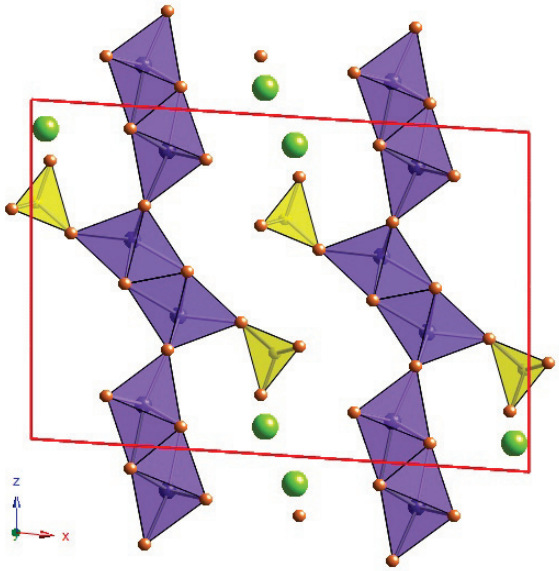

Fig. 1: crystal structure of the new mineral seen along [010].

The crystal structure is composed by ribbons of edge-sharing Fe-octahedra running along [010], linked together by corner-sharing to form wavy layers. As it is not possible to locate two $[SO_4]$ groups at distance of only 3 Å, it is probable that a regular alternation of $[SO_4]$ groups and H_2O molecules takes place along the **b** direction. Such ordered sequence should double the *b* parameter, with the occurrence of additional superstructure reflections. Actually, only continuous streaks were detected in the diffraction patterns.

According to the structural refinement and the bond-valence balance, the chemical formula of this new oxy-hydroxy iron(III) sulphate is $Fe^{3+}_4(SO_4)O_2(OH)_6{\cdot}2H_2O$.

Li-bearing pegmatites from Conţu, Romania

Călin, N.[*], Dumitraş, D.G. & Marincea, Ş.
Geological Institute of Romania, Bucharest, Romania
([*]nicolae_cln@yahoo.com)

Pegmatites from Conţu are hosted by micaschists and gneisses related to the Sebeş-Lotru Series (Southern Carpathians, Romania) [1]. Their mineralogical composition closely matches to that of the granitic Li-bearing pegmatites. The mineral composition is largely dominated by K-feldspar, spodumene, quartz, plagioclase, Li-bearing muscovite, but the accessory minerals include phosphates in the triphylite - lithiophilite heterosite – purpurite, and sicklerite – ferrisicklerite series, fluorapatite, cassiterite, tantalite, magnocolumbite, scarce schorl, beryl, uraninite, topaz and spessartine.

Spodumene is the main Li-bearing mineral, accounting for up to 20 % from the pegmatite volume. It occurs as large crystals of up to 20 cm in length, randomly distributed in the pegmatite mass and generally surrounded by feldspar and quartz. The color is greenish-white, which turns in bluish-green due to the alteration into kaolinite + cookeite. The cell parameters averaged for 17 spodumene samples, as refined by least-squares analysis of the X-ray powder data, are: a = 9.476(13) Å, b = 8.403(7) Å, c = 5.227(5) Å, β = 110.12(12)°, V = 390.8(7) Å^3.

Phosphates in the triphylite - lithiophilite series ($LiFePO_4$ - $LiMnPO_4$) generally occur as nests in the spodumene and feldspar mass. They form granular masses of greenish-gray color that turns locally into dark brown or black, due to the weathering. The mean unit-cell parameters, obtained as average of those refined by least-squares from the X-ray powder datasets obtained for two representative samples are: a = 4.713(7) Å, b = 10.378(3) Å and c = 6.043(6) Å.

Feldspar is the second phase as abundance in the pegmatites from Conţu, accounting for up to 25 % of the rock volume. Both primary and metasomatic phases were identified; chemical analysis and XRD revealed the presence of albite (cleavelandite), anorthite, oligoclase and microcline.

Muscovite is widespread in the pegmatite mass. Two types of muscovite could be distinguished: (1) a greenish Li-richer muscovite associated with spodumene, albite and quartz, resulted as secondary product of the rock metasomatism; and (2) a yellowish white Li-poor muscovite associated with quartz and K feldspar probably of primary origin. The cell parameters averaged for 23 muscovite samples, as refined by least-squares from the X-ray powder data, are a = 5.17(3) Å, b = 9.02(4) Å, c = 20.06(8) Å, β = 95,0(5)°, V = 931.6(48) Å^3.

Phosphates in the purpurite – heterosite series ($MnPO_4$ - $FePO_4$) occur as reddish-brown crusts, generally disposed on triphylite - lithiophilite. The unit-cell parameters taken as mean of those refined for four representative samples are: a = 5.83(2) Å, b = 9.77(3) Å, c = 4.776(5) Å.

Fluorapatite occurs as prismatic hexagonal crystals of up to 5 mm across and 8 mm in length, of white-greenish color. The unit cell parameters, determined as mean of 6 sets of individual values refined by least squares on the basis of X-ray powder data are a = 9.366(2) Å, c = 6.8833(7) Å and V = 522.81(2) Å^3. The Fourier-transform infrared spectrum recorded for a selected sample shows the presence of the OH and F stretching at 3570 cm^{-1}, of the OH libration at 634 cm^{-1} and of bands attributable to the PO_4 stretching motions (ν_3 antisymmetric stretching at 1033 cm^{-1}, ν_1 symmetric stretching at 971 cm^{-1}).

In situ high-temperature powder X-ray diffraction study of the synthetic $Ca_2Sb_2O_7$ weberite-type compound

Chelazzi, L.[1*], Boffa Ballaran, T.[2], Bindi, L.[3] & Bonazzi, P.[1]
[1]Dipto di Scienze della Terra, Università degli Studi di Firenze, Italy ([*]laura.chelazzi@unifi.it)
[2]Bayerisches Geoinstitut, Universität Bayreuth, Germany
[3]Museo di Storia Naturale, Università di Firenze, Italy

An *in situ* high-temperature powder X-ray diffraction study has been carried out from room temperature up to 1000°C on a sample of $Ca_2Sb_2O_7$ synthesised by direct reaction of the component oxides in a platinum crucible. The $Ca_2Sb_2O_7$ compound adopts an orthorhombic weberite structure (space group *Imma*) when synthesised under ambient pressure conditions, whereas the cubic pyrochlore structure is favoured with pressure higher than 6 GPa [1]. Most of the natural and synthetic $A_2B_2O_7$ oxides ($A=M^{2+}$; $B=M^{5+}$) adopt a zirconolite-polytype (commonly pyrochlore-like) or a weberite-polytype structure, depending on the kind of cations (ionic radius, electronegativity, etc.), as well as the pressure and/or temperature of crystallization. Therefore, investigation of their thermodynamics properties (e.g. thermal expansion and compressibility) is crucial in determining their stability fields.

In the range of temperature investigated in this study, the unit-cell parameters show a gradual increase with the increase of temperature and no phase transition has been observed. The bulk thermal expansion coefficient is $\alpha_V = 27.0 \times 10^{-6}$ K^{-1} and the cofficients of thermal expansion along various axes are: $\alpha_a = 9.52 \times 10^{-6}$ K^{-1}, $\alpha_b = 10.2 \times 10^{-6}$ K^{-1}, $\alpha_c = 7.51 \times 10^{-6}$ K^{-1}, showing an anisotropic behavior with increasing temperature.

The structure of the $Ca_2Sb_2O_7$ can be described as a sequence of pairs of polyhedral layers (*M* and *N*) stacked along [011]. As far as the cation sites are concerned, *M* and *N* layers have general formula AB_3 and A_3B respectively, where B are octahedral sites (B1 and B2) which accommodate Sb^{5+}. The octahedral framework gives rise to two types of larger cavities (A1 and A2) hosting Ca. With increasing temperature, the structure expands along the directions parallel to the layers more markedly than along the stacking axis, where the A1-O2 bonds are aligned. Indeed, being O2 oxygen the most underbonded of the structure, the A1-O2 bonds act as a constraint to the expansion in their direction. Due to the large uncertainties of the structural data, it is difficutl to constrain accurately the evolution of the polyhedral volumes with *T*. As general feature, the increase of temperature favours a regularization of the structure similar to that for the synthetic $Ca_2Os_2O_7$ [2].

Crystal chemistry of a new CaMnMn-dominant member of the whiteite group

Chernyatieva, A.P.[1*], Krivovichev, S.V.[1], Yakovenchuk, V.N.[2] & Pakhomovsky, Y.A.[2]
[1]Dept of Crystallography, St.Petersburg State University, St. Petersburg, Russia (*nastya250@mail.ru)
[2]Geological Institute, Kola Science Center, Russian Academy of Sciences, Apatity, Russia

According to Moore and Ito [1], minerals of the whiteite group have the general formula $XM(1)M(2)_2M(3)_2(PO_4)_4(OH)_2\ 8H_2O$, where M(3) = Fe^{+3} for the jahnsite series, and Al^{3+} for the whiteite series. During investigations of secondary pegmatite phosphates from Hagendorf, we have located a whiteite-group mineral with X =Ca, M(1) = Mn, and M(2) = Mn. This composition has not been observed in the whiteite series so far. The X-ray diffraction data were collected using both STOE IPDS II and Bruker Smart APEX II diffractometers. Crystal structure determination indicated that the mineral is monoclinic, space grope *P*2/*a*, a = 15.020(5), b = 6.959(2), c = 10.137(3) Å, β = 111.740(4)°, Z = 2, D_{calc} = 2.677 g/cm^3. The crystal studied was microscopically twinned on (100) (which is usual for whiteite group [2]) with partial overlap of the diffraction spots from two twin components. The program HKLF5 [3] was employed in order to account for the effects of twinning. Examination of diffraction space using STOE images demonstrated that, in reciprocal space, diffuse streaks parallel to the **a*** axis are present, indicative for strong layer stacking disorder along the [100] direction. The structure was refined to $R1$ = 0.068 on the basis of CCD data.

Electron microprobe data provided the empirical formula $(Ca_{0.57}Zn_{0.24}Na_{0.14})_{0.95}(Mn_{0.80}Fe_{0.20})_{1.00}(Mn_{1.24}Fe_{0.58}Mg_{0.19})_{2.01}Al_{2.03}(PO_4)_4(OH)_2x8H_2O$, ideally $CaMnMnAl_2(PO_4)_4(OH)_2x\ 8H_2O$. This formula is in general agreement with the results of crystal-structure refinement, which provides site occupancies for the X site as $Ca_{0.55}Zn_{0.30}Na_{0.15}$, for the M(1) site as $Mn_{0.80}Fe_{0.20}$ and for the M(2) site as $(Mn_{1.24}Fe_{0.58}Mg_{0.19})$. These data support our suggestion that the mineral studied is a new CaMnMn-dominant member of the whiteite series of the whiteite group.

Mineral-like *M*1–*M*2–H-arsenates ($M1^{2+}$ = Sr, Ba, Cd; $M2^{2+}$ = Mg, Co, Ni, Cu, Zn): crystal structure of $Cd_{0.74}Mg_{2.76}(AsO_4)(HAsO_4)_2$

Đorđević, T.[1*], Stojanović, J.[2] & Karanović, Lj.[3]
[1]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria (*tamara.djordjevic@univie.ac.at)
[2]Applied Mineralogy Unit, Institute for Technology of Nuclear and Other Mineral Raw Materials, Belgrade, Serbia
[3]Laboratory for Crystallography, Faculty of Mining and Geology, University of Belgrade, Serbia

An ongoing comprehensive study on hydrothermal synthesis, and crystallographic properties of arsenate(V) compounds in the insufficiently known system *M*1O–*M*2O–As_2O_5–H_2O yielded a large number of new *M*1–*M*2–H-arsenates that are characterized structurally, and, in part, by spectroscopic techniques. Among them are a few mineral-like compounds (Table 1).

Table 1: Mineral-like *M*1–*M*2–H arsenates

Chemical formula	Mineral-group	Ref.
$SrCo_2(AsO_4)(AsO_3OH)(OH)(H_2O)$	tsumcorite	[1]
$SrCo(OH)(AsO_4)$	descloizite-adelite	[2]
$CdCo(OH)(AsO_4)$	descloizite-adelite	[2]
$CdCu(OH)(AsO_4)$	descloizite-adelite	[3]
$BaZn_2(AsO_4)_2(H_2O)$	paracelsian	[4]
$Cd_{0.74}Mg_{2.76}(AsO_4)(HAsO_4)$	alluaudite	new

The crystal structure of the novel, hydrothermally synthesized Cd0.74Mg2.76(AsO4)(HAsO4) (Teflon-lined steel autoclave, 493 K, 8 days, Cd(OH)2 + MgO + 3As2O5·5H2O) was determined by single-crystal X-ray diffraction data. The compound is monoclinic, space group C2 with a = 11.992(2), b = 12.429(3), c = 6.7462(13) Å, β = 112.92(3)°, V = 926.2(3) Å³, Z = 4. The refinement yielded R1(F) = 0.031, wR2(F2) = 0.072 for 1895 unique reflections; for 1781 'observed reflections' with Fo2 ≥ 4σ(Fo2) R1(F) is 0.028. The crystal structure was solved from a racemic twin (twin ratio = 0.42(2):0.58(2)). All H atoms were found in a difference Fourier map and successfully refined as riding atoms, with restraints on the O–H bond distances of 0.82(2) Å. Uiso(H) values were fixed at 1.5 Ueq(O).

$Cd_{0.74}Mg_{2.76}(AsO_4)(HAsO_4)$ is related to the alluaudite-like compounds. They adopt general formula $A1A2M1M2_2(X1O_4)(HX2O_4)_2$. In minerals, *A*-position is mostly occupied with Na, Ca, Mn, *M*-position with Mn, Fe, Al, Mg, and *X* with P. Synthetic members show much broader chemical variability. Alluaudites crystallize monoclinic, and the most common space group is *C*2/*c*. The crystal structure consists of kinked chains of edge-sharing *M*1 and *M*2 octahedra that are stacked parallel to [101] and are connected by the *X*1 and *X*2 tetrahedra in the *b*-direction. These interconnected chains produce channels parallel to *c*-axis, where the large *A*1 and *A*2 cations are located.

The new compound represents previously unknown structure variant among alluaudites. The symmetry reduction from *C*2/*c* to *C*2 is probably the consequence of the cation type and quantity. In the $Cd_{0.74}Mg_{2.76}(AsO_4)(HAsO_4)$ *A*1 site is empty. In the *A*2 site are situated Cd atoms. The *M*1 site is shared between Mg and Cd, and the *M*2 site is filled with Mg.

The Fe-Nb-S system

Drabek, M.[1*], Hybler, J.[2] & Rieder, M.[1,3]
[1]Czech Geological Survey, Prague, Czech Republic, ([*]milan.drabek@alumni.uni-heidelberg.de)
[2]Institute of Physics of the ASCR,v.v.i., Prague, Czech Republic
[3]CPIT, VŠB-TU Ostrava, Ostrava-Poruba, Czech Republic

Due to niobium's high affinity to oxygen, practically all of its minerals are oxides [1]. However, an iron niobium sulphide, edgarite ($FeNb_3S_6$), has been found in nature [2]. To better understand the phase relations of edgarite, we carried out experiments in the Fe-Nb-S system. The experiments were performed using the evacuated silica glass tubes technique, in the temperature interval 1000 – 400ºC. Because of unfavourable kinetics, some runs were performed in salt fluxes (in NaCl, KCl or KI) or in the presence of a small amount of iodine [3]. The central portion of the system is dominated by a broad solid solution Fe_xNbS_2 where 0.5>x>0 (14.2 - 0 at.% Fe). This Fe_xNbS_2 solid solution includes the composition of edgarite. Our experiments indicate that at T >742°C, the following univariant assemblages are stable: Fe_xNbS_2ss + $Fe_{1-x}S$ + S, Fe_xNbS_2ss + Nb_3S_4 + NbS, Fe_xNbS_2ss + $Fe_{1-x}S$ + Fe and Fe_xNbS_2ss + Fe + NbS. Below 742°C, pyrite comes into play, and the assemblage Fe_xNbS_2ss + $Fe_{1-x}S$ + S disappears in favour of assemblages, FeS_2 + Fe_xNbS_2ss + S and FeS_2 + Fe_xNbS_2ss + $Fe_{1-x}S$. Crystal structures of two phases were refined: 1) $Fe_{0.27-0.32}NbS_2$ (edgarite), space group *P*6322, *a*=5.7609(3) Å, *c*=12.1370(8) Å; 2) $Fe_{0.48}NbS_2$ ("Fe-rich phase"), space group *P*63/*mmc*, a=3.3322(2) Å, *c*=12.3533 Å. The experiments performed show that the Fe_xNbS_2 solid solution includes the composition of edgarite and participate in stable assemblages with iron sulphides. Under conditions prevailing in nature, Nb prefers oxides, but in order to bind with sulphur, apparently very specific sulphur/oxygen ratios are needed. So, the presence of edgarite probably indicates a low oxygen fugacity during its formation.

Andorite VI and owyheeite from the El Zancudo deposit, Colombia: chemistry and structure

Gallego, A.N.[1*], Akasaka, M.[1] & Nakamuta, Y.[2]
[1]Dept. of Geosciences, Shimane University, Matsue, Japan ([*]albanurygh@yahoo.com)
[2]Kyushu University Museum, Kyushu University, Fukuoka, Japan

The El Zancudo Pb-Sb-Ag-bearing sulfosalts have been regarded as members of the andorite series, $Ag_xPb_{3-2x}Sb_{2+x}S_6$ (And_n: $n = 100x$), and the owyheeite solid solution, $Ag_{3+x}Pb_{10-2x}Sb_{11+x}S_{28}$ ($-0.13 < x < 0.20$). These two sulfosalts occur as aggregates in interstices between quartz and carbonates, along with Pb-Cu-Ag-sulfosalts, Ag-rich tetrahedrite, arsenopyrite, sphalerite, pyrite, galena and electrum [1]. The purpose of this study is to describe the occurrence of Pb-Sb-Ag sulfosalts from the El Zancudo deposit based on both chemistry and structural data.

Andorite and owyheeite occur as acicular crystals up to 1 mm long and less than 0.05 mm wide. They are opaque, brittle, and light gray in reflected light. Andorites with compositions ranging from $Ag_{0.96-1.00}Pb_{0.93-1.11}Sb_{2.96-3.31}S_6$ (And_{100}) were found in ores from the Albertos, Povenir and Manuela veins (Fig. 1). Andorite with compositions of $Ag_{0.78}Pb_{1.28}Sb_{2.79}S_6$ (And_{87}) and $Ag_{0.75}Pb_{1.73}Sb_{2.84}S_6$ (And_{74}) were also found in ores from Albertos and Manuela veins, respectively. The chemical formulae of owyheeite in ores from the Albertos, Colombiana and Castano veins are $Ag_{2.62}Pb_{8.79}Sb_{10.44}S_{28}$, $Ag_{2.95}Pb_{9.35}Sb_{10.70}S_{28}$, and $Ag_{3.04}Pb_{11.95}Sb_{12.96}S_{28}$ respectively. Although the Ag, Pb and Sb contents are somewhat variable, Ag:Pb:Sb-ratios are 1:3.33-3.93:3.62-4.26, which are similar to an ideal value of 1:3.33:3.67.

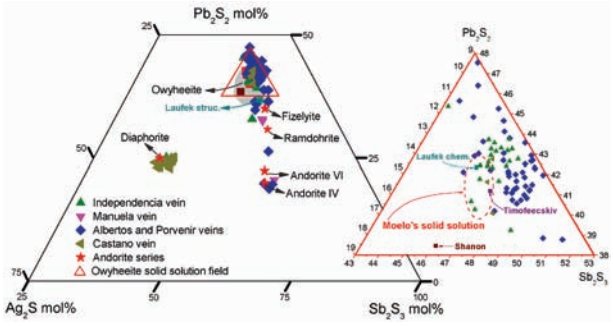

Fig. 1: Pb-Sb-Ag system showing the compositional variation of andorite and owyheeite from several veins in the El Zancudo deposit.

X-ray diffraction data of an aggregate (0.1×0.1×0.05mm) of $Ag_{1.0}Pb_{0.98}Sb_{2.96}S_6$ (And_{100})-andorite crystals from the Porvenir vein were collected using a Gandolfi camera and Imaging Plate system to reveal their structural properties. CuK_α radiation was generated using a rotating anode X-ray tube operated at 41 kV and 38 mA. The crystal structure was refined to that of andorite VI (a = 12.9864(5), b = 19.154(2), c = 25.6648(9) Å, V = 6383.9(6) Å^3 in space group $Pna2_1$) with R_{wp} = 6.89, R_e = 2.95 and S = 2.34. The unit-cell parameters are consistent with those of Sawada et al. [2]. The result that the andorite in this vein is andorite VI is consistent with the fact that And_{100} has the 6C type structure [2].

Although And100 was identified as andorite VI, andorite with calculated compositions of And87 and And74 cannot be identified as andorite IV (And93.75), ramdohrite (And68.75), or fizelyite (And62.5). Owyheeite also shows wide compositional variations, possibly due to the presence of very fine intergrowths of Pb-Sb-Ag sulfosalts.

Gehlenite-bearing high-temperature skarns from Oraviţa, Romania

Ghineţ, C.*, Marincea, Ş., Anason, A. & Iancu, A.
Geological Institute of Romania, Bucharest, Romania
(*ghinet.cristina@yahoo.com)

Beside the similar occurrences at Cornet Hill, Măgureaua Vaţei, Ciclova – Tiganilor Brook, the Oraviţa – Crişenilor Brook gehlenite-bearing high-temperature skarns are quite exotic: fewer then forty such occurrences were reported so far in the world. These four occurrences circumscribe the Banatitic Magmatic and Metallogenetic Belt from Romania, and occur at the very contact between dioritic or monzodioritic bodies of Upper Cretaceous age and carbonaceous sequences of Mesozoic age.

At Oraviţa, apart from the sporadic occurrence of brown dark skarn mainly composed of well-crystallized late-stage andradite associated with Cu, W and Bi mineralization, most of the skarns are barren, with a striking predominance of yellow-geen vesuvianite on the inner exoskarn zone and of some coarse grained wollastonite-2*M* on the outer exoskarn.

The most conspicuous exception to the general schema just described is a small occurrence on Crişenilor Brook, first reported by Constantinescu et al. [1]. The inner skarn zone has a massive metasomatic texture and is mainly composed by medium to coarse gehlenite (up to 98% from the volume of the rock), which associates with monticellite, grandites, hydroxylellestadite and scarce spurrite. Late-stage metasomatic replacement of gehlenite by vesuvianite and clintonite is common, as well as its replacement by hibschite, thomsonite, 11 Å tobermorite and allophane as a result of late hydrothermal and weathering processes.

Gehlenite forms euhedral, rarely subhedral, grains, 0.3 mm to nearly 1 cm across. Individual crystals show a short prismatic to tabular habit; they seem to consist of tetragonal prisms {100} simply terminated with {001} pinacoids. Macroscopically, gehlenite has a color that varies from dark gray to bluish gray. In thin section, the mineral is colourless to pale yellow.

The solid solutions toward åkermanite + Fe-åkermanite varies from Ak 34.10 to Ak 51.18 (mean Ak 41.18), wheareas at Măgureaua Vaţei and Cornet Hill the composition varies from Ak 30.36 to Ak 42.88 (mean Ak 38.29) and from Ak 24.31 to Ak 41.73 (mean Ak 32.94), respectively. The content in Na-melilite is low (up to 3.60 mol.%). The cell parameters are highly variable: for the analyzed samples, *a* ranges from 7.679(3) to 7.734(3) Å whereas *c* varies from 5.043(3) to 5.065(3) Å. In the analyzed samples, the cell parameter remains practically constant within experimental errors, in spite of the advancing åkermanite-for-gehlenite substitution, due to the opposite influence of Na-melilite component. The åkermanite substitution prevails over the opposite influence of Na-melilite in increasing the cell volume and sums with the influence of Na-melilite in decreasing the *c* cell parameter. The record in the infrared-absorption spectra of a couple of bands located at ~ 855 cm^{-1} and ~670 cm^{-1} respectively, that may be tentatively assigned to Al-O-Al stretchings, is indicative for the presence of gehlenite instead åkermanite.

Crystal chemistry of chromian pumpellyite from Osayama, Okayama Prefecture, Japan

Hamada, M.[1*], Akasaka, M.[1], Seto, S.[2] & Makino, K.[3]
[1]Dept. of Geoscience, Graduate School of Science and Engineering, Shimane University, Matsue, Japan
(*cr_pumpellyite@yahoo.co.jp)
[2]International Technical and Training Center EO Technical Division, EO Training andApplication Group, JEOL DATUM LTD., Akishima, Tokyo, Japan
[3]Dept. of Geology, Faculty of Science, Shinshu University, Matsumoto, Japan

The crystal structure and crystal chemistry of chromian pumpellyite from basic schist block in the Osayama ultramafic body, Okayama, Japan, were investigated to determine the distribution of chromium between two independent octahedral sites and structural changes caused by ionic substitutions in pumpellyite, $^{VII}W_8{}^{VI}X_4{}^{VI}Y_8{}^{IV}Z_{12}O_{56-n}(OH)_n$ (Z=1). The samples were collected from domains consisting of chromian pumpellyite, chromian phengite, chromian chlorite and chromite in a basic schist block [1,2]. Chromian pumpellyite is reddish gray to the naked eye, colorless in thin section, anhedral in form, and exhibits twinning. Grain size varies from 0.05 to 0.3 mm. Five pumpellyite crys-tals (ocp1211, ocp0604, ocp1028, ocp1013 and ocp1016) with 0.52, 1.65, 1.26, 1.94 and 1.43 Cr atoms per formula unit (EPMA data), respectively, were picked from a hand specimen for X-ray diffraction analysis. The reflection statistics and systematic absences were consistent with space groups *C*2/*m*. In the refinements including the H atoms for all samples, the *R*1 indices and *S*-values (goodness-of-fit) were converged to the smallest values of 4.08 % and 1.088 for ocp1211, 5.02 % and 0.954 for ocp0604, 6.32 % and 1.039 for ocp1028, 6.92 % and 1.564 for ocp1013 and 7.88 % and 1.583 for ocp1016. The resulting site populations at the *X* and *Y* sites are ocp1211: $(Mg_{1.88}Al_{1.51}Fe^{2+}_{0.38}Cr_{0.16}Mn^{2+}_{0.05}Ni_{0.02})^X(Al_{7.90}Ti_{0.07}V_{0.03})^Y$; ocp0604: $(Mg_{1.81}Al_{1.53}Cr_{0.42}Fe^{2+}_{0.18}Mn^{2+}_{0.04}Ni_{0.01})^X(Al_{7.34}Cr_{0.65}V_{0.01})^Y$; ocp1028: $(Al_{1.62}Mg_{1.60}Cr_{0.61}Fe^{2+}_{0.13}Mn^{2+}_{0.03}Ni_{0.01})^X(Al_{7.36}Cr_{0.61}V_{0.03})^Y$; ocp1013: $(Mg_{1.79}Al_{1.33}Cr_{0.47}Fe^{2+}_{0.33}Mn^{2+}_{0.08})^X(Al_{6.66}\ Cr_{1.31}V_{0.03})^Y$; ocp1016: $(Mg_{1.94}Al_{1.23}Cr_{0.38}Fe^{2+}_{0.37}Mn^{2+}_{0.08})^X(Al_{6.72}Cr_{1.25}V_{0.03})^Y$. Cr^{3+} ions in ocp1211 are distributed only in the *X* site. Cr/Al-ratio at the *X* site increases rapidly with the increase of total Cr content in contrast to the linear increase of Cr/Al-ratio at the *Y* site. The distribution coefficient of Cr and Al between the *X* and *Y* sites, defined as $(Cr/Al)^X/(Cr/Al)^Y$, is 1.66, 1.79, 3.09 and 4.54 for ocp1016, ocp1013, ocp0604 and ocp1028, respectively, indicating a stronger preference of Cr for the *X* site than the *Y* site as well as the result on the Sarany chromian pumpellyite [3]. The *a* and *b* axes increase with increasing Cr content, whereas the *c* axis is almost constant. The mean *Y*-O distances increase linearly with increased Cr^{3+} in the *Y* site. However, the mean *X*-O distances do not depend on the substitution of Cr^{3+} for Al^{3+} at the *X* site.

The bond valence sums and the difference Fourier synthesis indicate that hydroxyl groups are located at the O5, O7, O10 and O11 positions. FTIR spectrum shows main absorption bands at ca. 2911, 3220, 3397 and 3512cm^{-1} of OH stretching vibrations, indicating the presence of OH···O hydrogen bonds.

These results on the site populations of cations at the *X* and *Y* sites are significant not only for construction of a general rule on the behavior of transition elements in pumpellyite, but also for nomenclature.

An Al-Si order and composition model for scapolite solid solutions with conformation from HRPXRD data

Hassan, I.[1] & Antao, S.M.[2*]
[1]Dept. of Chemistry, University of the West Indies, Mona, Kingston, Jamaica
[2]Dept. of Geoscience, University of Calgary, Calgary, Alberta, Canada ([*]antao@ucalgary.ca)

An Al-Si order-disorder and compositional model is proposed for the scapolite solid solution. The model predicts the Al-Si order and average <T-O> distances from Me_0 to Me_{100}. This model is based on the observed order of clusters and on two solid solutions that meet at Me_{75} coupled with predicted composition and <T-O> distances. The $[Na_4{\cdot}Cl]^{3+}$ and $[NaCa_3{\cdot}CO_3]^{5+}$ clusters are ordered from $Me_{0\text{-}75}$, whereas the clusters $[NaCa_3{\cdot}CO_3]^{5+}$ and $[Ca_4{\cdot}CO_3]^{6+}$ are disordered from $Me_{75\text{-}100}$. To confirm the structural model, the structure of scapolite samples between $Me_{6\text{-}93}$ has been obtained by using synchrotron high-resolution powder X-ray diffraction (HRPXRD) data and Rietveld structure refinement. The structures were refined in space group $P4_2/n$. The <T-O> distances indicate that the T1 (= Si), T2 (= Al), and T3 (= Si) sites are fully ordered at $Me_{37.5}$, where complete cluster order occurs and gives rise to antiphase domain boundaries (APBs) based on Cl-CO_3 order instead of Al-Si order. From $Me_{37.5}$, the Al-Si order changes in a regular and predictable manner toward the end members, Me_0 and Me_{100}. For the first time, the observed cell parameters and several structural parameters show a discontinuity at Me_{75}, where the series is divided into two. There is no structural evidence to support any other transition. The T1 site contains only Si from Me_0 to $Me_{37.5}$; from $Me_{37.5}$ to Me_{100}, Al atoms enter the T1 site and the <T1-O> distance increases linearly to Me_{100}.

Brushite and gypsum in phosphogypsum deposits from Turnu Măgurele and Valea Călugărească (Romania)

Iancu, A.M.[*], Dumitraş, D.G. & Marincea, Ş.
Geological Institute of Romania, Bucharest, Romania
([*]aurash83@yahoo.com)

Phosphogypsum is a technogenic product remaining after the extraction of phosphoric acid from raw phosphate, mainly apatite [ideally $Ca_5(PO_4)_3(F,OH,Cl)$]. The technology of extraction consists normally in sulfuric leaching of apatite, which is the case in all the Romanian deposits. Huge quantities of phosphatic rock, of both sedimentary and magmatic origin were imported by Romania from Morocco, Jordan, Tunisia Syria, and Russia, respectively. This importation increases the volume of phosphogypsum wastes, which represent about 50 % in volume and 60 % in surface of the hazardous industrial wastes in the country. The major waste dumps are located at Valea Călugărească (56 ha of phosphogypsum stacks), and Turnu Măgurele (64 ha of phosphogypsum stacks).

This paper aims to give new data on the mineralogy and geochemistry of Romanian phosphogypsum, based on X-ray powder data (XRD), and scanning electron microscopy (SEM). XRD analyses of phosphogypsum from the four occurrences, corroborated with Fourier-transform infrared absorption spectra, showed that the main crystallized phases in this kind of material are gypsum ($CaSO_4{\cdot}2H_2O$), and bassanite ($CaSO_4{\cdot}0.5H_2O$), reaching up to 90 wt.% and 5 wt.% from the mass, respectively. A phosphate-bearing phase identified as ardealite or brushite is common. Impurities consist of quartz, calcite (probably resulted from the treatment of the plants with CaO, in order to reduce their acidity) and minor clay minerals. The SEM study shows that the masses macroscopically perceived as powder crusts are composed of randomly oriented or compact radiating aggregates of platy crystals Two kinds of aggregates were identified: (1) aggregates of randomly oriented interlocking or subparallel platy crystals, having locally rosette-like nuclei and (2) rosette-like aggregates of spherical shape, resembling to the gypsum "sand roses". These aggregates are sometimes composed by fully idiomorphic crystals issued by recent precipitation from acidic solutions, but normally they are composed by "broken" aggregates of parallel grown crystals sometimes reduced to cauliflower-like concretions.

The unit-cell parameters were refined by least squares, on the basis of the lines in the X-ray powder patterns recorded for "n" samples, indexed on an *I* 2/a monoclinic cell.

Table 1: Unit-cell parameters of gypsum from the Romanian phosphogypsum deposits

Cell parameter	Turnu Măgurele	Valea Călugărească
n	6	14
a (Å)	5.664 – 5.680	5.662 – 5.683
b (Å)	15.183 – 15.209	15.139 – 15.190
c (Å)	6.514 – 6.526	6.499 – 6.516
β (°)	118.35 – 118.46	118.08 – 118.47
V (Å^3)	493.0 – 495.8	491.3 – 493.9

The infrared absorption spectra of representative phosphogypsum samples from the two occurrences show vibrations which could be assumed to gypsum or bassanite, quartz and rarely calcite. The bands assumable to molecular water (the H-OH stretching vibrations at about 3610, 3550, 3405 and 3240 cm^{-1}, the corresponding bending vibrations at ~1685 and 1620 cm^{-1} and the composed modes at 2220 and 2130 cm^{-1}) are particularly well developed, suggesting a high level of hydration of the samples.

Structure refinement of high-pressure K- and Na- hexagonal aluminous phases

Kojitani, H.*, Iwabuchi, T., Kobayashi, M. & Akaogi, M.
Dept. of Chemistry, Gakushuin University, Tokyo, Japan
(*hiroshi.kojitani@gakushuin.ac.jp)

Hexagonal aluminous phase is one of Al-rich phases observed in high-pressure phases of the mid-ocean ridge basalt under lower mantle conditions. The general chemical formula of the hexagonal aluminous phase is $[M3][M2]_2[M1]_6O_{12}$ where the small-, middle-, and large-sized cations occupy the M1, M2, and M3 sites, respectively. Large size cations like K, Na and Ca can be accommodated in the M3 site. It was found that the hexagonal aluminous phase has relatively high K abundance [1]. It is also well known that ^{40}K is one of major heat sources in the Earth's history. Therefore, structure and properties of the hexagonal aluminous phase are of interest as a host phase of Al and K in the deep mantle. In this study, we tried to synthesize a hexagonal aluminous phase in the $KAlSiO_4$-$MgAl_2O_4$ system, described hereafter as K-hexagonal aluminous phase. Also, Rietveld analyses of K-hexagonal aluminous phase and a hexagonal aluminous phase in the $NaAlSiO_4$-$MgAl_2O_4$ system (Na-hexagonal aluminous phase) were performed to examine detailed crystal structures.

K-hexagonal aluminous phases was synthesized by heating a gel with $KMg_2Al_5SiO_{12}$ composition at 20 GPa, 1500 °C for one hour using a Kawai-type high-pressure apparatus. Similarly, Na-hexagonal aluminous phase was synthesized by keeping a mixture of high carnegieite-type $NaAlSiO_4$ and $MgAl_2O_4$ spinel ($NaAlSiO_4$:$MgAl_2O_4$ = 2:3 in mole ratio) at 22 GPa, 1500 °C for two hours. Compositions of recovered samples were analysed by SEM-EDS. Their XRD profiles for the Rietveld analysis were obtained by a powder X-ray diffractometer (Rigaku RINT2500V, 45 kV, 250 mA, Cr Kα). Crystal structures of the K- and Na-hexagonal aluminous phases were refined by the RIETAN-2000 program using a crystal structure model based on $CaMg_2Al_6O_{12}$ hexagonal aluminous phase [2].

Measured compositions of K- and Na-hexagonal aluminous phases were $K_{1.01(3)}Mg_{2.01(1)}Al_{4.81(2)}Si_{1.13(2)}O_{12}$ and $Na_{1.04(2)}Mg_{1.88(2)}Al_{4.64(2)}Si_{1.32(2)}O_{12}$, respectively. This is the first report of the synthesis of K-hexagonal aluminous phase in which half of the M3 sites are occupied by only K. The results of the Rietveld refinement indicate that the average sizes of all cation sites in both the K- and Na-hexagonal aluminous phases are consistent with those expected from ionic radii of accommodated cations. Size and shape of $M1O_6$ octahedra are changed by the substitution of Si for Al in the M1 site. It is suggested that this change in the M1 site may make possible to adjust the size of the M3 and M2 sites. Furthermore, it was found that average size of $(Al, Si)O_6$ octahedra in a crystal structure consisting of double chains of $(Al, Si)O_6$ octahedra decrease linearly with increasing Si content by combining our results with those of calcium ferrite-type $MgAl_2O_4$ and $NaAlSiO_4$, and hollandite-type $KAlSi_3O_8$. In the $NaAlSiO_4$-$MgAl_2O_4$ join, Na-hexagonal aluminous phase is formed in the relatively wide compositional range from 50 to 70 mol% in $NaAlSiO_4$ at pressure above about 18 GPa [3]. The fact can be explained by possible exchange of Mg^{2+} for Na^+ in the M2 site and by shrinkage and deformation of $M1O_6$ octahedra with the coupled substitution: $^{M1}Mg^{2+} + {}^{M1}Al^{3+} \rightarrow {}^{M2}Na^+ + {}^{M1}Si^{4+}$.

The ternary skutterudites – ordered or disordered? The case of $FeSb_2Te$ and $IrGe_{1.5}Se_{1.5}$

Laufek, F.[1*] & Navrátil, J.[2]
[1]Czech Geological Survey, Prague, Czech Republic
(*frantisek.laufek@geology.cz)
[2]Joint Laboratory of Solid State Chemistry of IMC ČR and University of Pardubice, Pardubice, Czech Republic

The compounds with the skutterudite structure (general formula MX_3 where M = Co, Rh or Ir; X = P, As or Sb; $Im\bar{3}$ symmetry) have become of interest in materials science in last two decades because these compounds posses attractive transport properties for thermoelectric applications. Ternary skutterudites are phases isoelectronic to the binary skutterudites and can be obtained by isoelectronic substitution on the anion site, X (e.g. $CoGe_{1.5}Te_{1.5}$ [1]) or on the cation site M (e.g. $Fe_{0.5}Ni_{0.5}Sb_3$ [2]).

The ternary skutterudites $FeSb_2Te$ and $IrGe_{1.5}Se_{1.5}$ were synthesised from individual elements by high-temperature solid-state reactions using silica glass tube technique. Their crystal structures were characterized by powder X-ray diffraction.

The crystal structure of $IrGe_{1.5}Se_{1.5}$ compound ($R\bar{3}$, a = 12.09 Å, c = 14.88 Å) can be derived from simple cubic skutterudite structure, where Ge and Se atoms show long-range ordering in planes perpendicular to the [111] of the original cubic cell. This ordering lowers the symmetry from cubic to trigonal ($R\bar{3}$). Nevertheless, the $a^+a^+a^+$ tilt system of octahedra of the parent skutterudite structure MX_3 is preserved. This compound is isostructural with $CoGe_{1.5}Te_{1.5}$ [1] synthetic phase and both compounds can be considered as anion-ordered ternary skutterudites.

Contrary to that, the $FeSb_2Te$ phase shows simple cubic skutterudite structure with cubic symmetry ($Im\bar{3}$, a = 9.10 Å). No indication of ordering of Sb and Te atoms was observed. Hence this phase can also be viewed as a ternary skutterudite, however with a disordered crystal structure.

New features in VESTA: a three-dimensional visualization system

Momma, K.[1*], Izumi, F.[1,2] & Ida, T.[2]
[1]Quantum Beam Center, National Institute for Materials Science, Tsukuba, Japan ([*]MOMMA.Koichi@nims.go.jp)
[2]Ceramics Research Laboratory, Nagoya Institute of Technology, Nagoya, Japan

VESTA is a crystallographic tool for visualization and investigation of crystal structures and volumetric data such as electron and nuclear densities, Patterson functions, electrostatic potentials, wave functions, *etc*. [1]. Recently, we have added a new feature of drawing the external morphology (faces) of crystals to VESTA. All the symmetrically equivalent faces are automatically generated from indices input by users according to point-group symmetry. Faces inconsistent with point-group symmetry may also be added for ease of modelling crystal habits. Crystal faces can be overlapped with a structural model (Fig. 1) and isosurfaces of volumetric data. Multiple lattice planes, which serve to show orientation of cleavages, can be inserted as well.

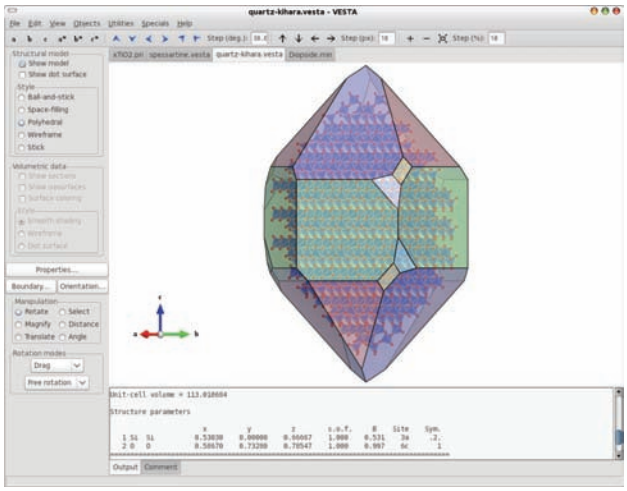

Fig. 1: A composite image of coordination polyhedra and external morphology for quartz.

For close investigation of volumetric data, we implemented another new feature of their integration by Voronoi tessellation. Integration of electron densities or densities of coherent scattering lengths, b_c, allows us to calculate site occupancies and assign chemical species to sites during structure refinement because the resulting values of integral are little affected by thermal motion of target atoms. Table 1 exemplifies an application of Voronoi tessellation to electron densities determined for rutile from X-ray powder diffraction data by a maximum entropy method.

Table 1: Voronoi tessellation for electron densities in rutile

	Peak density ($Å^{-3}$)	Number of electrons	Voronoi volume ($Å^3$)
Ti	303	20.0	7.7
O	57	9.0	11.8

Other new features added to VESTA include (a) overlaying multiple structures, (b) calculation of electron and nuclear densities from structure parameters, (c) extended bond-search algorithm to allow more sophisticated search for complex molecules and cage-like structures, (d) support for custom symmetry operations input by users, and (e) improved support for various file formats.

[1] Momma, K. & Izumi, F. (2008) *J. Appl. Cryst.*, **41**, 653-658.

X-ray Rietveld and ^{57}Fe Mössbauer studies of epidote and piemontite on the join $Ca_2Al_2Fe^{3+}Si_3O_{12}(OH)$ – $Ca_2Al_2Mn^{3+}Si_3O_{12}(OH)$ formed by hydrothermal synthesis

Nagashima, M.[1,2*] & Akasaka, M.[1]
[1]Dept. of Geoscience, Faculty of Science and Engineering, Shimane University, Matsue, Japan
[2]Dept. of Earth Science, Graduate school of Science and Engineering, Yamaguchi University, Yamaguchi, Japan
([*]piemontite@gmail.com)

Fe^{3+} and Mn^{3+} distributions on octahedral M1, M2 and M3 sites in synthetic epidote/piemontite from $Ca_2Al_2Fe^{3+}{}_qMn^{3+}{}_{1-q}Si_3O_{12.5}$ starting material and their effects on the crystal structure were investigated using X-ray Rietveld and ^{57}Fe Mössbauer methods. Epidote and piemontite were crystallized as almost single phases from q = 1.0, 0.75, 0.5 and 0.25 starting materials at P_{fluid} of 200–400 MPa and a temperatures of 500°C, using standard cold-seal pressure vessels. The Mn_2O_3-MnO_2 buffer was used to produce fO_2 adequate to maintain Fe^{3+} and Mn^{3+}. The Rietveld refinements converged to goodness-of-fit ranges from 1.21 to 1.60 (Fig. 1).

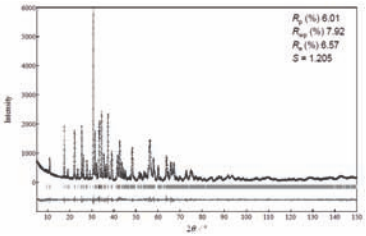

Fig. 1: Rietveld refinement plot for the product from q = 0.25 starting material at 370 MPa and 500°C (Run No. 30).

At this temperature, site preferences of $\Sigma(Fe^{3+} + Mn^{3+})$ for octahedral sites are M3 > M1 (>> M2) (Fig. 2). K_D-values of $\Sigma(Fe^{3+} + Mn^{3+})$, where $K_D = [(Fe^{3+} + Mn^{3+})/Al]^{M1}/[(Fe^{3+} + Mn^{3+})/Al]^{M3}$, (0.05–0.13) are similar to those of individual Mn^{3+} and Fe^{3+} versus Al^{3+}, respectively. However, the K_D-values of Fe^{3+} and Mn^{3+} for M1 and M3, where $K_D = (Fe^{3+}/Mn^{3+})^{M1}/(Fe^{3+}/Mn^{3+})^{M3}$, vary with $Fe^{3+}{}_{Total}$: $Mn^{3+}{}_{Total}$-ratios. In epidote with Fe^{3+} content larger than 0.4 atoms per formula unit (apfu) and Mn^{3+} less than 0.6 apfu, Fe^{3+} has a stronger preference for M1 than Mn^{3+}. In piemontite with 0.12 Fe^{3+} and 0.73-0.78 Mn^{3+} apfu, the preference of Mn^{3+} for M1 is greater than that of Fe^{3+}. The site occupancies of individual Mn^{3+} and Fe^{3+} are governed by the individual K_D values and the Mn^{3+} and Fe^{3+} concentrations in corresponding epidote and piemontite. Variations of the unit-cell parameters indicate the combined result of linear variation due to Al ↔ Fe^{3+} substitution and nonlinear variation due to Al ↔ Mn^{3+} substitution.

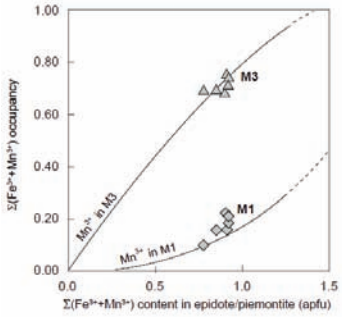

Fig. 2: Variations of the $\Sigma(Fe^{3+} + Mn^{3+})$ occupancies at M1 and M3 against $\Sigma(Fe^{3+} + Mn^{3+})$ contents in synthetic epidote/piemontite.

Re-investigation of structure of vanadinite, $Pb_5(VO_4)_3Cl$: libration of VO_4 tetrahedron and anisotropic ADPs of Cl

Niinou, M. & Okudera, H.*
Dept. of Earth Sciences, Kanazawa University, Kanazawa, Japan (*okudera@kenroku.kanazawa-u.ac.jp)

Vanadinite, $Pb_5(VO_4)_3Cl$, is one of Pb-bearing chlorapatites. Its structure has been known [1,2], and its structure had not been refined with anisotropic displacements of oxide ions in precision.

Crystals we employed (from Mibladen, Morocco) were nearly perfect: Impurity was undetectable with JEOL 8800 EPMA, and X-ray photographs showed no sign of superstructure in any direction.

Conventional single-crystal X-ray diffraction experiments (a Rigaku AFC-5S, Mo-Kα radiation, 2θ up to 70°, 12664 Bragg points) on nearly spherical vanadinite ($r \approx 0.08$ mm) yielded reasonable results. Least-squares calculation converged at $R_{(F)}$ = 3.76% for 40 parameters with 610 averaged F_{obs}s. Anisotropy in ADPs at oxide ion sites and smaller ADPs at V site than those at Pb sites indicate librational motion of the VO_4 tetrahedron. These observations indicate VO_4 tetrahedron behaving as a rigid body in the structure.

Thermal vibration ellipsoid at the Cl site is elongated along [001], while that in pyromorphite was nearly isotropic [3]. In $A_5(PO_4)_3Cl$ chlorapatites, the amplitude along [001] of the thermal vibration ellipsoid at the Cl site becomes larger with decreasing $rA(2)^{2+}$ [3,4].

Similar consideration can be made among $A_5(BO_4)_3Cl$ compounds: The larger the void in the $A(2)_3$ regular triangle (at z = 1/4) the larger the u_{33} (vibrational amplitude along [001], Å^2) at the Cl site. The size of the void (approximated as a sphere) and u_{33} were r = 1.337 Å and 0.013 Å^2 for pyromorphite, r = 1.346 Å and 0.022 Å^2 for $Sr_5(PO_4)_3Cl$, and r = 1.389 Å and 0.023 Å^2 for vanadinite. Similarly, the larger the void in the $A(2)_6$ octahedron the larger the u_{11} (amplitudes in directions normal to [001], Å^2). As a result, anisotropy in ADPs (= u_{33}/u_{11}) is larger in vanadinite than in pyromorphite, while not as highly anisotropic as in $Sr_5(PO_4)_3Cl$.

Crystallographic data: space group $P6_3/m$, $a = b$ = 10.317(1) Å, c = 7.336(1) Å.

The structural deformations of three $Ca_2(Ge_x, Si_{1-x})O_4$ olivines

Nishi, F.[1*] & Miyawaki, R.[2]
[1]Saitama Institute of Technology Fukaya, Saitama, Japan (*nishi@sit.ac.jp)
[2]National Museum of Nature and Science, Tokyo, Japan

Three kinds of structures of olivine whose compositions were Ca_2SiO_4, $Ca_2Si_{1/2}Ge_{1/2}O_4$ and Ca_2GeO_4 were synthesized. The average bond lengths of the M1 octahedron among three structures were not significantly different. Moreover, those of the M2 octahedron among three were not significantly different, too. We paid attention to the O-M-O bond angles of M1 and M2 octahedra. In case of the olivine structures, the oxygen atoms are almost arranged in the scheme of the hexagonal closest packing. Although the ideal bond angles of the O-M-O of the ortho-octahedra are just 90°, those values of this study derived from the structure analysis showed the values between 80° and 100° widely. As an indicator of the structural deformation of the real octahedra, we noticed of the differences between each O-M-O bond angle and 90° (the ideal bond angle). Those differences are 12 values per a octahedron and they were summed up after being made the absolute values. The indicators were calculated about the M1 and the M2 octahedra in three structures (Fig. 1).

As the result, the indicators of the M1 octahedra are 135.1(3), 125.2(3) and 119.0(6) degrees for Ca_2SiO_4, $Ca_2Si_{1/2}Ge_{1/2}O_4$ and Ca_2GeO_4 respectively. Those of the M2 octahedra are 108.2(3), 97.4(3) and 88.4(6) degrees for Ca_2SiO_4, $Ca_2Si_{1/2}Ge_{1/2}O_4$ and Ca_2GeO_4. It may be said that the more those indicators increase, the more the structure is unstable. We may conclude that Ca_2GeO_4 is most stable but Ca_2SiO_4 is most unstable among three structures, judging from this geometrical consideration.

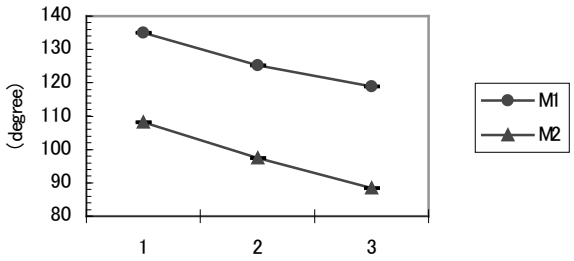

Fig. 1: Variations of the indicators for three olivines (1=Ca_2SiO_4, 2=$Ca_2Si_{1/2}Ge_{1/2}O_4$, 3=Ca_2GeO_4).

As seeing the crystal structure of olivine, we can realize that the deformations are caused by the shared edges of the octahedra and the tetrahedra. The lengths of the shared edges are increasing in accordance with increasing the Ge amounts at the (Si, Ge)-tetrahedral site where Si and Ge atoms are disordered. The lengths of the more shared edges become closer to the lengths of the edges of the ideal ortho-octahedron. As the results, the octahedra which have the longer shared edges have the less structural deformations. In other words, they are more stable. This conclusion supports our conclusion.

Crystal-chemistry of synthetic Mn-bearing clinoamphiboles and phyllosilicates

Papin, A. & Robert, J.-L.*
Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France
(*jean-louis.robert@impmc.upmc.fr)

The behaviour of Mn in rock-forming minerals strongly depends on its valence state, i.e. of oxygen fugacity. The crystal-chemistry of Mn in series of synthetic clinoamphiboles (richterite - $^{[M4]}$Mn-richterite, richterite - $^{[M4]}$Mn-cummingtonite and tremolite - $^{[M4]}$Mn-cummingtonite) and phyllosilicates (talc and phlogopite) prepared by hydrothermal synthesis at 700°C for amphiboles and 600°C for phyllosilicates, under different fO_2 conditions has been investigated mainly by XRD and FTIR spectroscopy. Mn^{2+} is a quite large cation (0.83 Å) intermediate in size between Mg^{2+} and Ca^{2+}. Therefore, it is supposed to be able to occupy different sites in the clinoamphibole structure, replacing Ca^{2+} at M4 sites and/or Mg^{2+} at M(1,2,3). The $Ca^{2+} \rightarrow Mn^{2+}$ substitution is observed along the join richterite $Na(NaCa)Mg_5Si_8O_{22}(OH)_2$ - $^{[M4]}$Mn-richterite $Na(NaMn)Mg_5Si_8O_{22}(OH)_2$, under NNO buffering conditions. Mn^{2+} completely replaces Ca^{2+} and partially Na^+ at M4, the charge imbalance is compensated by the loss of Na^+ at the A-site. The composition shifts towards $^{[M4]}$Mn-cummingtonite $\square Mn_2Mg_5Si_8O_{22}(OH)_2$. The is no evidence for $Mg^{2+} \rightarrow Mn^{2+}$ substitution at M(1,2,3) sites in this case. Along the tremolite $\square Ca_2Mg_5Si_8O_{22}(OH)_2$ - $^{[M4]}$Mn-cummingtonite join, the situation is different. Mn^{2+} also replaces Ca^{2+} at M4, but also Mg^{2+} at M(1,2,3) and some Mg^{2+} shifts to M4. All M-sites incorporate Mn^{2+} in this case. The introduction of Mn at M(1,2,3) sites in clinoamphiboles is observed along the richterite - $^{[M(1,2,3]}$Mn - richterite, nominally $Na(NaCa)Mn_5Si_8O_{22}(OH)_2$. The behaviour of Mn depends on fO_2 conditions. The larger solid solution extent is reached under MW and NNO conditions, with a maximum value of X_{Mn} = Mn/(Mg + Mn) = 0.5, without accessory phases. For higher X_{Mn} values, additional phases appear, mainly serandite. In no case, the X_{Mn} value is larger than 0.7. Under oxidizing conditions (HM buffer), the solid solution range is much restricted and accessory phases (diopside and quartz) are present for X_{Mn} > 0.3. The same is observed with amphiboles along the tremolite - $^{[M(1,2,3]}$Mn-tremolite join, where no single phase amphibole is obtained, whatever X_{Mn}, under HM buffering conditions. The analysis of OH-stretching band intensities with increasing X_{Mn}, under oxidizing conditions, clearly indicates a progressive deprotonation of the amphibole. It is related to the presence of Mn^{3+}, confirmed by optical spectrometry.

In talc, the Mg→ Mn substitution is limited to X_{Mn} = 0.2 under reducing conditions, probably for dimensional reasons. In phlogopite, maximum X_{Mn} values are 0.3 with MW buffer, 0.4 with NNO and 0.6 with HM. Clearly, under oxidizing conditions, Mn^{3+} enters the structure and the excess of charge is balanced by a deprotonation, like in clinoamphiboles.

Dimensional misfits between the I-beam and the double chains of tetrahedra, in amphiboles, and between tetrahedral and octahedral layers, in phyllosilicates, generated by the incorporation of the large Mn^{2+} explain these limited solid solution extends.

Crystal chemistry of synthetic amphiboles along the richterite - ferro-richterite join

Robert, J.-L.[1*], Della Ventura, G.[2], Redhammer, G.J.[3], Iezzi, G.[4], Bellatreccia, F.[2] & Sergent, J.[1]
[1]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France
(*jean-louis.robert@impmc.upmc.fr)
[2]Università di Roma Tre, Rome, Italy
[3]Rheinisch-Westfälische Technische Hochschule, Aachen, Germany
[4]Dipartimento di Scienze della Terra, Università G. D'Annunzio, Chieti Scalo, Italy

In this work we relate the synthesis and crystal-chemical study of amphiboles along the join richterite - ferrorichterite [nominally $Na(NaCa)(Mg_{5-x}Fe^{2+}_x)Si_8O_{22}(OH)_2$], at 700°C, 1 kbar, under redox conditions imposed by a MW solid buffer. XRPD shows essentially single-phase run products at both end-member compositions, with minor (10-15%) pyroxene and quartz for intermediate compositions. Interestingly, there is a significant evolution of the amphibole morphology across the solid-solution series: Mg end-member richterite is extremely acicular (length up to 15 μm, diameter up to 1 μm) whereas for increasing Fe in the system the amphibole becomes increasingly stubby, with a length:diameter ratio≈ 3:1 for the Fe -rich end-member. Notably, the refined cell parameters show linear variations across the series, suggesting a complete Mg-Fe^{2+} solid-solution along the join. The OH-stretching FTIR spectra show complex patterns for intermediate compositions with up to eight bands which can be assigned to the various configurations involving Mg/Fe^{2+} at M(1,3), locally associated with both full and empty A-sites. Combination of Mössbauer and FTIR spectroscopy however shows that the composition of the amphibole is much more complex than expected just from XRPD data: Fe^{2+} is in fact disordered among all M-sites, and, despite the strongly reducing conditions during syntheses, there is significant Fe^{3+} in the amphibole; it is fully ordered at M(2). For increasing Fe in the system, the amount of Fe_{tot} in the amphibole is systematically lower than expected as is Fe^{2+} at the M(1-3) octahedra, while $^{M(2)}Fe^{3+}$ increases toward more iron-rich compositions (Fig. 1). These results definitively stress the need for a proper characterization of the experimental run products because these may depart from the expected stoichiometry in a significant way.

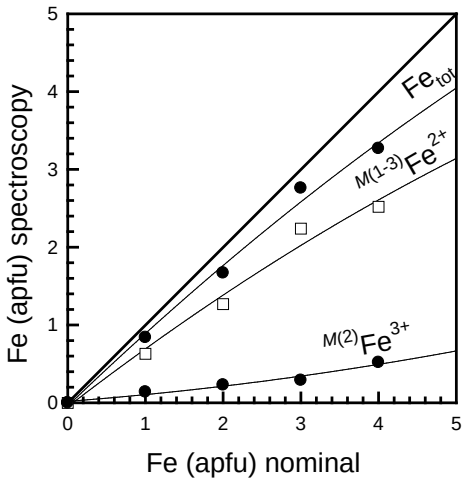

Fig. 1: The Fe^{2+}/Fe^{3+} distribution in synthetic richterites as a function of the nominal Fe in the system.

Direct EMP or single-crystal X-ray refinement is highly desirable, however spectroscopic methods may provide a valuable alternative, particularly when the Fe^{3+} *vs.* Fe^{2+} composition is needed.

Reappraisal of the crystal structure of Tinaksite from Murun massif (Russia): cation partition and structural disorder

Scordari, F.[1], Mesto, E.[1*], Vladykin, N.[2] & Koneva A.[2]
[1]Dipto Geomineralogico, Università degli Studi di Bari, Italy
([*]mesto@geomin.uniba.it)
[2]Institute of Geochemistry, Irkutsk, Russia

Tinaksite is a widespread mineral in the rocks of charoite complex of the Murun massif (Russia). The structure of tinaksite was reported for the first time in 1971 by Petranunia [1]. Until now, it is the only one silicate known based on a hybrid anion. According to Libeau [2], the latter can be described briefly by {**hB**, 2^1_∞}[$^3Si_6O_{17}(SiO_2)$], which represents the joint of an unbranched dreier single chain with a loop-branched dreier single chain. In 1980 von Bissert [3] confirmed the general structure architecture of tinaksite proposed by Petranunia [1], but found a more regular tetrahedral conformation. According to von Bissert [3], tinaksite is triclinic with the following chemical composition: $NaK_2Ca_2Ti[^3Si_7O_{19}]OH$. The compound here investigated has been solved in P1, *a*=7.0565(1) Å, *b*=10.3750(1) Å, *c*=12.1885(2) Å, α=92.802(1)°, β=90.763(1)° , γ=99.241(1)°, but differently from those studied by Petranunia [1] and von Bissert [3], it shows a more complex chemistry ($(Na_{0.855}K_{1.993}Ca_{2.008}Ti_{0.792}Mg_{0.082}Fe^{3+}_{0.142}Mn_{0.100}Ba_{0.006}Sr_{0.006}Zr_{0.007}Zn_{0.004}Ni_{0.003}Cr_{0.002})[^3Si_7O_{19}]OH$) and a more interesting structural details.

In this work, the cation partition, derived by means of SCXRD and EMPA measurements, is presented. The structure has been anisotropically refined to a R(F) = 0.025 (for 5238 observed reflections with $F_o > 3\sigma(F_o)$). The highest peak in the Fourier difference map seems due to some structural disorder inside the Ti octahedron. This disorder likely is related to the entrance of the large K in place of six-fold coordinated Na atom. The replacing of Na by K seems to change the coordination number of the polyhedron from 6 to 7, so perturbing the neighbouring Ti atom position.

Another point of interest concerns the K1 and K2 potassium atom located inside the system of one-dimensional channels of the structure, formed by double chains of silicate. According to von Bissert [3], the higher K1 thermal parameters with respect to the K2 one indicates the disorder on K1 site. The structural refinement shows that in the first case K occupies at least three different positions. A charge distribution analysis, performed by means of the Chardi-It software [4], has returned an ECON number [5] of 11 and 9 for the K1 and K2 site respectively. The bond distances for the three K atoms concerning K1 show these atoms are not always bonded to the same oxygens. In fact, K can move inside a cage formed by 14 oxygen atoms with a volume of about 90 Å^3. This volume results to be much larger than of one assigned to K atom.

Rietveld refinement of stibnite crystal structure

Şeclăman, A.C.
Dept. of Mineralogy, University of Bucharest, Bucharest, Romania (seclaman_alexandra@yahoo.com)

The stibnite samples used in this study are from Băiuţ mine, Maramureş, Romania. The powders were prepared from large crystals, through fine grinding.

The data collection was done using a PANalytical X'Pert Pro MPD diffractometer fitted with an X'Celerator detector, which allows for very short acquisition times. Several measurement settings were used in an effort to find highest quality data possible. The final data collection was set with the following parameters: 2θ range: 5 - 90°, 0.01° steps and 30 seconds acquisition time per step. The scan was continuous and a standard Cu X-ray source was used.

For the Rietveld refinement the parameters and atomic coordinates described by Lundegaard et al. [1] – at normal values of temperature and pressure – were used. The Rietveld refinement was performed with the help of General Structure Analysis Software. After approximately 300 refinement cycles, the residual value R has reached a minimum of 0.1387 beyond which no further improvements could be done.

Table 1: The refined unit-cell parameters (*Pnma*)

	a	b	c
Å	11.197438	3.799043	11.121890

The newly refined unit-cell parameters are shown in Table 1. The unit cell volume is 473.1201 Å^3. The atomic fractional coordinates are presented in Table 2.

Table 2: The atomic fractional coordinates

Atom	x	y	z
Sb_1	0.9707 (04)	0.25	0.1730(05)
Sb_2	0.6487 (06)	0.25	0.9646 (05)
S_1	0.7958 (18)	0.25	0.3099 (20)
S_2	0.4324 (22)	0.25	0.8787 (21)
S_3	0.6307 (17)	0.25	0.5558 (15)

The standard deviations for each atomic coordinate did not exceed 0.0022. The *y* parameters correspond to special positions and remained unchanged through the refinement. The results of this Rietveld refinement are not ideal, because of the data acquisition procedure. The results can further be improved through longer acquisition times.

Acknowledgements: I would like to thank Gh. Ilinca and B. Soare for their support in apprehending the basic operating techniques of the X-ray powder diffraction device and for assistance during refinement.

Compositional trends in hakite, possible discrepancies from ideal structure

Škácha, P.[1*], Vlček, V.[1], Sejkora, J.[2], Plášil, J.[2] & Goliáš, V.[1]
[1]Inst. of Geochemistry, Mineralogy and Mineral Resources, Charles University, Prague, Czech Republic
([*]skachap@seznam.cz)
[2]Dept. of Mineralogy and Petrology, National Museum, Prague, Czech Republic

Stoichiometry and site occupancies of minerals of the tetrahedrite group was suggested by simplified general formula [1] – $^{[III]}A_6{}^{[IV]}(B,C)_6{}^{[III]}X_4{}^{[IV]}Y_{12}{}^{[VI]}Z$, where *A* = Cu, Ag; *B* = Cu, Ag and *C* is generally divalent metal (typically Fe, Zn but also Hg, Mn, Cd etc.) in the same coordination as *B*; *X* = Sb, As, Bi, Te; *Y* and *Z* = S and Se. Hakite is Se – dominant member of tetrahedrite group. Since the experimental determination of the hakite structure is lacking the structure model based on the crystal structure of tetrahedrite with fully substituted *Y* and *Z* sites was adopted. Studied samples of hakite were found in a rich paragenesis of Ag, Hg, Pb, Cu, Sb, Cd, Tl selenides and other minerals containing As, Te, Sb, and U at the new occurrence in Příbram (uranium-base metals ore district, Czech Republic). Amount of 69 microprobe (WDS) analyses on 11 individual samples were performed. Based on different substituents detected by the microprobe study, several types of hakite were determined. *A* position is represented by Ag and Cu contents. At the *B* site Cu and at the *C* site Hg, Zn and lower amounts of Fe and Cd occur (Table 1). *X* site was occupied by Sb, minor contents of As and trace amounts of Te were detected. S-Se substitution was ascertained according to the abundant association of sulphides.

Table 1: Content of elements in Příbram hakite based on 29 apfu

	B	**C**			
	Cu	*Cd*	*Zn*	*Hg*	*Fe*
	3,41-4,85	0-1,05	0,01-1,82	0,01-1,95	0-0,73
mean	4,31	0,16	0,60	1,19	0,06
	A		**X**		
	Cu	*Ag*	*Sb*	*As*	*Te*
	5,71	0,03-1,20	3,36 - 4,18	0 - 0,67	0-0,52
mean	5,71	0,29	3,90	0,15	0,07
	Y, Z				
	S	*Se*	sum of anions		
	0,01 - 4,52	8,00 - 12,75	12,28-13,19		
mean	1,35	11,20	12,55		

According to the Table 1, it is obvious that the sum of anions is deficient compared to the ideal structure model of tetrahedrite. Mean of anions sum of 17 wds analyses on coexisted tetrahedrite gave 12,89 apfu. In spite of the rarity and small grain size of hakite, several samples were prepared for the X-ray powder diffraction study. Compared to the theoretical diffraction patterns calculated from the crystal-structure data the observed patterns of the hakite samples exhibited few additional reflections probably of the superstructure character.

Based on the chemistry and XRD results, we suppose presence of structural disorder and distortions of the hakite lattice with respect to the idealized structure adopted from tetrahedrite.

Structure of nagelschmidtite $Ca_7Si_2P_2O_{16}$

Sugiyama, K.[1*], Kato, Y.[1] & Mikouchi, T.[2]
[1]Institute for Materials Research, Tohoku University, Sendai, Japan ([*]kazumasa@imr.tohoku.ac.jp)
[2]Dept. of Earth and Planetary Science, University of Tokyo, Hongo, Japan

The metallugical properties of steelmaking slags are influenced by the formation of silicophosphates in the binary $2CaO{\cdot}SiO_2$ (C2S) - $3CaO{\cdot}P_2O_5$ (C3P) system. Silicophosphates with high concentration of phosphate in the slag are important as lime- and phosphorus-containing fertilizer. Several phase diagrams for the C2S-C3P system are found in the literatures and a wide stability region of α-C2S and $\bar{\alpha}$-C3P solid-solutions was confirmed at high temperatures above 1450°C [1,2]. In this context, nagelschmidtite [$Ca_7Si_2P_2O_{16}$] is generally inferred to be structurally similar to α-C2S [3]. Nevertheless, structural details of nagelschmidtite have not been revealed yet.

The single crystals of nagelschmidtite were prepared from a sintered pellet with the chemical composition $CaO:SiO_2:P_2O_5:Fe_2O_3$=49.2: 25.7: 12.0: 13.1mass%). The sintered sample was first melted at 1600°C and cooled down to 1400°C at a rate of 10°C/h. Almost colourless crystal ($P6_1$; a=10.82≈2*5.4Å, c=21.46≈7.1*3Å) could be selected and the structure was analyzed by the single crystal X-ray diffraction. The structure was solved by a combination of direct-methods and difference Fourier syntheses and Fig. 1 shows the obtained structural model. The structure is constructed by Ca layer and Ca-T layer similar to that of α-C_2S. Ca vacant site due to the substitution of PO_4 for SiO_4 is ordered in the Ca-T layer. The arrangement of TO_4 units (T=Si and P) is similar to that found in α–, α'$_H$-, α'$_L$- and β-C_2S structures.

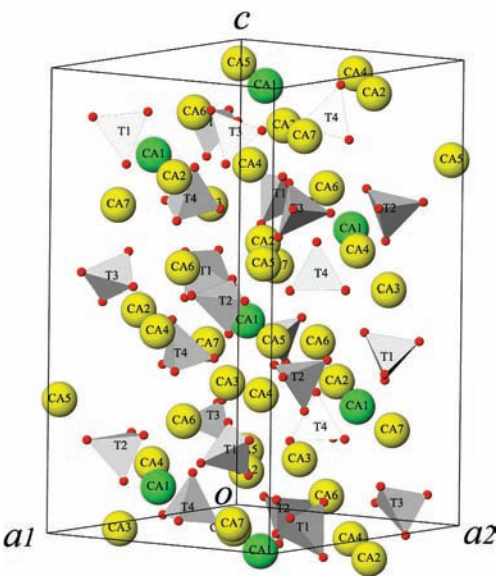

Fig. 1: Structure of nagelschmidtite [$Ca_7Si_2P_2O_{16}$].

The crystal structure of esperite, with a revised chemical formula, $PbCa_2(ZnSiO_4)_3$, isostructural with beryllonite

Tait, K.T.[1*], Yang, H.[2], Downs, R.T.[2], Li, C.[2] & Pinch, W.W.[3]
[1]Dept. of Natural History, Royal Ontario Museum, Toronto, Ontario, Canada ([*]ktait@rom.on.ca)
[2]Dept. of Geosciences, University of Arizona, Tucson, Arizona USA
[3]19 Stonebridge Lane, Pittsford, New York, USA

Esperite from Franklin, New Jersey was first described as monoclinic with a well-developed "superlattice" a = 2 × 8.814(2) Å, b = 8.270(3) Å, c = 2 × 15.26(1) Å, $\beta \approx 90°$, space group $P2_1/n$ (subcell), and a chemical formula $PbCa_3(ZnSiO_4)_4$ [1]. They attributed "superlattice" reflections to the ordered distributions of Pb and Ca cations over four beryllonite-type subcells for esperite with the Ca:Pb ratio greater than 2:1.

A fragment of esperite from the holotype sample (CMNMC 56855), Parker Shaft, Franklin, Sussex Co., New Jersey, U.S.A. was obtained for this study. We examined two esperite fragments from this sample using single-crystal X-ray diffraction, electron microprobe analysis, and Raman spectroscopy.

Although both fragments have Ca:Pb ≈ 1.8, one exhibits the "superlattice" reflections as observed in previous studies [1], whereas the other does not. The sample without "superlattice" reflections has unit-cell parameters a = 8.7889(2), b = 8.2685(2), c = 15.254(3) Å, β = 90.050(1)°, V = 1108.49(4) Å^3 and the chemical composition $Pb_{1.00}(Ca_{1.86}Fe^{2+}_{0.07}Mn_{0.04}Cr^{3+}_{0.02})_{\Sigma=1.99}(Zn_{1.00}Si_{1.00}O_4)_3$. Its crystal structure was solved in space group $P2_1/n$ (R_1 = 0.022). Esperite is isostructural with beryllonite, $NaBePO_4$, and its ideal chemical formula should, therefore, be revised to $PbCa_2(ZnSiO_4)_3$, Z = 4. The ZnO_4 and SiO_4 tetrahedra in esperite share corners to form an ordered framework, with Pb^{2+} occupying the nine-coordinated site in the large channels and Ca^{2+} occupying the two distinct octahedral sites in the small channels. The so-called "superlattice" reflections are attributed to triple twins, a twilling of ~60° rotational twinning around the b-axis, similar to those observed in many other beryllonite-type materials. A phase transformation from a high-temperature polymorph to the esperite structure is proposed to be responsible for the twinning formation.

A new acentric silicate: $K_{2.9}Rb_{0.1}ErSi_3O_9$

Wierzbicka-Wieczorek, M.[1,2*], Kolitsch, U.[2] & Tillmanns, E.[1]
[1]Institute for Mineralogy and Crystallography, University of Vienna, Austria ([*]maria.wierzbicka@univie.ac.at)
[2]Dept. of Mineralogy and Petrography, Natural History Museum, Vienna, Austria
[3]*present address*: Institute for Geosciences, Friedrich-Schiller University Jena, Germany

In a comprehensive study we had focused on the preparation, structural characterisation and classification of novel microporous and small-pore mixed-framework silicates containing seven specific octahedrally coordinated M^{3+}-cations (M = Sc, V, Cr, Fe, In, Y, Yb) [1] and, in a subsequent step, syntheses of representatives with REE^{3+} cations (REE = Eu, Gd, Tb, Ho and Er). The latter work yielded thirteen new REE-silicates, including colourless crystals of $K_{2.9}Rb_{0.1}ErSi_3O_9$, one of four new Er silicates. All compounds were grown with a high-temperature flux-growth technique in air (MoO_3–based flux mixtures in Pt crucibles; T_{max} = 1150°C, cooling rate 2 K/h, T_{min} = 900°C).

The crystal structure was determined from single-crystal X-ray intensity data (Mo$K\alpha$, 293 K) in space group $P\bar{1}$ (no. 1), with a = 6.672(1), b = 6.719(1), c = 6.725(1) Å, α = 108.87(3), β = 106.72(3), γ = 107.61(3)°, V = 245.82(6) Å^3, Z = 1, $R(F)$ = 2.81 %, Flack parameter 0.062(9).

The title compound represents a novel, pseudorhombohedral structure type. It is characterised by a mixed octahedral-tetrahedral framework, in which each corner of the isolated ErO_6 octahedra (<Er-O> = 2.26 Å) is linked to infinite $[Si_3O_9]$ chains extending approximately along [111] (Fig. 1). Narrow channels host three non-equivalent K sites, one of which is partially substituted by Rb. The unusual space group symmetry is mainly caused by the alkali sites that violate $R\bar{3}$ symmetry.

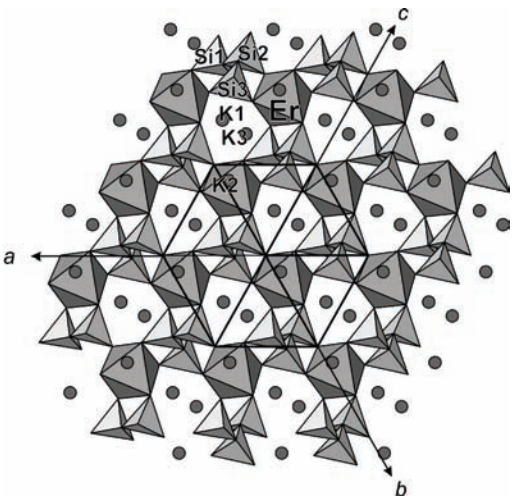

Fig. 1: View of $K_{2.9}Rb_{0.1}ErSi_3O_9$ along [111].

The geometry of the chain in $K_{2.9}Rb_{0.1}ErSi_3O_9$ is similar to that in pectolite, $NaCa_2[HSi_3O_9]$ [2]. The structural relation to further natural or synthetic chain $[Si_3O_9]$ silicates is less pronounced.

Crystal structure of (REE, Fe)-rich rengeite (saimaite) from Saima alkalic complex, NE China

Yang, Z.[1*], Giester, G.[2], Ding, K.[1] & Tillmanns, E.[2]
[1]Key Laboratory of Engineering Geomechanics, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China ([*]yangzhm@mail.igcas.ac.cn)
[2]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria

Saimaite was first described as a new mineral from Saima alkalic complex in Liaoning Province, NE China, and is an unconfirmed mineral. Previous single crystal and powder X-ray study gave monoclinic symmetry, space group *C*2/*m*, a = 13.8934, b = 5.6703, c = 11.9120 Å, β = 114.083°, V = 856.73 Å^3. Electron microprobe analyses indicate a general formula $(Sr,REE)_4Fe(Ti,Zr)_2Ti_2Si_4O_{22}$, where Fe is dominant in the B site [1]. Saimaite was also suggested to be the equivalent of strontio-chevkinite [2].

The present single crystal X-ray study on the type material was performed on a Nonius KappaCCD diffractometer. The structure was solved and refined in space group *C*2/*m*, with a = 13.973(3), b = 5.6984(11), c = 11.988(2) Å, β = 114.10(3)°, V = 871.3(3) Å^3, to R1 = 0.037, wR2 = 0.098. The formula of saimaite is $(Sr, Ce)_4Zr(Ti, Fe)_2(Ti, Fe)_2(Si_2O_7)_2O_8$ with Z = 2 according to the crystal structure refinement.

Saimaite is basically isostructural with rengeite (Fig. 1). According to the structural refinement strontium and rare earths were assigned into Sr sites. Zirconium occupies preferentially one of three octahedral sites. Iron shares the other two octahedral sites with Ti. Based on the study of Mössbauer spectroscopy, Fe^{3+} occupies two octahedral sites and Fe^{2+} occupies only one octahedral site. On the basis of cation radii Ca preferentially was assigned into the 8-coordinated Sr sites, then into Zr octahedral site. The formula of saimaite can be expressed as: $(Sr_{2.39}\,REE_{1.21}\,Ca_{0.35}\,Na_{0.09})_{\Sigma 4.04}\,(Zr_{0.80}\,Ca_{0.16}\,Hf_{0.02}\,Nb_{0.02}Th_{0.02}U_{0.01})_{\Sigma 0.99}\,(Ti_{1.44}Fe^{2+}_{0.32}Fe^{3+}_{0.20}Mg_{0.03}\,Mn_{0.02})_{\Sigma 2.01}\,(Ti_{1.80}\,Fe^{3+}_{0.20})_{\Sigma 2.00}\,(Si_{3.94}\,Al_{0.03})_{\Sigma 3.98}\,O_{22}$, where Zr is dominant in the B site. Compared with rengeite, saimaite is rich in rare earths, iron and calcium.

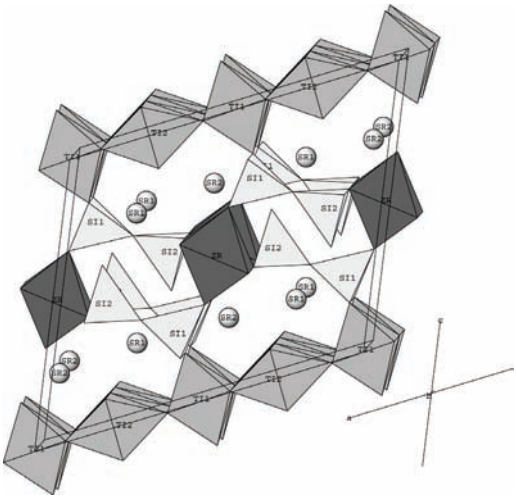

Fig. 1: Crystal structure of (REE, Fe)-rich rengeite (saimaite).

The crystal structure of saimaite was refined in space group *C*2/*m*, while the true space group of rengeite is $P2_1/a$. Although there are no significant differences in both refinements for rengeite[3], saimaite may be considered as a (REE, Fe)-rich polymorph of rengeite.

Hemimorphic wulfenite crystals from lead-zinc ore deposit Mežica, Slovenia

Zavašnik, J.[1*], Rečnik, A.[1], Samardžija, Z.[1], Meden, A.[2] & Dódony, I.[3]

([*]janez.zavasnik@ijs.si)
[2]FKKT, University of Ljubljana, Slovenia
[3]Eötvös L. University, Budapest, Hungary

Mežica lead-zinc ore field is located in the Northern Karavanke geotectonic unit, which belongs to Eastern Alps. The ore bodies span over a 64 sq. km wide area in the upper Meža valley. The ore is emplaced mostly in Triassic carbonate rocks. In addition to primary sulphides galena and sphalerite, the major oxidation product is lead molybdate ($PbMoO_4$) wulfenite that crystallized in economic quantities along shattered fault zones permeable for descending meteoric waters. While being abundant, Mežica wulfenites possess some peculiar morphological features, which are not observed on wulfenites from other localities. In addition to regular crystals with I4/m symmetry (tetragonal bipyramidal) we frequently encounter hemimorphic crystals with lower I4 symmetry (tetragonal pyramidal) with one of basal terminations flat, and the other pyramidal. In first reports on hemimorphism of Mežica wulfenites lower symmetry was proved by etching and piezoelectricity [1]. As a consequence of this low symmetry two different twinning laws have been described based on the macroscopic morphological characteristics of the crystals [2]. With the availability of modern analytical methods this problem was assessed by single crystal X-ray spectroscopy, transmission electron microscopy using high-resolution phase contrast and electron micro-diffraction techniques [3]. Our preliminary WDS analysis showed that wulfenites from Mežica are stoichiometric with Pb/Mo atomic ratio of 1:1 containing up to 0.30 at% of V replacing Mo in tetrahedral sites. Other impurity elements may be present below the detection limit. Micro-diffraction analysis showed a slight difference in intensity of **+g** and **-g** Friedel pairs of reflections related to the polar *c*-axis. Similar asymmetry is observed in the fine contrast features on high-resolution phase contrast images (below). Full structural analysis of the Mežica wulfenite and related planar defects; (001) basal plane inversion boundaries and interpenetration (110) twins is in progress.

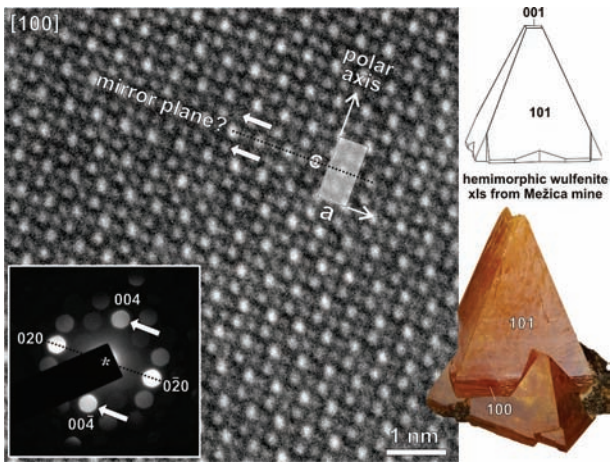

Fig. 1: HRTEM image with superimposed micro-diffraction pattern from hemimorphic Mežica wulfenite imply possible non-centrosymmetricity along the *c*-axis. The breakdown of Friedel's law is visible by difference in intensity of reflection pairs and by differences in image contrast.

Crystal structure of dumortierite from Lower Silesia, Poland

Zelek, S.M.[1*], Pieczka, A.[2] & Stadnicka, K.M.[1]
[1]Faculty of Chemistry, Jagiellonian University, Krakow, Poland
([*]zelek@chemia.uj.edu.pl)
[2]Faculty of Geology, Geophysics and Environment Protection, AGH University of Science and Technology, Krakow, Poland

X-ray structure analysis was used to investigate single crystals of dumortierite $(Al,Fe,Ti,\square)_7[O_3|BO_3|(SiO_4)_3]$ from Krucze Rocks, Karpacz, where this boro-silicate is an accessory mineral of Karkonosze pegmatites (Fig. 1). The mineral was found as grey-violet aggregates, up to 1 cm in size, formed by violet blades up to 1 mm long.

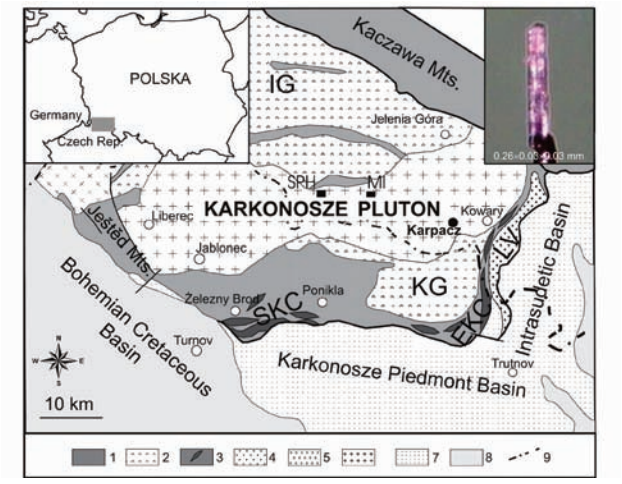

Fig. 1: Sketch map of Karkonosze-Izera massif (after [1]) with the view of dumortierite crystal from Krucze Rocks, Karpacz, inserted in the right-top corner.
1: Low-grade metasediments with subordinate metavolcanics, 2: Medium-grade metasediments and metagranitoids, 3: Low-grade metamorphosed volcano-sedimentary sequences with abundant bimodal metavolcanics, 4: Low- and medium-grade metamorphosed volcano-sedimentary sequances dominated by mafic rocks, 5: Late Proterozoic and Cambria/Ordovican granitoids, 6: Variscan granitoids, 7: Carboniferous and Permian syn- and post-orogeic deposits, 8: Mesozoic platform deposits, 9: Polish - Czech border, IG: Izera gneisses with mica schist belts, EKC: East Karkonosze Complex, LV: Leszczyniec unit, SKC: South Karkonosze Complex; SHP: Szklarska Poręba Hute, MI: Michałowice quarries.

Lattice cell parameters of the dumortierite from Poland are shown in Table 1 with respect to those of dumortierite of different origin.

Table 1: Comparison of the lattice cell parameters (Å) for dumortierite minerals of different origine. Space group setting: Pnma

	[2]: Saharina, Madagascar	[3]: Dora-Maira, Western Alps	[4]: Gföhl, Lower Austria	[4]: Weißenkirchen in der Wachau, Lower Austria	This work: Krucze Rocks, Karpacz
a	4.7001(5)	4.730(2)	4.6900(3)	4.6948(2)	4.6935(1)
b	11.828(1)	11.91(3)	11.7875(6)	11.8037(5)	11.7894(3)
c	20.243(3)	20.40(3)	20.1823(11)	20.2106(8)	20.2197(6)

The violet colour of the dumortierite from Krucze Rocks may suggest, according to [5], the existence of two types of Fe-Ti dimers: [-□-Fe^{2+}-Ti^{4+}-□-] and [-M-Fe^{2+}-Ti^{4+}-□-], with some disorder in the M(1) chains including the voids.

Crystal structure of NO_3 – bearing haüyne from Oldoinyo Lengai volcano, Northern Tanzania

Zolotarev, A.A. Jr.[1*], Krivovichev, S.V.[1], Zaitsev, A.N.[1,2] & Keller J.[3]
[1]Saint-Petersburg State University, Saint-Petersburg, Russia
([*]aazolotarev@gmail.com)
[2]Dept. of Mineralogy, Natural History Museum, London, UK
[3]Institute of Geoscience Mineralogy - Geochemistry, Freiburg University, Freiburg, Germany

We have studied crystal structure of sample of gem-quality haüyne from alkaline plutonic rock of the active Oldoinyo Lengai volcano in northern Tanzania [1]. Single crystal experiment (Stoe IPDS II, MoKα radiation) provided space group *P*-43*n*, a = 9.0319(9) Å, V = 736.8(1) $Å^3$. Final refinement converged to agreement indices (R_1) 0.0525 for 332 unique observed reflections. Crystal chemical formula calculated on the basis of chemical analysis [1] is in accord with the results of crystal-structure refinement: $(Na_{6.75}Ca_{0.87}K_{0.37})_{\Sigma 7.99}(Al_{5.97}Fe^{3+}_{0.03}Si_{6.00}O_{24})[(SO_4)_{0.89}(OH)_{0.54}(NO_3)_{0.23}Cl_{0.20}(CO_3)_{0.12}]_{\Sigma 1.98}$.

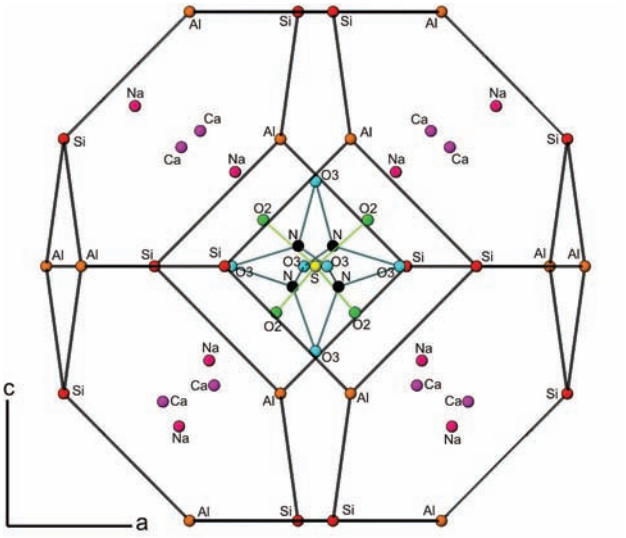

Fig. 1: The content of NO_3 – bearing haüyne cage.

The Al-Si ordered tetrahedral framework of our mineral is typical for sodalite-group minerals. The content of haüyne cages (Fig. 1) is highly disordered [2-4]. Our mineral is the first naturally occurring NO_3-bearing species from the sodalite group [1].

Is the oxygen really involved in the β-As_4S_4 – pararealgar transformation?

Zoppi, M.[1*] & Pratesi, G.[1,2].
[1]Museo di Storia Naturale – Sezione di Mineralogia, Università di Firenze, Florence, Italy ([*]matteo.zoppi@unifi.it)
[2]Dipto. di Scienze della Terra, Università di Firenze, Florence, Italy

The mineral realgar (As_4S_4) and its polymorphs have often attracted the attention of mineralogists and chemists for their peculiar alteration process induced by light. Realgar, along with orpiment (As_2S_3), have been employed as orange and yellow pigments, respectively, by artists through different ages, from the ancient Egypt to the Middle Age and the Renaissance. During the alteration, the orange colour of realgar turns yellow; such process is highly interesting both from the structural point of view and owing to the implications regarding the study and conservation of antique paintings. The process of light-induced alteration of the high temperature polymorph of realgar, β-As_4S_4, has been studied through X-ray powder diffraction applying the Rietveld method, thus giving a structural interpretation of the χ-phase, a precursor of pararealgar already recognized as playing an important role in the alteration process. Synchrotron radiation has been employed to use the highest X-ray intensities and counting statistics in a case where the material undergoes strong degradation and reorganization of its structure. The light-induced alteration carried out on the β-As_4S_4 crystalline powder, encapsulated in kapton tape, brought to the full transformation to pararealgar with the remarkable result that any presence of arsenolite was detected. The alteration causes an anisotropic increase of the unit-cell volume of the β- As_4S_4, with the decreasing of the a and β parameters, and the increasing of b and c. The process takes place through different stages that have been described using a different structural model with respect to that previously proposed. Initially the structure of β- As_4S_4 begins changing because of the transformation of its molecules into those typical of pararealgar, still maintaining the same packing. The alteration proceeds until about half of the As_4S_4 molecular units are replaced, then this phase progressively disappears transforming into pararealgar which still retains a certain amount of molecules of the β- As_4S_4 in its lattice. The last part of the process shows a contraction of the unit-cell volume of pararealgar, performed through a decreasing of the a, b and c parameters and an increasing of the β angle. The χ-phase is here described as a disordered molecular mixing of different units, those of the β- As_4S_4 and pararealgar. The formation of arsenolite, observed in many cases, might be rather an effect of the rupture of the realgar-type molecule in the presence of oxygen and the only creation of As-O bonds.

The topologies of nano-scale uranium clusters

Burns, P.C.[*], Ling, J., Sigmon, G.E., Unruh, D.K. & Forbes, T.Z.
Dept. of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN, USA
([*]pburns@nd.edu)

The topological details of approximately 30 nano-scale uranium oxide clusters will be examined. These clusters form through the edge-sharing of uranyl hexagonal bipyramids. Some are fullerene topologies containing 12 pentagons and an even number of hexagons, whereas others also containing squares, leading to considerable topological diversity.

Novel crystal-chemical relations in layered Ti silicates

Cámara, F.[1*] & Sokolova, E.[2]
[1]CNR-IGG, UOS Pavia, Italy ([*]camara@crystal.unipv.it)
[2]Dept. of Geological Sciences, University of Manitoba, Winnipeg, MB, Canada

We consider structure topology for a group of Ti disilicates based on our single-crystal X-ray structure work on four Ti-disilicate minerals, jinshajiangite, cámaraite, bornemanite and nechelyustovite, and two possible new mineral species with preliminary ideal formulae $Na_4BaTi_2Nb(Si_2O_7)_2O_3(OH)(H_2O)_2$ (mineral A) and $Na_3KBaTi_2Nb(Si_2O_7)_2O_3(OH)(H_2O)_6$ (mineral B). These minerals belong to a group of Ti silicates with a TS (titanium silicate) block [1-4]. Structure types of cámaraite, bornemanite, nechelyustovite and minerals A and B are new.

The general formula of the TS block is $A^P{}_2B^P{}_2M^H{}_2M^O{}_4(Si_2O_7)_2X_{4+n}$, where $M^H{}_2$ and $M^O{}_4$ are cations of the H and O sheets; M^H = Ti, Nb, Zr, Mn^{2+}, Ca; M^O = Ti, Zr, Fe^{2+}, Mn^{2+}, Ca, Na; A^P and B^P = cations at the peripheral (*P*) sites = Na, Ca, Ba, K; X = O, OH, F; n = 0,2,4 [4]. The TS block is composed of a central trioctahedral (O) sheet and two adjacent (H) sheets of [5-7]-coordinated polyhedra and (Si_2O_7) groups. All structures consist of a TS block and an **I** (intermediate) block that comprises atoms between two TS blocks. The **I** block consists of alkali and alkaline-earth cations, (H_2O) groups and the oxyanions (PO_4), (SO_4) and (CO_3). Structures of Ti disilicate minerals have been divided into four groups, each characterized by different linkage, content and stereochemistry of Ti (= Ti+Nb) in the TS block. In Groups I, II, III and IV, Ti = 1, 2, 3 and 4 *apfu*, respectively [4]

In jinshajiangite and cámaraite, Ti = 2 *apfu* and the TS block exhibits the stereochemistry of Group II. In bornemanite, nechelyustovite, minerals A and B, Ti = 3 *apfu*, the TS block is as in Group III. Jinshajiangite contains one type of **I** block (as in perraultite); cámaraite, bornemanite and minerals A and B, two types of **I** block; nechelyustovite, three topologically and chemically different **I** blocks. The structures of nechelyustovite and mineral B contain a new (for TS-block minerals) type of **I** block, an array of H_2O groups of ideal composition $(H_2O)_5$. Structures with a new type of TS block (more than one **I** block and more than one type of self-linkage of TS blocks) are related to structures of other minerals from the same Group: cámaraite, to bafertisite and jinshajiangite (Group II); bornemanite, to vuonnemite and barytolamprophyllite (Group III); nechelyustovite, to epistolite, barytolamprophyllite and a yet unknown structure (Group III); mineral A, to epistolite and barytolamprophyllite (Group III); mineral B, to barytolamprophyllite and a yet unknown structure. Minerals with a new type of TS-block structure and related minerals occur in the same environment and often form intimate intrgrowths. Discovery of five minerals with a new type of a TS-block structure (a) confirms that the chemical composition of the **I** block dictates the type of self-linkage of TS blocks [5]; (b) emphasizes the role of Ba↔Na exchange which results in changes in the topology of the **I** block and subsequently self-linkage of TS blocks (e.g. the bafertisite-cámaraite-jinshgagiangite series); (c) enlarges the number of transformation-mineral series [6] due to Na-depletion, bornemanite → nechelyustovite, Group III.

From chemical composition to structure topology in Ti silicates

Sokolova, E.[1*] & Cámara, F.[2]
[1]Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada ([*]elena_sokolova@umanitoba.ca)
[2]CNR-Istituto di Geoscienze e Georisorse, Unità di Pavia, Italy

Sokolova [1] developed general structural principles and established the relation between structure topology and chemical composition for 24 Ti disilicate minerals containing the TS (titanium-silicate) block. The TS block is composed of a central trioctahedral (O) sheet and two adjacent (H) sheets of [5-7]-coordinated polyhedra and (Si_2O_7) groups. The general formula of the TS block is $A^P{}_2B^P{}_2M^H{}_2M^O{}_4(Si_2O_7)_2X_{4+n}$, where $M^H{}_2$ and $M^O{}_4$ are cations of the H and O sheets; M^H = Ti (= Ti + Nb), Zr, Mn^{2+}, Ca; M^O = Ti, Zr, Fe^{2+}, Mn^{2+}, Ca, Na; A^P and B^P = cations at the peripheral (*P*) sites = Na, Ca, Ba, K; X = anions = O, OH, F; n = 0, 2, 4. All structures consist of a TS block and an **I** (intermediate) block that comprises atoms between two TS blocks. Usually, the **I** block consists of alkali and alkaline-earth cations, (H_2O) groups and the oxyanions $(PO_4)^{3-}$, $(SO_4)^{2-}$ and $(CO_3)^{2-}$. Structures of Ti disilicate minerals naturally fall into four groups, each characterized by the topology and stereochemistry of the TS block. In Groups I, II, III and IV, Ti = 1, 2, 3 and 4 *apfu*, respectively. General structural principles of Sokolova [1] have been developed for structures that contain one type of a TS block, one type of an **I** block and exhibit one type of self-linkage of TS blocks. We define them as ***basic*** structures.

Here we consider 32 Ti disilicates. Of those 24 minerals [1], structure refinement was done for rinkite, barytolamprophyllite, nabalamprophyllite, murmanite and lomonosovite. *Basic* structures have been reported for mosandrite [2], nacareniobsite-(Ce) and jinshajiangite. Our recent work on 5 titanium disilicates, bornemanite, nechelyustovite and cámaraite, and two possible new mineral species, with preliminary ideal formulae $Na_4Ba\ Ti_2Nb\ (Si_2O_7)_2\ O_3\ (OH)\ (H_2O)_2$ (mineral A) and $Na_3KBa\ Ti_2Nb\ (Si_2O_7)_2\ O_3\ (OH)\ (H_2O)_6$ (mineral B), has resulted in discovery of a new type of TS-block structure. These new structures have more than one type of **I** block and one or more types of self-linkage of TS blocks. We define them as ***derivative*** structures. A *derivative* structure is usually related to two *basic* structures of the same Group, and all three structures have the same topology of the TS block and content of Ti. All derivative structures occur in Groups II and III (Ti = 2 and 3 *apfu*) and contain Ba in at least one **I** block. Discovery of *derivative* structures allows us to predict possible new structure topologies for Groups II and III. Those structure models will be developed in our talk.

Here, we also address another problem: different topologies for Ti and Fe^{3+} disilicates. The crystal structure of orthoericssonite, ideally $BaMn_2Fe^{3+}(Si_2O_7)O(OH)$, does not obey the general topological principles for Ti disilicates with the TS block. The substitution $Ti^{4+} \rightarrow Fe^{3+}$ is quite common because of the similar size of the cations: 0.58 Å for $^{[5]}Fe^{3+}$ and 0.51 Å for $^{[5]}Ti^{4+}$. The O sheet of the HOH block in orthoericssonite is identical to the O sheet in the structures of Group-II Ti disilicates: $M^O = Fe^{2+}$, Mn^{2+}, but the topology of the HOH block is different from the structures of Group II. We explain how bond-valence requirements of anions shared by the O and H sheets dictate different topologies for Ti and Fe^{3+} disilicates.

Based on new structural information, revised structural principles for Ti disilicates are outlined.

The role of Be in the formation of beryllosilicate crystal structures

Grice, J.D.
Research Division, Canadian Museum of Nature, Ottawa, Ontario, Canada (jgrice@mus-nature.ca)

Topological diagrams, based on the primary building units (PBU), the tetrahedral coordination sites, were constructed for all layered [1] and framework [2] beryllium silicates. These diagrams are used to calculate topological density (TD), identify secondary building units (SBU) and to extract vertex symbols (VS) and coordination sequences (CS). The SBU's, are used to create a structural classification and hierarchy among beryllosilicates. The VS's facilitate identification of the most common ring formations; 4-, 5- and 8-fold rings in layered structures and 3-, 4-, and 6-fold rings in framework structures. CS's give insight into relationships between crystal structures of widely varying chemical composition. CS's may be used to calculate the cluster population (CP) for any shell volume within the structure. In beryllosilicates the FD and CP are highly correlated (R^2 = 0.94). Using the CP has some advantages over the CP for determining crystal structures versus chemical composition correlations as it is independent of the tetrahedral cation size.

The effect of the Be content on CP or FP is of great interest as it can be used in the design parameters of a framework. Si alone cannot form 3-fold rings in framework silicates. The addition of Be increases the number 3-fold rings. A Be proportion of up to 30% of the tetrahedral sites decreases FD but further addition of Be rapidly increases FD. Zeolite formation, which requires a low FD, can be adjusted with the Be content.

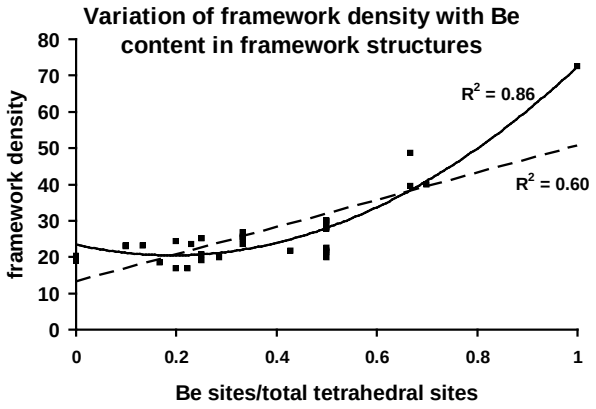

Fig. 1: Variation of framework density with Be content in framework structures.

[1] Grice, J.D. et al. (2009) *Can. Mineral.*, **47**, 193-204. [2] Grice, J.D., Raade, G. & Cooper, M.A. (2010) *Can. Mineral.*, **48(2)**, 255-266.

Some topological aspects of the crystal chemistry of actinide borates

Alekseev, E.V.[1*], Wang, S.[2], Albrecht-Schmitt, T.E.[2] & Depmeier, W.[1]
[1]Dept. of Crystallography, University of Kiel, Germany
([*]ea@min.uni-kiel.de)
[2]Dept. of Civil Engineering and Geological Sciences and Dept. of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana, USA

The methods of nuclear fuel vitrification in borate or boroaluminate glasses are very common in nuclear industry. The glasses contain actinides and the products of their decay. For a long time this type of storage of very dangerous components has been considered as very safe because of the high kinetic and chemical stability of the borate glasses. The study of the products (actinyl borates) of the potential re-crystallization of the corresponding glass-blocks is very important in view of understanding their stability on geological time scales (thousands and million years).

Recently, we have found a very easy and efficient method for the synthesis of actinide borates. Using a H_3BO_3 flux, we have synthesized several actinyl borates (24 uranyl borates, 4 neptunyl borates, 1 plutonyl and 1 thorium borate) [1-4]. These phases were characterized by X-ray diffraction, spectroscopic and other methods. Several synthesized phases possess unique structural properties, both in actinide chemistry and in chemistry in general. For example, in the structure of Np-borates we have found three different oxidation states (+4, +5 and +6) and three different coordination polyhedra of Np (coordination numbers 6, 7 and 8). The thorium borate (NDTB-1) has a unique supertetrahedral cationic framework with large open channels and pores. This structure allows fast anionic exchange of MnO_4^-, CrO_4^{2-}, $Cr_2O_7^{2-}$. The most important particularity of NDTB-1 is that it exchanges TcO_4^-. The results are very promising as NDTB-1 removed 72% of Tc from solution in 36 hours. Many of the synthesized uranyl borates are non-centrosymmetric and demonstrate non-linear optical properties.

Many of these properties appear because of the special topologies of oxo-borate sheets and clusters which is passed on to the resulting layered or framework structures. Nine different types of oxo-borate sheet topology have been observed by now in uranyl, neptunyl and plutonyl compounds. Only one of these structures has oxo-borate chains as a structural fragment. Some of the topologies are enantiomorphic, while others are not. The centro-symmetric and non-centrosymmetric structures achieved in the uranyl borates depend on the type of the oxo-borate sheets, their alteration and orientation within the crystal structures. A classification of the crystal structures and oxo-borate sheets based on their topological aspects is proposed.

Finite automata, formal languages and bond topologies in mineral and inorganic structures

Krivovichev, S.V.
Dept. of Crystallography, St. Petersburg State University, St. Petersburg, Russia (skrivovi@mail.ru)

The basic property of crystalline matter that makes possible their investigation by means of X-ray diffraction is its periodicity, which means that topological graph of chemical bonds in the structure is always periodic. In turn, this means that the structure is the result of periodic process, i.e. its construction involves a finite number of local chemical interactions that repeats over and over during structure growth. The process of growth of periodic mathematical structure that symbolizes a real chemical structure (e.g., graph, tiling [1]) may be modeled using theory of finite automata.

A finite automaton (FA) is defined as consisting of finite number of states (each equivalent to a certain chemical configuration) and finite number of transition rules that describe transformation of chemical configurations during growth process. Deterministic FA (=DFA) produces completely ordered structures, whereas non-deterministic FA (=NDFA) may generate structures with a certain degree of chemical or configurational disorder. In some sense, crystals are results of performance of computer programs, which were identified by A. Mackay [2] as 'inorganic genes'. Since structures of many minerals and inorganic compounds are known and their formal topological classifications are elaborated [3], it is an interesting task to classify their programs or 'genes' (the last term makes a perfect sense from the viewpoint of mineral evolution [4,5]), and to see how these genes evolve over micro or macro geological history.

Another interesting aspect of application of FA to crystal structures is that, in computer science, FA are put in direct correspondence to formal languages [6], and the formal structure (state diagram) of FA is associated with rules that govern formation of words from a finite set of symbols (production rules). From this viewpoint, FAs generating related bond topologies may be grouped into families of languages that may be derived from one superlanguage or pra-language.

It should be noted that formal language is a highly abstract construction. Its construction may be represented by FA, and the projection of the FA into topological space produces a graph, which, in turn, projects into real chemical space to produce a bond topology. How many different pra-languages are behind mineral structures? Do these pra-languages mix? How languages are related to chemical properties of ions, coordination polyhedra or fundamental building blocks? Questions of this type are highly provocative but are absolutely justified from the viewpoint of automata and formal language theory of mineral structures.

A special class of DFA is cellular automata that are used as models of discrete dynamic systems in different branches of science and can be used to model structures of minerals and inorganic materials [7].

Generating functions for structure and chemical composition

Hawthorne, F.C.
Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada (frank_hawthorne@umanitoba.ca)

Any crystal structure may be represented by a weighted chromatic digraph, the vertex set of which represents atoms and the edge set of which represents chemical bonds. We may write tetrahedrally coordinated cations and their associated anions as $\{T_{2n}\Theta_m\}$. For $\{T_{2n}\Theta_m\}$ to be a chain or ribbon, $5n < m \leq 6n$, and we may write m as 5n + N, where N is an integer. Within the $\{T_{2n}\Theta_{(5n+N)}\}$ unit, we may recognize three types of anion vertices: (1) bridging anions, Θ^{br}, that are bonded to two T cations; (2) apical anions, Θ^{ap}, that are involved in linkage to other cations out of the plane of the bridging anions; and (3) linking anions, Θ^{l}, that link to non-T cations in the plane of the bridging anions. We can incorporate the connectivity of the cations our algebraic representation of the chain as follows: $\{T_{2n}\Theta^{br}{}_a\Theta^{nbr}{}_b\Theta^{ap}{}_c\}$ where a + b + c = 5n + N. The apical anions of the T-layer map onto a 6^3 net which, in turn, maps onto the 3^6 net of anions of the O-layer. We may use the handshaking dilemma of graph theory to examine the interaction between the two types of layers, and write a *Structure-Generating Function*, $S_{\mathbf{n}}$, that gives both the stoichiometry and aspects of the bond topology of the structures. Where N = 1, the T component is $\{T_{2n}\Theta_{5n+1}\} = \{T_{2n}\Theta^{br}{}_{3n-1}\Theta^{ap}{}_{2n}\Theta^{l}{}_2\}$. Each T-$\Theta^{br}$-T linkage spans an octahedron, and hence there are 3n-1 octahedrally coordinated cations between opposing $\{T_{2n}\Theta^{br}{}_{3n-1}\Theta^{ap}{}_{2n}\Theta^{l}{}_2\}$ ribbons. In the biopyribole series, the $\{T_{2n}\Theta^{br}{}_{3n-1}\Theta^{ap}{}_{2n}\Theta^{l}{}_2\}$ ribbon is unbranched and contains (n-1) loops. Each loop must correspond to one additional anion (denoted φ) that is bonded to the M cations and not bonded to a T cation. We may thus write the structure-generating function, $S_{\mathbf{n}}$, for the biopyribole structures as follows: $S_n = [M_{(3n-1)}\Psi_{2(n-1)}\{T_{2n}\Theta^{br}{}_{(3n-1}\Theta^{ap}{}_{2n}\Theta^{l}{}_2\}_2]$; note that the anion notations Θ^{br}, Θ^{ap} and Θ^{l} carry information on the structural linkage that the chemical formula does not. Interstitial sites are occupied by $X_{\mathbf{I}}$ cations so as to (1) achieve electroneutrality, and (2) satisfy the local-sum rule of bond-valence theory. For n = 1, $S_1 = X_{\mathbf{I}}[M_2\Psi_0\{T_2\Theta_6\}_2]$, the pyroxenes. For n = 2, $S_2 = X_{\mathbf{I}}[M_5\Psi_2\{T_4\Theta_{11}\}_2]$, the amphiboles. For n = 3, $S_3 = X_{\mathbf{I}}[M_8\Psi_4\{T_6\Theta_{16}\}_2]$, the triple-chain pyriboles. For n = 4, $S_4 = X_{\mathbf{I}}[M_{11}\Psi_6\{T_8\Theta_{21}\}_2]$; no structure of this formula has yet been found. For $n = \infty$, $S_\infty = X_{\mathbf{I}}[M_{(3n-1)/n}\Psi_{2(n-1)/n}\{T_2\Theta_{(5n+1)/n}\}_2 = X_{\mathbf{I}}[M_{(3-1/n)}\Psi_{2-2/n}\{T_2\Theta_{5+1/n}\}_2] = X_{\mathbf{I}}[M_3\Psi_2\{T_2\Theta_5\}_2]$ (*e.g.*, phlogopite). Where N = 2, the general form of the T component is $\{T_{2n}\Theta_{5n+2}\}$ which corresponds to the T component of H-layers in the polysomatic H-O-H series in which the ribbons are linked laterally by [5]- or [6]-coordinated cations, D, which have the coordination $(D\Theta^{l}{}_4\Phi^{\mathbf{ap}}\Phi^{\mathbf{t}}_{\mathbf{0\text{-}1}})$. The general formula for an H layer is $[D\Phi^{\mathbf{ap}}\{T_{2n}\Theta^{br}{}_{3n-2}\Theta^{ap}{}_{2n}\Theta^{l}{}_4\}\Phi^{\mathbf{t}}_{\mathbf{0\text{-}1}}]$, where $\Phi^{\mathbf{t}}$ after the T component occurs on the outside of the H-layer and is involved in linkage between adjacent H-O-H sheets. The H-layer links via its apical anions to the O-layer, giving the general formula of an H-O-H sheet as $[M_{3n+1}(D\Phi^{\mathbf{ap}}\Psi_n\{T_{2n}\Theta_{5n+2}\}\Phi^{\mathbf{t}})_2]$. These H-O-H sheets can link directly through the $\Phi^{\mathbf{t}}$ anions of the $(D\Theta^{l}{}_4\Phi^{\mathbf{ap}}\Phi^{\mathbf{t}}_{\mathbf{0\text{-}1}})$ octahedra, giving $S_{\mathbf{n}} = X_{\mathbf{I}}[M_{(3n+1)}\Psi_{2n}(D_2\Phi_2\{T_{2n}\Theta_{5n+2}\}_2)\Phi_{0\text{-}2}]$. For n = 1, $S_1 = X_{\mathbf{I}}[\{M_4\Psi_2(D_2\Phi_2\{T_2\Theta_7\}_2)\Phi_{0\text{-}2}]$, the group-1 TS-block structures (*e.g.*, seidozerite: $Na_2[Na_2MnTiO_2(Zr_2\{Si_2O_7\}_2)F_2]$). For n = 2, $S_2 = X_{\mathbf{I}}[M_7\Psi_4(D_2\Phi_2\{T_4\Theta_{12}\}_2)\Phi_{0\text{-}2}]$, the astrophyllite-group structures (*e.g.*, $K_2Na[Fe^{2+}{}_7O_2(OH)_2F(Ti_2\{Si_4O_{12}\}_2)(OH)_2]$). For n = 3, $S_3 = X_{\mathbf{I}}[M_{10}\Psi_6(D_2\Phi_2\{T_6\Theta_{17}\}_2)\Phi_{0\text{-}2}]$, *e.g.*, nafertisite: ideally $Na_2[Fe^{2+}{}_{10}O_2(OH)_6(Ti_2\{Si_{12}O_{34}\})](H_2O)_{0\text{-}2}$. For n = 4, $S_4 = X_{\mathbf{I}}[M_{13}\Psi_8(D_2\Phi_2\{T_8O_{22}\}_2)\Phi_{0\text{-}2}]$, *e.g.*, $Na_2[Fe^{2+}{}_{13}O_2(OH)_8(Ti_2\{Si_{16}O_{44}\})(OH)_2]$; no structure of this formula has yet been found. For $n = \infty$, $S_\infty = X_{\mathbf{I}}[M_{(3n+1)/n}\Psi_{2n/n}(D_{2/n}\Phi_{2/n}\{T_2\Theta_{(5n+1)/n}\}_2)\Phi_{2/n}] = X_{\mathbf{I}}[M_{(3-1/n)}\Psi_2(D_{2/n}\Phi_{2/n}\{T_2\Theta_{(5+1/n}\}_2)\Phi_{2/n}] = X_{\mathbf{I}}[M_3\Psi_2\{T_2\Theta_5\}_2]$ (e.g., phlogopite , $K[Mg_3(OH)_2\{AlSi_3O_{10}\}]$).

Crystal structure of $Na_3Fe(SO_4)_3$, a high temperature product of thermal decomposition of sideronatrite, $Na_2Fe(SO_4)_2(OH)3H_2O$

Scordari, F.[1], Ventruti, G.[1*], Gualtieri, A.F.[2] & Lausi, A.[3]

([*]ventruti@geomin.uniba.it)
[2]Dipto. di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia, Modena, Italy
[3]Sincrotrone Trieste, Basovizza(TS), Italy

The iron sulphate $Na_3Fe(SO_4)_3$ studied here has been obtained as a high temperature (HT) product (~400°C) of the thermal decomposition of a hydrated sulphate of sodium and ferric iron, sideronatrite ($Na_2Fe(SO_4)_2(OH)\cdot 3H_2O$), from Sierra Gorda, Chile [1]. Its structure has been determined and refined using high resolution powder diffraction data collected at the MCX beamline at ELETTRA synchrotron source (Trieste, Italy). The $Na_3Fe(SO_4)_3$ compound is trigonal, space group: R-3 with a = 13.6452(1), c = 9.0842(2) Å, V = 1464.80(2) $Å^3$ and Z = 6. Building blocks of the structure are FeO_6 octahedra linked by corner-sharing $(SO_4)^{2-}$ tetrahedra to form infinite columns $[Fe(SO_4)_3]^-$ running along the c axis. These columns occur around three-fold axes and are linked to each other by interstitial Na.

The characteristic topology of this compound is also present in the mineral ferrinatrite, $Na_3(H_2O)_3Fe(SO_4)_3$ [2], where adjacent chains are linked both by interstitial Na atoms and hydrogen bonds belonging to H_2O coordinated by Na cations. The structure of the $Na_3Fe(SO_4)_3$ HT phase can be described as the 'imploded' version of ferrinatrite. The structure of a new mineral pyracmonite, $(NH_4)_3Fe(SO_4)_3$, has been recently solved by Demartin et al [3]. Like our compound, it is based on infinite $[Fe(SO_4)_3]_\infty$ chains but, differently from it, interchain linkages involve only hydrogen bonds from the ammonium ions. Recently a further new mineral having the same composition $Na_3Fe(SO_4)_3$, was found among fumarolic encrustations at Eldfell volcano, Heimaey Island, Iceland [4]. It occurs in association with eldfellite, ralstonite, anhydrite, gypsum, bassanite, hematite, opal and tamarugite. The mineral is hygroscopic and unstable in the open air. Synthetic $Na_3Fe(SO_4)_3$ played an important role in several high temperature solid state reactions in the industrial processes of pigments, catalysis and magnetic materials.

Between modular and modulated: composite layer structures of complex sulfosalts

Makovicky, E.
Dept. of Geography and Geology, University of Copenhagen, Denmark (emilm@geol.ku.dk)

Complex sulfides of Pb, Sn, Sb, Bi or As, often with minor Cu, Ag and/or Fe, contain structural families with a modular or modulated character. Modularity and modulation occur in different proportions, types and combinations in the new/recently refined structures of sulfosalts with a composite layer character shown here.

Cylindrite, exemplified here by its synthetic representative, $Sn_{31.5}Sb_{6.2}Fe_{3.1}Se_{59.1}$ [1], is composed of alternating pseudotetragonal (Q) layers Me_2Se_2, two atomic planes thick, and pseudohexagonal (H) layers MeS_2. The composite structure is noncommensurate in two dimensions and sinusoidally modulated in one of them, with OD phenomena in layer stacking. It is an accretional homologue N = 1, whereas N = 2 homologue is *franckeite*, $Pb_{4.6}Ag_{0.2}Sn_{2.5}Sb_2Fe_{0.8}S_{12.6}$, with a newly determined crystal structure in which the Q layers are of double thickness (four atomic planes thick), with a central gap accommodating lone electron pairs of cations in an SnS-like manner. Orientation of the Q layers in this family of Pb-Sn^{2+}-Sn^{4+} structures differs from the following Pb-Bi sulfosalts.

Cannizzarite is a modulated, 1D-incommensurate composite structure in which the M_2S_3 H-layer has double thickness. The hypothetical sectioning of cannizzarite layers into ideally commensurate moduli by [2] has been substantiated when we found one of these component moduli as an independent structure. The accretional *proudite-felbertalite* homologous series of Cu-Pb-Bi sulfosalts [3] is based on pseudohexagonal double-octahedron H-layers alternating with Q layers. Its accretional character (interface modulation) is demonstrated by the variable width of straight layer portions between copper-bearing step-like offsets. This series, however is the N =2 homologue in the thickness of H layers; the N =1 variety is *junoite*, $CuPb_3Bi_7(S,Se)_{14}$.

A new family of structures has Q layers that are three atomic planes thick and H layers only one atom thick. They are composite *lock-in* structures with a simple ratio of subperiodicities of the two layer types. The Q layer contains linear-coordinated Ag or Cu whereas the H layer has triangular-to-tetrahedral Cu or Ag. *Berryite*, $Cu_3Ag_2Pb_3Bi_7S_{16}$ [4], is composed of two alternating types of Q moduli whereas the two new isotypic structures, Cu-based *watkinsonite*, $Cu_2PbBi_4Se_8$, and the Ag-based *litochlebite*, $Ag_2PbBi_4Se_8$, have only one type.

Disordered structures and polytypism – the OD approach

Merlino, S.
Dipto. di Scienze della Terra, Università di Pisa, Italy (merlino@dst.unipi.it)

The OD approach in dealing with polytypic structures, one-dimensional disorder and twinning (mainly polysynthetic twinning) has been introduced more than fifty years ago [1]. Notwithstanding the theory is firmly built and a number of practical tools for its utilization are available [2], it is still far from constituting a 'normal' professional equipment for mineralogists, and crystal chemists and crystallographers as well.

The main reasons for that are probably the assumption that OD structures are relatively few in number and that their arrangements may be solved and described without the introduction of OD theory and its apparently abstruse terminology.

On the contrary, it may be pointed that the number of substances which display OD features is very large, especially among inorganic compounds, both synthetic and natural. Moreover, sometimes it is just through an OD approach that the 'real' structure of some compounds may be understood. It is the case of the various members of tobermorite group; their real structures, which for long time eluded the efforts of mineralogists and cement chemists, could be effectively modelled and refined just through the application of the OD procedures.

In any case, the OD approach gives a deeper insight into the structural problem, suggesting interesting relations and pointing to possible new natural or synthetic compounds.

In this contribution, after a short presentation of the basic aspects of the OD approach, few examples of complex mineral structures will be presented (charoite, molybdophyllite and fukalite) where OD theory is extraordinarily helpful in dealing with their polytypic features and disorder.

Polysomatic defects in astrophyllite

Grobéty, B.
Dept. of Geosciences, University of Fribourg, Switzerland
(bernard.grobety@unifr.ch)

Astrophyllite belongs to the heterophyllosilicate mineral group [1], which can be represented as a polysomatic series based on beam modules taken from the endmembers bafertisite (B module) and mica (M module). The group can also be described as T'OT' sheet silicates with modified tetrahedral layers i.e. the T'-layers contain cations with non-tetrahedral coordination. Different members of the series may be derived by variation in the module sequence and orientation in two directions. Stacking errors may, therefore, occur also in two directions i.e along the heterophyllosilicate sheet (basal plane, *b*-direction) and in the stacking direction of the latter (along [001]). A set of astrophyllite samples has been analyzed by high resolution electron microscopy (HRTEM). The most common faults consist of module multiplicity faults i.e presence of additional bafertisite or mica modules along *b* changing the normal astrophyllite sequence from ..MBMB.. to .. MBMBBMB.. or ..MBMMBMB.. These multiplicity faults propagate usually through the entire crystal. Stacking disorder along [001] (=polytypic stacking faults) are much rarer. The faults are most likely growth defects. There is no indication of solid state reaction which may change the module sequence as it is observed in the biopyribole polysomatic series.

Polytypic and polysomatic structures based on hydromagnesite layers

Mills, S.J.[1*], Christy, A.G.[2], Wilson, S.A.[3], Dipple, G.M.[1], Whitfield, P.S.[4] & Raudsepp, M.[1]
[1]Dept. of Earth and Ocean Sciences, University of British Columbia, Vancouver, Canada ([*]smills@eos.ubc.ca)
[2]Research School of Earth Sciences, Australian National University, Canberra, Australia
[3]Dept. of Geological Sciences, Indiana University, Bloomington, USA
[4]Institute for Chemical Process and Environmental Technology, National Research Council of Canada, Ottawa, Canada

Hydromagnesite, $Mg_5(CO_3)_4(OH)_2{\cdot}4H_2O$, is a secondary carbonate mineral that commonly occurs in weathered ultramafic rocks (particularly serpentinites), in low temperature hydrothermally altered dolostones and in cave assemblages. Hydromagnesite and carbonate assemblages are of great interest for their ability to sequester greenhouse gasses directly from the atmosphere. Dypingite, $Mg_5(CO_3)_4(OH)_2{\cdot}{\sim}5H_2O$, is an environmentally benign, metastable carbonate mineral that also acts as a host for greenhouse gases. Dypingite is more easily precipitated than the more stable hydromagnesite under conditions at the Earth's surface. Given time and temperature, it decomposes to the better ordered hydromagnesite structure. Hydromagnesite is known to further decompose to magnesite, which is among the most stable mineral traps for CO_2.

The hydromagnesite structure is based on a three-dimensional corrugated framework of corner-connected MgO_6 octahedra and carbonate triangles. The hydrogen atoms and water molecules form hydrogen-bonded crankshaft chains running parallel to **c**. The structure is strongly pseudo-orthorhombic (*Bbcm*), but in the standard monoclinic $P2_1/c$ setting, a = 10.105, b = 8.954, c = 8.378 Å, β = 114.44º and Z = 4. Infinite superstructures of the *Bbcm* average structure can be produced by ordering polarities of the H-bonded chains in different ways, producing stacking of layers along **b**, each of width $(b/2)_{hydromag}$. Because alternate layers have opposite point directions along **a**, there must be an even number 2n of layers in a unit cell, which then has a *B*-centred cell with a = 18.399 Å, b = 8.954 × n Å, c = 8.378 Å, β = 90º and Z = 4n.

The maximum-degree-of-order arrangements of H-bonded changes both have n = 2, but with space groups *Bbc*2 for *ferro* ordering, $B12_1/c1$ for the *antiferro* structure of hydromagnesite. The only possible space groups (with multiplicity > 2) for longer periodicities are these two for n = odd, or $B112/b$ for n = even. The number of different polytypes grows rapidly with n, even for these maximal-symmetry cases. There are 3 possible $B12_1/c1$ and 3 *Bbc*2 structures for n = 5, and 7 of each for n = 7, both of which periodicities have been observed in nature and in synthetic compounds. The cases with even n have not been observed, possibly due to greater resistance to monoclinic lattice strain on (001) as opposed to (010).

Dypingite and widgiemoolthalite, $Ni_5(CO_3)_4(OH)_2{\cdot}{\sim}4H_2O$, both have **b** repeats ca. 7× that of hydromagnesite. In widgiemoolthalite, minor relaxations of the layers are present, while for dypingite, **b** is expanded significantly to accommodate extra water, which can be modelled by replacing some hydromagnesite layers by a second type of structural module. Thus, the system shows polytypic and polysomatic variability. Other minerals such as giorgiosite are also likely to be based on the hydromagnesite parent structure.

Modular structures as modulated crystals

Perez-Mato, J.M.[*] & Elcoro, L.
Dept. Fisica de la Materia Condensada, Fac. Ciencia y Tecnologia, Universidad del Pais Vasco, Bilbao, Spain
([*]jm.perez-mato@ehu.es)

The use of the superspace formalism has been recently extended to the description and refinement of homologous series of modular structures. Ideal modules can be quantitatively described as modulated configurations with step-like atomic occupation modulations and sawtooth displacive modulation functions (see Fig. 1 and [1]). A single superspace symmetry for the whole series can be defined, and an idealized model for any member of the series can automatically be obtained by choosing the width of the occupation domains and the modulation wave vector. Different orientations of the same module can be introduced by means of large zigzag modulation functions.

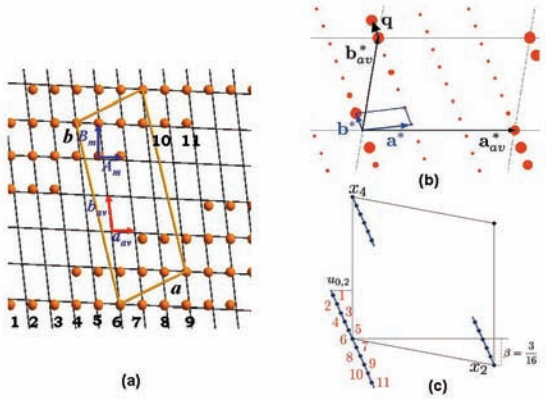

Fig. 1: Superspace description of an ideal module as a modulation. (a) average, module and superstructure unit cell, (b) Fourier spectrum with the choice of modulation wave vector, (c) superspace unit cell on the x_2x_4 plane with sawtooth occupation and displacive modulation.

The deviations of the atomic positions from the idealized modules are given by additional small displacive modulations. If the size of the modules is large, they can be refined using less parameters than in a conventional approach. These additional modulations show hidden fustrated competitions between different length scales for the interatomic distances (see Fig. 2).

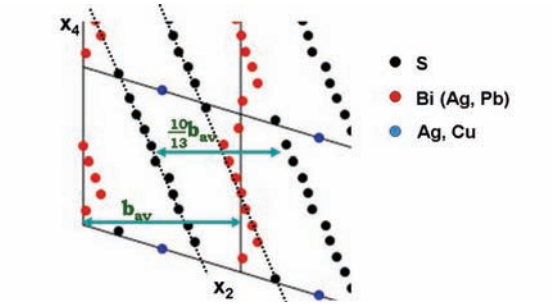

Fig. 2: Superspace embedding on the x_2x_4 plane of the experimental structure of benjaminite ($Cu_{0.5}Ag_{2.3}Pb_{0.4}Bi_{6.8}S_{12}$ [2]) of the pavonite series showing competing average interatomic distances.

After a brief introduction to the superspace description of modulated structures, its application in the field of modular structures, outlined above, will be reviewed by means of a few examples.

Superspace description of modulated wagnerite polytypes

Lazic, B.[1*], Armbruster T.[1], Chopin, C.[2], Grew, E.S.[3], Baronnet, A.[4] & Palatinus, L.[5]
[1]Institute of Geological Sciences, University of Bern, Switzerland ([*]biljana.lazic@krist.unibe.ch)
[2]Ecole Normale Supérieure, CNRS, Paris, France
[3]Dept. of Earth Sciences, University of Maine, Orono, Maine, USA
[4]CRMCN-CNRS, Marseille, France
[5]Institute of Physics, Academy of Sciences of the Czech Republic, Prague, Czech Republic

More than 40 wagnerite samples $(Mg,Fe,Mn)(PO_4)(F,OH)$ from diverse geological environments have been investigated by EMP, X-ray single-crystal diffraction, and HRTEM analysis. Results suggested a major role for compositional control in determining modulation periodicity: 2*b*, 3*b*, 5*b*, 7*b*, and 9*b* [1]. All modulated structures share the same topological arrangement of cations and oxygen atoms, but differ mainly in positional modulation of F, (OH). In wagnerite F, (OH) occupies one of two positions, leading to two distinct arc configurations along *a*: arc up (U) or arc down (D). Different periodicities of U and D sequences lead to multiplication of the structural periodicity along *b* and hence various polytypes (five are known to date).

In this study, a unified superspace model [2] is constructed for ordered stacking sequences of four polytypes 3*b*, 5*b*, 7*b*, and 9*b* based on the average triplite structure model with a ≈ 12.8 Å, b ≈ 6.4 Å, c ≈ 9.6 Å, β ≈ 117 º and the (3+1)-dimensional superspace group $C2/c(0b0)s0$. Modulation vectors are $\mathbf{q} = \beta\mathbf{b}^*$, where $\beta = 0.3460(3) \approx 1/3$; $\beta = 0.4106(4) \approx 2/5$; $\beta = 0.4275(4) \approx 3/7$ and $\beta = 0.4466(3) \approx 4/9$ for 3*b*, 5*b*, 7*b*, and 9*b* structures, respectively. As the β components of the **q** vectors are close to commensurate values, it is not surprising that refinements using superstructure models also give reasonable results [3]. However, **q**-vector refinements show small but significant deviations from commensurate values.

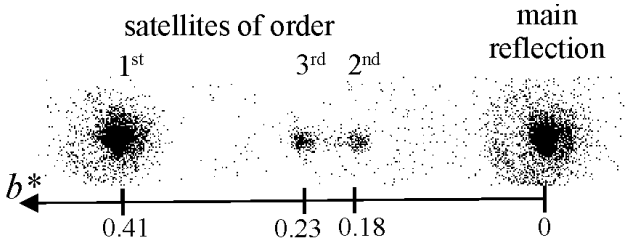

Fig. 1: Position of satellite reflections for a 5*b* wagnerite polytype: Splitting of 2nd and 3rd order reflections from a position at 1/5 = 0.2 proves the incommensurate nature of the structure.

In the four studied polytypes incommensurate models are converging to better agreement factors. In addition to the better refinements, the superspace approach provides a unified model with a common space group, and simplifies description of positional and occupational modulation of Mg/Fe and F/OH in wagnerite polytypes.

Rational *ab initio* modeling for low energy hydrogen-bonded phyllosilicate polytypes

Mercier, P.H.J.* **& Le Page, Y.**
Institute for Chemical Process and Environmental Technology, National Research Council of Canada, Ottawa, Ontario, Canada
(*patrick.mercier@nrc-cnrc.gc.ca)

This abundantly illustrated talk details the very simple concepts subtending an ongoing recent series of papers [1-3] that has so far rationalized the disparate known facts about the kaolin system at ambient and low pressures [1], correctly predicted the existence at high pressure of two new translations (-**a**/3 and (**a**+**b**)/3) allowing 5-fold coordination for Si [2], correctly predicted [1,2] two newly and independently observed [4] kaolinite polytypes (kaolinite II and III), predicted the existence of a still unobserved (SU) kaolinite IV phase at a pressure no higher than 60 GPa [3], and predicted the SU transformation of dickite II [5] into dickite III around 10 GPa [3] as well as that of nacrite at similar pressure into SU nacrite II. Optimized crystal structures for the most likely low enthalpy polytypes are printed [3], allowing simplification of their identification when they will be observed, as they did in [4] for kaolinite II and III.

The concept of energy independence of non-neighbouring hydrogen-bonded phyllosilicate layers is shown to imply that low energy models derive from an initial undistorted ideal layer for the phyllosilicate through repetition of either (a) a same [**R**,**T**]= operation or (b) the succession [**R**,**T**]=[**R***,**T***]= where **R*** denotes the enantiomorph of rotation **R**, and **T*** that of translation **T**, while the = symbol indicates hydrogen bonding between layers enclosed within brackets [ ]. Combination of the application of this most simple concept with total energy *ab initio* DFT calculations has allowed derivation of the above wealth of scientific results.

Whereas the new kaolin phases taking place under compression can occur because they only involve translations by at most a couple Å between adjacent layers, we argue that no solid-state transformations between kaolinite, dickite and nacrite can occur at any pressure without dissolution and recrystallization, even under conditions where any one of those phases would have lower enthalpy. Indeed, as such polytype transformations would involve rotation between adjacent kaolin layers, they require macroscopic atom displacements that cannot occur in the solid state, but just at crystallization time. Interpretation of polytype abundances in sedimentary rocks, particularly the evolution of kaolinite-to-dickite ratios observed as function of burial depths will be discussed.

Our goal in this research effort has been to print inexpensive theoretical results that can be verified/falsified with a single powder pattern, thus pointing directions for exploratory experimental studies in an experimentally difficult system as well as exposing the complementarity of theory and experiment. While waiting for literature results of discriminative structural, thermochemical, or hydrothermal experiments in the kaolin system, we are currently extending the above concepts to the high pressure phases of additional hydrogen-bonded phyllosilicate families where observed phase transitions in the literature are awaiting polytype identification and thermodynamical interpretation. In all our studies, all DFT calculations were performed with *VASP* [6] while all structure modeling as well as VASP file preparation and interpretation was performed with *Materials Toolkit* [7].

Self-organisation in the modulated structure of pyrrhotite: direct observations by TEM

Harries, D.*, Pollok, K. & Langenhorst, F.
Bayerisches Geoinstitut, University of Bayreuth, Germany
(*dennis.harries@uni-bayreuth.de)

Pyrrhotite is a layered iron sulfide of the general non-stoichiometric composition $Fe_{1-x}S$ ($x < 0.125$) and is one of the most abundant iron sulfides in the Earth's crust. Due to variable Fe deficiency large numbers of possible structural variants arise from the ordering of Fe vacancies within the NiAs-based structure. The resulting superstructures show very different physicochemical and magnetic properties bearing on pyrrhotite's contribution to rock magnetisation and the paleomagnetic record, as well as on many issues in geochemistry, petrology, and technical mineral processing.

In ferrimagnetic monoclinic 4*c*-pyrrhotite ($Fe_{0.875}S$) vacancies are ordered into every second Fe layer of the NiAs substructure, alternating along the *c*-axis with fully occupied Fe layers. In (pseudo-)hexagonal N*c*-pyrrhotites ($Fe_{0.875}S$ to ~$Fe_{0.92}S$) Fe deficiency and ordering sequences of vacant and filled Fe layers are different and commonly lead to vanishing net magnetic moments at ambient temperatures. TEM-SAED observations on such samples frequently show them to be of a structure variant in which the superstructure periodicity relates in a non-integral manner to the substructure periodicity. As N*c*-pyrrhotites are generally richer in Fe compared to the 4*c* variety, structural models suggest that Fe enrichment is accomplished by insertion of additional fully occupied Fe layers, forming double layers in which all lattice positions are filled by Fe. We suggest that the variably ordered periodic or aperiodic arrangements of such double layers, being equivalent to non-conservative anti-phase domain boundaries of the 4*c* Fe sublattice, result in translation interface modulated structures.

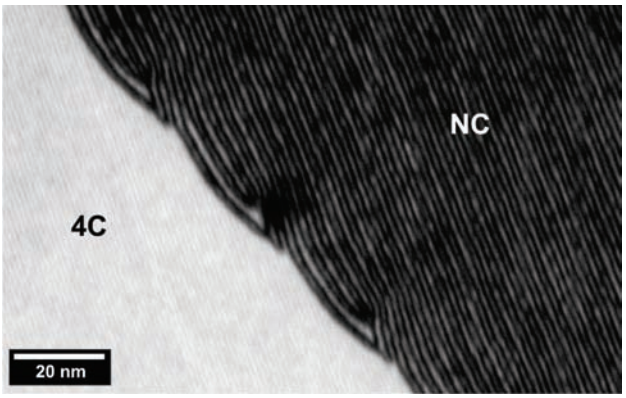

Fig. 1: TEM-SDF image of the interface between 4*c*- and N*c*-pyrrhotite.

We illustrate the usefulness of TEM to decipher microstructural complexity in pyrrhotite by obtaining dark field images from superstructure reflections (TEM-SDF). This imaging technique allows direct observation of double Fe layers and their complex behaviours at internal phase boundaries formed from exsolution of 4*c*-pyrrhotite lamellae in the host N*c*-pyrrhotite. In different samples from various geological settings we found large (tens of nm) and very similar node structures in which double layers annihilate (Fig. 1), pointing to a common mechanism of self-organisation. The driving forces of such structure formation and the consequences for physicochemical and magnetic properties are matter of current research and may have important implications for the geophysical and geochemical understanding of pyrrhotite in nature.

The crystal structure of a 4-layer pyrrhotite and a comparison of the vacancy distribution in 4-layer pyrrhotites

de Villiers, J.P.R.[1*], Becker, M.[1] & Liles, D.C.[2]
[1]Dept. of Materials Science and Metallurgical Engineering, University of Pretoria, South Africa
([*]johan.devilliers@up.ac.za)
[2]Dept. of Chemistry, University of Pretoria, South Africa

The crystal structure of a novel 4-layer pyrrhotite was determined from single crystal measurements on a crystal from the Impala platinum mine in South Africa. The crystal is monoclinic, with cell dimensions a = 11.890(4) Å, b = 6.872(2) Å, c = 22.786(8) Å, and β = 90.124(5)°, with space group $C2$. The cell dimensions are very similar to those of the 4-layer pyrrhotite described by Tokonami et al. [1] in the $F2/d$ setting, and the structure differs from the latter in that there is only one cation layer containing cation vacancies. All the other layers are characterized by layers containing fully occupied cation sites, alternating with layers containing partially occupied sites. This is contrasted with the structure described by Tokonami et al. [1] where layers containing fully occupied sites alternate with layers containing vacant sites. The two structures are however, very similar and this can be seen in the detailed cation arrangements of the two structures (Fig. 1).

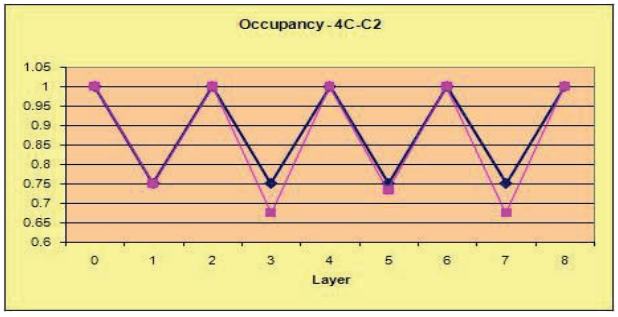

Fig. 1: Occupancy of iron atoms in the layers of 4-layer pyrrhotite in this structure (purple) as compared with that of the structure described by [1] (An occupancy of 1 denotes a fully occupied layer).

The structure described here is postulated to be the most cation deficient of all the pyrrhotites,($Fe_{6.83}S_8$), and this is allowed by the structure, whereas the Tokonami structure is stoichiometric Fe_7S_8 and does not accommodate any other non-stoichiometric composition.

HT-study on fettelite, $[Ag_6As_2S_7][Ag_{10}HgAs_2S_8]$: ionic phase transition indicating the possible existence of different polytypes

Bindi, L.[1] & Menchetti, S.[2*]
[1]Museo di Storia Naturale, Università di Firenze, Italy
[2]Dipto. di Scienze della Terra, Università di Firenze, Italy
([*]crystal@unifi.it)

The crystal structure of fettelite, $[Ag_6As_2S_7][Ag_{10}HgAs_2S_8]$, a rare silver sulfosalt, was recently solved and described by Bindi et al. [1] from a twinned crystal from Chañarcillo, Copiapó Province, Chile. The structure consists of the stacking of two module layers along [001]: an *A* module layer with composition $[Ag_6As_2S_7]^{2-}$ and a *B* module layer with composition $[Ag_{10}HgAs_2S_8]^{2+}$. The As atoms form isolated AsS_3 pyramids typical of sulfosalts, Hg links two sulfur atoms in a linear coordination, and Ag occupies sites with coordination ranging from quasi linear to almost tetrahedral. The *A* module layer found for fettelite is identical to that described for the minerals belonging to the pearceite-polybasite group [2]. Differential Scanning Calorimetry experiments were carried out on the sample from Chañarcillo on 25 mg of powders sealed in aluminium pans using a Mettler DSC 30 instrument from 218K to 423K. The experiments did indicate a phase transition occurring at about 380K. To analyze the HT-structural behaviour by means of X-ray diffraction, a crystal was mounted on a CCD-single-crystal diffractometer equipped with a N_2-heating device. Unfortunately, the highest temperature allowed by the nitrogen device we used (i.e., 350K) was not sufficient to explore the eventual phase transition in fettelite, but the structural results we obtained clearly point toward a structural phase transition likely due to the increase of ionic conductivity with the increase of temperature. The structural data we collected seem indicate a halving of cell along the **a** and **b**-directions and an increase of structural disorder in the *B* module layer. This does mean that at least two polytypes could exist for fettelite. The ordered, monoclinic structure (with unit-cell parameters: a = 26.0388(10), b = 15.0651(8), c = 15.5361(8) Å, β = 90.48(1)° and space group $C2$ – [1]), and a fast ion conducting, disordered HT-form with a and b parameters halved. The two unit-cell types (corresponding to two different polytypes) could be also found in nature. This would account for the different unit-cell types observed for different fettelite samples coming from different localities (e.g., Odenwald, Chañarcillo, Imiter). In addition, slightly different chemical compositions for different fettelite samples (e.g., different Ag/Hg ratios) could play a crucial role as driving forces for different unit-cell stabilizations.

[1] Bindi, L. et al. (2009) *Am. Mineral.*, **94**, 609-615. [2] Bindi, L. et al. (2007) *Am. Mineral.*, **92**, 918-925.

Structural study of members of the polysomatic series epidote-törnebohmite from Stetind pegmatite, northern Norway

Bonazzi, P.[1*], Bindi, L.[2], Chopin C.[3], Husdal, T.A. [4] & Lepore, G.O.[1]
[1]Dipto. di Scienze della Terra, Università di Firenze, Italy
([*]paola.bonazzi@unifi.it)
[2]Museo di Storia Naturale, Università di Firenze, Italy
[3]Ecole normale supérieure–CNRS, Paris, France
[4]T. A. Husdal, Høglia 81, Bodø, Norway

Modules (*E*) of epidote-type structure were found to match easily with those (*T*) of törnebohmite, $(REE)_2Al[SiO4]_2(OH)$, to form a polysomatic series (*E*, *ET*, *T*). In particular, the presence of REE being essential to form *T* modules, *E* modules of epidote members belonging to the allanite or dollaseite subgroups are expected to form *ET* polysomes. Up to now, two minerals – gatelite-Ce [1] and västmanlandite-(Ce) [2] – were found which can be regarded as a regular alternation of (001) slabs of epidote-type structure and (-102) slabs of törnebohmite-type structure. They differ in unit-cell, space-group symmetry and in composition of the epidote-type module, which is of dissakisite-(Ce) composition in gatelite-(Ce) and of dollaseite-(Ce) composition in västmanlandite-(Ce).

This work reports the results of a structural study on crystals resembling gatelite-(Ce) found by one of the author (T.A.H) in the yttrian fluorite masses within the Stetind pegmatite of the Tysfjord granite, northern Norway. The Stetind pegmatite is a granitic REE-pegmatite enriched in niobium, yttrium and fluorine (NYF family) and hosts a large number of different REE- and Y-bearing silicates, REE-bearing carbonates and niobian oxides [3].

The unit-cell dimensions of the examined crystals are in the range a = 8.907-8.933.0, b = 5.639-5.699, c = 17.525-17.600 Å, β =116.3-116.6 °, without any evidence of doubling of the translation unit along the **a**-axis observed in gatelite-(Ce). Although all the crystals were examined with long exposure times on a CCD-equipped diffractometer (Oxford Xcalibur™ 2), neither superstructure reflections such as in gatelite-(Ce) nor the weak, continuous streaking as in västmanlandite-(Ce) were detected. Thus, like in the case of västmanlandite-(Ce), the average structure was refined in the $P2_1/m$ instead of $P2_1/a$ space group, disregarding the slight distortion away from the mirror plane normal to the **b**-axis. However, whereas the continuous streaking in västmanlandite-(Ce) is due to the offset from the (010) mirror plane of two sites (A3 and O15, occupied by REE and oxygen, respectively), in the crystals here studied only O15 exhibits an offset from the mirror plane; therefore, continuous streaking at $a^*/2$ due to short-range order, if any, would be here even weaker than in västmanlandite-(Ce).

Semiquantitative SEM-EDS analyses together with structural data point toward a mineral related to gatelite-(Ce) having the *E* module approaching that of allanite-(Ce).

Atomic structure of {110} interpenetration twin boundary in pyrite from St. Katarina (Slovenia)

Daneu, N. & Rečnik, A.*
Dept. for Nanostructured Materials, Jožef Stefan Institute, Ljubljana, Slovenia (*aleksander.recnik@ijs.si)

Pyrite crystals from St. Katarina (Slovenia) are found in yellow to greenish marls concordant with the Upper Permian micritic dolomite. Most of the crystals have well-developed pentagon-dodecahedral {210} faces, modified by accessory cube {100} facets. Their morphology varies with the depth of the marl. Iron-cross pyrite twins are only found in a thin layer of pink-coloured marl on the Tehovec locality. The twinned pyrites are at least twice as large (3-5 mm) as the untwinned crystals in this layer. Morphologically, the twinned crystals are composed of two interpenetrating pentagon dodecahedrons rotated by 180° about the [110] twin axis. While crystallographically the twinning law is well understood, the real cause of twinning in pyrite at the atomic scale has not been properly explained.

For our study, the twinned pyrite crystals were cut parallel to the (001) plane near the centre of the crystal. We found that the boundaries between two interpenetrating twin domains follow {110}, as well as {100} planes. The primary {110} twin (type-A) can be split into secondary {100} twins (type-B), following a simple crystallographic relation: (110) → a·(100) + b·(010), where a=b in an idealised interpenetration twin, while a≠b in the case of realistic twins. The two types of twin boundaries (TB) can also be distinguished by their chemical composition. While the type-A TB comprise a significant amount of Cu, type-B TB appear to be devoid of any dopant element. The amount of Cu at the type-A TB was measured by collecting several EDS spectra at the TB using the concentric electron probe (CEP) method. The arbitrary width of Cu atoms present on the twin boundary is 0.18±0.03 nm, which would correspond to one octahedral layer of Cu, or about two monolayers of tetrahedrally coordinated Fe and Cu, as found in chalcopyrite. Based on our results we may conclude that the primary twin boundaries of type-A are growth boundaries, while the secondary type-B twin boundaries form after impingement of the growth twin domains.

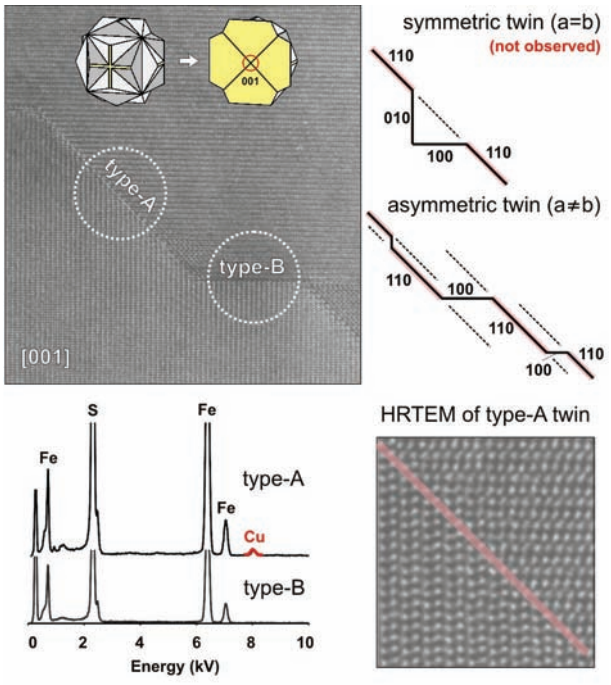

Fig. 1: TEM image of two types of TBs in pyrite twins from Katarina. The EDS analyses show Cu-enrichment at the type-A twin boundary.

First finding of a 94-layer long-period mica nano-polytype by HRTEM

Fregola, R.A.* & Scandale, E.
Dipto. Geomineralogico, Università di Bari "Aldo Moro", Bari, Italy (*r.fregola@geomin.uniba.it)

The stacking sequences of long-period mica polytypes can be unambiguously determined using high resolution transmission electron microscopy (HRTEM) images recorded down two zone axes rotated 30° apart about **c*** (*e.g.* [010] and [-110]). Up to now, the longest ordered stacking sequence in micas was a 36-layer found in a crystal of oxybiotite from the Ruiz Peak rhyodacite rocks [1].

A longer periodicity 94-layer mica nano-polytype was observed by transmission electron microscopy for the first time in this work. It was found in a fragment (γ1a) of the same Mg-rich annite crystal (Bt9568a) from dacite rocks of Džep, Serbia, of a previous study [2]. The prefix "nano" accounts for the sub-micrometer-sized extension along **c*** (about 800 nm) of the crystal region containing the 94-layer polytype. One-dimensional lattice fringe images obtained by bright-field (BF) illumination along the [-110] zone axis showed a high number of stacking faults repeating in the same periodic sequence eight consecutive times along **c***. The c_0 period of this sequence is 95.9214 nm. The 94-layer nano-polytype is bordered by a cleavage surface on one side, whilst on the other side no physical discontinuity occurs and it turns into a different sequence of non-periodic stacking faults. The eight consecutive repetitions of the 94-layer period contain just a single localized planar defect (D). The atomic structure of D was observed by HR images. It is made-up of atomic extra-sheets whose total extension along **c*** is less than that of a mica unit layer (10.2044 Å in this case). D does not alter the regular repetition of the 94-layer stacking sequence.

Selected area electron diffraction (SAED) and HRTEM images taken along the [010] zone axis showed that the observed polytypic stacking sequence belongs to the subfamily-*A* of mica polytypes. SAED patterns and HR images viewed down the [-110] zone axis allowed to identify the inhomogeneous stacking sequence belonging to the $2M_1$ structural series. The otherwise ordered $2M_1$ (2-2) stacking sequence is broken-up by an ordered sequence of two kinds of stacking faults: -22 and 20-2. The Ross-Takeda-Wones (RTW) symbol [3] of the whole 94-layer stacking sequence is: [(2-2)$_3$20-2(2-2)$_3$-22(2-2)$_2$-22(2-2)$_3$-22(2-2)20-2(2-2)-22(2-2)$_3$-22(2-2)$_2$-22(2-2)$_4$–22(2-2)$_2$-22(2-2)$_3$-22(2-2)$_4$-22(2-2)$_2$-22].

Using the planar defect D as reference position, the fringe contrasts of the BF images were correlated to the 94-layer stacking sequence determined by HR images. Specific fringe contrasts had been associated to each type of stacking fault (-22 and 20-2) recurring in the sequence as well as to the $2M_1$ (2-2) unit layer. This correlation allowed to verify that the same 94-layer stacking sequence occurred for eight consecutive times. It also confirms the usefulness of one-dimensional lattice fringe images for a simple and immediate evidence of mica stacking "disorder" [4], especially when such disorder turns into ordered stacking arrays as it is the case of mica very long-period inhomogeneous polytypes. In fact, the one-dimensional lattice fringe images show the modulation due to the superstructure having longer periodicity than that of the unit layer. However, the analysis of HR images is needed to accurately associate the fringe contrasts to the correct stacking sequence.

Crystal structure of a new member of the polysomatic series törnebohmite-epidote from carbonatites of Eastern Siberia

Gurzhiy, V.V.[1*], Karimova, O.V.[2], Kartashov, P.M.[2] & Krivovichev, S.V.[1]
[1]Dept. of Crystallography, Faculty of Geology, St. Petersburg State University, St. Petersburg, Russia ([*]vladgeo17@mail.ru)
[2]Laboratory of Crystal Chemistry of Minerals, Institute of Geology of Ore Deposits RAS, Moscow, Russia

A new member of the polysomatic series törnebohmite-epidote was found in three carbonate veins that crosscut surrounding fenitized gneisses at Biraya REE-Fe ore occurrence (Vitim highland, Russia). One of the veins, a törnebohmite vein, is enriched with a new mineral species, which constitutes a metasomatic zone up to 2 cm thick. The vein has the following zonation from margin to center: compact ferriallanite rim, ferriallanite-calcite zone, strontianite-calcite, törnebohmite-carbonate and axial carbonate zones with biraite-(Ce)-bastnäsite-(Ce) segregations. Therefore three zones marked out by REE-silicates are present in the vein: outer ortho-diortho-silicate, intermediate orthosilicate and inner diorthosilicate. The new mineral being mixture of ferriallanite-(Ce) and törnebohmite modules in ratio 1:1, formed along the boundary of the ferriallanite-(Ce)-törnebohmite zones as a metastable relict phase.

A crystal was mounted on a STOE IPDS II diffractometer equipped with an Image Plate area detector. The unit cell parameters were determined by the least squares method. It is monoclinic, $P2_1/m$, a = 8.955(1), b = 5.7335(5), c = 15.856(2) Å, β = 94.33(1)°, V = 811.8(2) Å^3. The crystal structure was solved by direct methods and refined to R_1 = 0.059 (wR_2 = 0.137) for 1703 reflections with $|F_o| \geq 4\sigma_F$.

The structure consists of chains of edge sharing Fe, Mg and Al octahedra running along the *b* axis and cross-linked by SiO_4 and Si_2O_7 groups to form layers. Cavities within the layer are occupied by Ca atoms. Channels between the layers are occupied by Ce atoms. Using modular approach, the structure can be described as sequence of epidote and törnebohmite-(Ce) layers parallel to the (001) plane.

The mineral formula according to the results of the structure analysis is $Ce_3(Ca_{0.94}Ce_{0.06})(Fe^{II}_{0.54}Mg_{0.46})(Fe^{II}_{0.91}Mg_{0.09})(Al_{1.90}Fe^{III}_{0.10})$ $Si_5O_{19}(OH)_2(O,OH)$. Thus the new mineral species is a Fe-rich and F-deficient analogue of västmanlandite-(Ce).

Acknowledgements: This work was supported for VVG and SVK by the Russian Ministry of Science and Education (State contract # 02.740.11.0326).

Redetermination of crystal structure of semseyite, $Pb_9Sb_8S_{21}$

Matsushita, Y.
Beamline BL15XU, SPring-8, NIMS-branch office, Sayo-cho, Hyogo, Japan (MATSUSHITA.Yoshitaka@nims.go.jp)

Sulfosalt-mineral semseyite $Pb_9Sb_8S_{21}$ belongs to the plagionite series ($Pb_{3+2n}Sb_8S_{15+2n}$, $\boldsymbol{n}$ = 0, 1, 2, 3) [1]. All of minerals in this series have same space group (C2/c) with similar lengths of $\boldsymbol{a}$ and $\boldsymbol{b}$ axes. On the other hand, $\boldsymbol{c}$ axes are systematically changed varying with $\boldsymbol{n}$ number, and the $\boldsymbol{\beta}$ angles are alternatively changed with odd number or even number of $\boldsymbol{n}$. [2] The crystal structure of semseyite had been reported by Kohatsu and Wuensch [3] and Matsushita, Nishi and Takéuchi [4]. The results suggest that the structure has PbS-like substructure elongating to two different directions, parallel to (112) layer and (-112) layer. Each of substructures to form the semseyite structure is alternatively connected by the (112) layer and by the (-11-2) layer, and they are related by the twofold axes. The {112} planes correspond to the cleavage plane of the series minerals. However, previous refinement levels are relatively low (R = ~10 % and ~7 %) to discuss with details of the structure. Therefore, we re-examined single-crystal diffraction work.

A crystal of semseyite for this work was found in the sample labelled as plagionite ($Pb_5Sb_8S_{17}$, Wolfsberg, Germany). From the EPMA analysis, the chemical composition of the crystal is $Pb_{9.05(3)}Sb_{8.01(3)}S_{21.05(3)}$. The crystallographic checks and the intensity collections were carried out on a CCD area detector (Bruker SMART APEX) and graphite-monochromatized MoKα radiation (λ = 0.71069 Å) at room temperature. The crystal belongs to space-group C2/c with a = 13.6267(10) Å b = 11.9742(9) Å, c = 24.5891(18) Å, β = 105.997(3) °, V = 3856.8(5) Å^3, Z = 4, Dc = 4.400 g/cm^3, and R1 = 4.71 %. The crystallochemical details will be presented.

Structural refinement and OD character of a 4-layer ferrophlogopite

Pignatelli, I.* & Nespolo, M.
CRM^2 UMR-CNRS 7036, Institut Jean Barriol, Nancy-Université, Mancy, France
(*Isabella.Pignatelli@crm2.uhp-nancy.fr)

In this study we analysed a new non-MDO 4–layer polytype from the Ruiz Peak ferrophlogopite [1], with cell parameters: a = 5.3312(7), b = 9.2237(8), c = 39.978(6), β = 92.48(1)°. The space group $C2/c$ has been obtained by the stacking sequence calculated from the PID analysis [2] and expressed by the OD symbols 2040 in the homo-octahedral approximation [3]. The initial model was obtained from the atomic positions of the 1M polytype [4] by applying the stacking sequence. Refinement was performed in $C2/c$ with Jana2006 [5] and converged to about 6%. The structure of this polytype is characterized by two kinds of mica layers (M layers) in the asymmetric unit. The first has layer symmetry $C12/m(1)$: the $M1$ (trans) site is in special position (site-symmetry group $\bar{1}$, Wyckoff position 4c), whereas the $M2$ (cis) site is in general position, like the two independent tetrahedral sites. The second layer, instead, has layer symmetry $C12(1)$; the octahedral sites are all independent and in special position (on a twofold axis, Wyckoff position 4e). The analysis of the peaks in the experimental Fourier map suggests a non-homogeneous distribution of the cations in the octahedral sites. The peaks corresponding to the $M1$ sites are significantly different from those in the $M2$ sites; for the second layer, the peaks in the sites $M2$ and $M3$ are close. Both layers are therefore meso-octahedral. The origin of a meso-ochtahedral sheet is chosen on the site with different occupancy [6], *i.e.* in the *trans* site ($M1$) of both our layers. This type of layer is called the M1-layer to distinguish it from that whose origin is in a *cis* site, called the M2-layer [7]. The meso-octahedral OD symbol is:

5	. 5	3	. 3	1	. 1	5	. 5
2	*	0	*	4	*	0	*

Being the first occurrence of a polytype with layers of different symmetry, we checked whether this difference could be an artefact of the model, by repeating the refinement in all the *translationengleiche* subgroups of $C2/c$ (Cc, $C2$, $C\bar{1}$ and $C1$). No improvement in the refinement results was obtained, while a number of correlations appeared, clearly indicating that the true symmetry of this structure is indeed $C2/c$.

Coexistence of 1M and 2M_1 polytypes in Ti-phlogopite from the Central Fields volcanics of the Southwest Uganda

Scordari, F., Schingaro, E., Mesto, E.* & Lacalamita, M.
Dipto. Geomineralogico, University of Bari, Italy.
(*mesto@geomin.uniba.it)

In the present work, the crystal chemistry of natural Ti-phlogopites from alkali-rich igneous rocks from the Central Fields of Bunyaruguru and Katwe-kikorongo (Southwest Uganda) has been investigated. The host rocks are characterized by olivine – melilitite and olivine – kalsilite – nepheline – clinopyroxene assemblages [1]. The phlogopites from the former rock are labelled BU (specifically, BU1, BU3 and BU4) whereas those from the latter are labelled KK (in detail, KK8 and KK13). All samples underwent chemical (Electron Micro Probe Analysis, EMPA), structural (Single Crystal X-ray Diffraction, SCXRD) and spectroscopic (FTIR) investigation.

EMPA yielded the following ranges: MgO (17.87-21.48 wt%), FeO_{tot} (5.40-9.22 wt%) and TiO_2 (4.59-7.05 wt%) for BU samples whereas MgO (17.98-18.51 wt%), FeO_{tot} (8.17-8.86 wt%) and TiO_2 (6.02-6.49 wt%) for KK crystals.

SCXRD analyses showed the coexistence of both the 1M and the 2M_1 polytypes within the same sample. The BU3 mica is an exception because, to date, only crystals belonging to the 2M_1 polytype have been found. Average cell parameters are a = 5.33, b = 9.22, c = 10.22 Å and β = 100.06° for the 1M whereas a = 5.33, b = 9.23, c = 20.22 Å and β = 95.08° for the 2M_1 phlogopites. Structure refinements using anisotropic displacement parameters were performed in space group $C2/m$ for 1M and $C2/c$ for 2M_1 samples and converged at $1.63 \leq R \leq 4.64$ %, $1.96 \leq R_w \leq 5.45$ % and $2.46 \leq R \leq 4.00$ %, $1.37 \leq R_w \leq 4.41$ % for the two polytypes, respectively.

Micro-FTIR provides insightful informations about octahedral cationic environments, the substitution mechanisms trough which cations enter the mica structure and the hydrogen orientation [2-4]. The samples so far analyzed display, to different extent, fine structure in the OH^- stretching region.

In terms of substitution mechanisms this implies that the samples contain different combination of M^{3+}-Tschermak, M^{3+}-oxy substitutions, whereas they are not affected by M^{3+}-vacancy substitutions. Indeed the bands at about 3620 and 3535 cm^{-1}, which correspond to $Al^{3+}Al^{3+}$-OH and $Fe^{3+}Fe^{3+}$-OH local configurations [5] are missing.

Authigenic pyrite is a common mineral in the sediments on continental slopes and is thought to form by reaction of dissolved sulfide (produced by microbial sulfate reduction) with detrital iron-bearing minerals [1]. Pyrite dominantly occurs as framboids in modern anoxic environments. Its ubiquity and remarkable physical appearance has attracted many researchers. However, the mechanism controlling formation of pyrite framboids is not known.

The two polymorphs of FeS_2 are pyrite and marcasite. Fe atoms are octahedrally coordinated in both minerals.

We studied pyrite rods in seafloor core sediments near Dongsha Island in the South China Sea using scanning electron microscopy and high resolution transmission electron microscopy (HRTEM). The water depth of sampling area is about 3000m. Most pyrite is formed of spherical and pyritohedron aggregates of submicron pyrite microcrystals, which occur as framboids and have later pyrite overgrowths. HRTEM and select area electron diffraction analyses show pyrite has planar faults parallel to (001). As described by Dódony et al. [2], marcasite is found in the faults, and single (101) layers of marcasite disrupt the regular sequence of (002) layers in pyrite. Marcasite layers in pyrite might limit the growth of the pyrite crystal and be responsible for the characteristic framboid morphology of the pyrite spherules [2].

Butler and Rickard [3] propose that the framboidal texture forms by rapid nucleation in an aqueous environment strongly supersaturated with respect to pyrite. Marcasite forms in acidic aqueous solutions (pH<5) at low temperatures (T<240°C) [2,4]. The samples in this study were collected from an area with the potential for gas hydrates [5]. Both methane and sulfate are needed for anaerobic oxidation of methane to produce sulfide and dissolved inorganic carbon. The existence of marcasite layers in pyrite restricts the pH condition and the concentration of Fe^{2+} and H_2S in the aqueous solution. According to the hypothesis offered by Valentine and Reeburg [6], $2CH_4+2H_2O \rightarrow CH_3COOH + 4H_2$ and acetate and hydrogen are both consumed by sulfate reducing bacteria to produce S^{2-} and H_2S: $SO_4^{2-} +4H_2 \rightarrow S^{2-}+4H_2O$ and $SO_4^{2-} +CH_3COOH \rightarrow H_2S+2HCO_3^-$. When the supply of methane is continuous and the rate of acetate and H_2 production is higher than SO_4^{2-} consumption, the aqueous solution becomes acidic and marcasite can form. Therefore, the occurrence of marcasite lamellae in framboidal pyrite shows there is an almost inexhaustible supply of methane under the site.

Quantification and identification of illite/smectite interstratifications at nanometric scale: association of TEM/EDS/SAED

Fernandez, J.-B.[1*], Kohler, E.[1], Gay, A.-S.[2] & Jullien, M.[3]
[1]Geology-Geochemistry-Geophysics Division, IFP, Rueil-Malmaison, France ([*]jean-baptiste.fernandez@ifp.fr)
[2]Physics and Analysis Division, IFP, Solaize, France
[3]Nuclear Energy Direction, CEA, St Paul lez Durance, France

In the context of CO_2 sequestration, studies aimed at characterizing the sealing capacity of the argillaceous barriers and at constraining their evolution. In that case, clayey cap-rocks play a key role on confining function supported by their petrophysical properties. The illites-smectites are one of the main components of the CO_2 storage cap-rock in the studied area, the Paris basin. A study [1] points out an illitization of the initial matrix upon micrometric reactive fronts when samples are subjected to supercritical CO_2 in laboratory conditions (with mix of CO_2/H_2O from pure water to pure CO_2). For a good enough safety assessment, the numerical modellings must take into account the geochemical interactions at the reaction's scale: identification of initial/new crystallized minerals and their evolution along the I:S ratio. Such characterizations can be performed by a few precise and routinely practical methods [2]. The technical difficulties of characterization are related to the clays crystals small size and their apparent chemical composition heterogeneity due to the deposition and burial history through diagenesis transformations. A method has been developed that combine both crystallographic data obtained from selected area electron diffraction (SAED) and chemical analyses obtained by energy dispersive spectrometry (EDS) using a transmission electron microscope (TEM). This association allows to determine the ratio I:S and their chemical composition at nanometric scale of the same I/S crystal. Natural references and synthetic I/S, which have been characterized by X-Ray Diffraction (XRD) are used to test the method. The natural I/S are constitued of both ISCz-1 which is a Clay Mineral Society standard and samples from Saint Martin de Bossenay (Paris Basin, France). The synthetic I/S result from an illitization process of synthetic smectites. The advantage of these synthetic materials is the strict control of the chemical composition and the mixed-layering level. The results of SAED patterns along c* obtained from specific preparation (resin exchange, preferential orientation, ultrathin cut) allow the discrimination between illite, smectite and illite/smectite. The chemical analyses confirm an illitization process and ratios.

Comparison of approaches for modelling disorder of clay structures in Rietveld phase analysis

Kleeberg, R.[1*], Ufer, K.[1], Bergmann, J.[2] & Dohrmann, R.[3]
[1]Institut für Mineralogie, TU Bergakademie Freiberg, Germany ([*]kleeberg@mineral.tu-freiberg.de)
[2]Ludwig-Renn-Allee 14, Dresden, Germany
[3]BGR/LBEG, Hannover, Germany

The complicated and variable disorder of the common clay minerals hampers the adequate modelling of the diffraction profiles as necessary for correct structure and phase analysis by the Rietveld method. Various types of stacking faults occur solely and mixed in natural layer silicates, e.g. well-defined translations and rotations of adjacent identical layers, turbostratic stacking, and mixed-layering of different layer types. Consequently, a number of approaches have been introduced to fit the experimental diffraction patterns. Typically, the anisotropic line broadening by well-defined stacking faults is described by any *hkl*-dependent line broadening model, e.g. [1,2], based on an ideal mean structure. Turbostratic disorder can be approximated by the single-layer approach [3]. Mixed-layering may be modelled by introducing the recursive calculation [4] in a supercell structure model [5]. However, in practice the true type of disorder may be unknown, or a complex disorder model in recursive description needs overmuch computing time for routine purposes. In such cases, an empirical approximation based on manually modified *hkl*-lists [6] may be useful. Such *hkl*-lists can be used together with all other types of structural models.

The presentation discusses the advantages and limitations of the different approaches, focusing on their application in quantitative phase analysis using the Rietveld method. The problem is demonstrated for 1:1 and 2:1 dioctahedral minerals with different types of disorder (pure phases and mixtures). Typically, *hkl*-dependent line broadening models can be applied just to a certain degree of disorder, but may fail when applied to minor components. Flexible but complicated models tend to yield overestimation of phase abundances in mixtures if phases with similar structures are present. Recursive calculation may approximate real patterns very well, but even an extensive fixing and constraining of parameters does not always prohibit tedious computation time. The application of *hkl*-lists [6] may help to speed up routine work to obtain reliable mineral quantification, but does not allow structural investigations of those phases described with the proposed *hkl*-lists.

Globular layer silicates of the illite-glauconite series, the Upper Proterozoic, northern Siberia, Russia

Ivanovskaya, T.A.
Geological Institute RAS, Moscow, Russia
(ivanovskaya@ginras.ru)

A representative collection of globular dioctahedral 2:1 layer silicates from marine deposits (predominantly silicoclastic, rarely, glauconitites, limestones, dolomites, clayey rocks) of the Lower and Middle Riphean (Osorchayata and Arymass, Debengda, Khaipakh Formation, respectively) and the Vendian (Maastakh Formation) of the Olenek Uplift and of the Lower (Ust'-Il'ya Formation) and the Lower-Middle Riphean (Ysmastakh Formation) of the Anabar Uplift (Northern Siberia, Russia) has been studied. The mineralogical studies were performed by a complex of modern chemical and physical methods (X-ray diffraction, oblique-texture electron diffraction, scanning electron microscopy, classical chemical and micro-probe analyses, Mössbauer spectroscopy etc.), which allowed determining structural and crystal-chemical varieties of the minerals. Best-preserved grains were used for isotope dating.

The glauconite grains have globular, irregular and platy shapes. In the diagenesis zone glauconite globules seem to have been formed by synthesis from colloidal solution, and platy glauconite, by transformation of terrigenous Fe-mica (biotite). Glauconite was mainly formed with the active influence of microorganisms.

Among the studied layer silicates continuous series of solid solutions from illite ($^{VI}Al/^{VI}Al+ {}^{VI}Fe^{3+} \geq 0.6$) via Al-glauconite (Fe-illite) to glauconite ($^{VI}Al/^{VI}Al+ {}^{VI}Fe^{3+} \leq 0.5$) has been observed. Some samples consist entirely or partly of proper glauconite of the Middle Riphean (Debengda Formation) and the Lower Riphean (Ust'-Il'ya Formation). Illite (rarely, Al-glauconite) have been revealed in the Lower and Middle Riphean (Osorchayata and Arymass, Debengda, Khaipakh, respectively) and the Vendian (Maastakh Formation).

Structural varieties from mica to mixed-layer phyllosilicates (≤10 and >10% smectite layers respectively) have been determined. Mixed-layer silicates with a trend to ordering in the alternation of mica and smectite layers (short-range order factor S>1) have been found in Debengda and Khaipakh Formations. The transition from Al-species to Fe-species is accompanied by a variation of the unit cell *b* parameter from 9.00 to 9.08Å.

Mg-rich Al-glauconite has been found in dolomites of the Ysmastakh Formation. This mineral is characterized by unique structural and crystal-chemical peculiarities caused by non-equilibium conditions in reduction zone of shallow dolomite deposits.

Among the studied samples there are globules consisting of two mica (glauconite, illite) phases (Ust'-Il'ya Formation) (b=9.00−9.08Å). The compositional division in biphase globules occurred at the level of individual microcrystals (0.5−5μm) of micaceous minerals. These minerals form an isomorphic series from Al to Fe-varieties within a single globule.

The studied rocks containing globular glauconite-illite minerals are altered by deep diagenesis. Globular and platy grains of illite (Osorchayata Formation) show the same rejuvenated ages. The isotopic ages of globular glauconite-illite minerals of other studied formations correspond to their stratigraphic positions.

Deposition of layered double hydroxides on alumina support

Kovanda, F.[1*], Jirátová, K.[2] & Koloušek, D.[1]
[1]Dept. of Solid State Chemistry, Institute of Chemical Technology, Prague, Czech Republic
([*]Frantisek.Kovanda@vscht.cz)
[2]Institute of Chemical Process Fundamentals of the ASCR, v.v.i., Prague, Czech Republic

Layered double hydroxides (LDHs) are often used as precursors for preparation of mixed oxide catalysts. A deposition of LDHs on supports would be advantageous due to a better utilization of usually expensive active components. In this work, a formation of LDHs on anodized aluminum foil is studied; the hydrothermal reaction in aqueous solutions containing divalent metal nitrates [1,2] was adopted to obtain supported LDH and mixed oxide layers. The composition and molar ratios of metal cations in used solutions were adjusted as follows: Ni-Mn (2:1), Co-Mn (2:1), Ni-Co-Mn, Ni-Cu-Mn and Co-Cu-Mn (all 1:1:1); total metal ion concentration of 0.1 mol l^{-1} and pH of 6.8 and 8.5 were applied and the deposition was carried out under hydrothermal conditions at 140°C for 65 h.

Powder XRD patterns of the samples obtained after hydrothermal reaction showed well-crystallized hydrotalcite-like phases. A formation of M^{II}-Al and M^{II}-Cu-Al LDHs (M^{II} = Ni and/or Co) with only a slight Mn content can be expected. An increasing pH in the solutions enhanced the LDH deposition and facilitated incorporation of Co and Mn in the solid; on the other hand, products with lower Cu content were obtained. It can be explained by a difference in the pH, at which various divalent metal hydroxides are precipitated. The products obtained at higher pH showed an increased lattice parameter *a*; it also indicates a higher concentration of Mn cations in the formed LDHs.

Relatively homogeneous layers consisting of thin curved platelets oriented nearly perpendicularly to the support were observed in SEM images. The same morphology of the deposited products was found also in the samples calcined at 500°C (Fig. 1). NiO-like and spinel-like mixed oxides were formed during calcination of Ni- and Co-containing samples, respectively, but no distinct Cu-containing phases were detected by XRD in the obtained M^{II}-Cu-(Mn)-Al oxides. The LDH-related mixed oxides deposited on Al_2O_3/Al support exhibited a worse reducibility in comparison with those obtained by calcination of coprecipitated precursors; it could be explained by a high structure ordering of the formed oxide phases. The deposited mixed oxides containing Cu showed reduction peaks at relatively low temperatures (250 – 300°C) and consequently also a reasonable catalytic activity in total oxidation of ethanol.

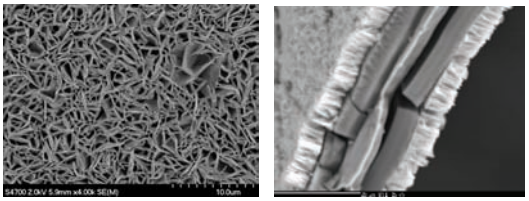

Fig. 1: SEM images of the deposited Co-(Mn)-Al LDH layer (left) and profile of the calcined sample (right).

Hydrothermal synthesis of Al-Fe^{3+} smectites: a crystal chemistry study

Andrieux, P.[1*], Petit, S.[1], Gates, W.[2], Marichal, C.[3] & Grauby, O.[4]
[1]Laboratoire HydrASA, Université de Poitiers, France ([*]pauline.andrieux@univ-poitiers.fr)
[2]Dept. of Civil Engineering, Monash University, Clayton, Australia
[3]Equipe Matériaux à Porosité Contrôlée, Institut de Science des Matériaux de Mulhouse, France
[4]Laboratoire CRMCN, Université de Marseille, France

Synthesis in laboratory allows control of the chemical makeup and the conditions for crystallization of clay minerals. Clay synthesis is then a useful approach for understanding natural clay minerals formation. Well defined samples having distinct chemical composition in series can be synthesized which are well suited for spectroscopic interpretations.

A series of Al-Fe^{3+} smectites with a wide range of chemical compositions have been synthesized for the first time. These smectites were synthesized by hydrothermal treatments from coprecipitated gels. The hydrothermal syntheses were performed at different temperatures and pHs. For Fe^{3+}-rich smectites, low temperature and relatively basic pH conditions are suitable whereas for Al-rich smectites, higher temperatures and more acidic pHs are appropriate [1].

These smectites have been analyzed by X-Ray Diffraction (XRD), infrared (IR in the near and the middle region, respectively NIR and MIR), Extended X-ray Absorption Fine Structure (EXAFS at the Fe K-edge and Fe L-edge) and Nuclear Magnetic Resonance (NMR) spectroscopies. Chemical analyses of the smectite particles have been performed using Transmission Electron Microscopy (TEM) equipped with an EDX (Energy Dispersive X-ray) system.

The smectitic nature of the synthesized samples is confirmed by their swelling behavior after ethylene-glycol treatment measured by XRD on oriented deposits. MIR and NIR spectra reveal variations of the relative intensities of the $Fe^{3+}{}_2OH$, $AlFe^{3+}OH$ and Al_2OH bands all along the chemical series indicating the crystal-chemical changes in these smectites in response to composition. Fe K-edge spectra reveal the presence of Fe in tetrahedral sites in the Fe-rich smectites. Fe L-edge spectra were fitted using ferrite spectrum as Fe(III) tetrahedral reference and NAu-1 nontronite as Fe(III) octahedral reference to obtain the percentage of Fe(III) in the different sites. The percentage of tetrahedral Fe(III) in these samples globally decreases with increasing Al in the structure.

^{27}Al MAS NMR spectra were recorded even for smectites very rich in iron providing information on at least some of the site occupancies (Al(4)/Al(6)) depending on the synthesis conditions.

"Mauritzite": a ferro/ferri-saponite transforming by immediate in-situ oxidation in dacite cavities, Erdőbénye, Hungary

Weiszburg, T.G.[1*], Pekker, P.[2], Jánosi, M.[1], Tóth, E.[3] & Kuzmann, E.[4]
[1]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]weiszburg@ludens.elte.hu)
[2]BAY-NANO Institute for Nanotechnology, Miskolc, Hungary
[3]Eötvös Museum of Natural History, Eötvös Loránd University, Budapest, Hungary
[4]Laboratory of Nuclear Chemistry, Chemical Research Center, Hungarian Academy of Science – Eötvös Loránd University, Budapest, Hungary

The pyroxene dacite laccolith of Mulató Hill (Erdőbénye, Tokaj Hills, NE-Hungary) formed as part of the Neogene Inner-Carpathian volcanic chain. Quarried since 1925, the laccolith is well-known for its hydrothermal cavity-filling mineral assemblage [1]. Amygdules host among others siderite, tridymite, chalcedony and an iron-rich saponite. Saponite is a cavity-lining, mostly vermicular phase forming few-mm-long fibres of ca. 0.1 mm diameter. It is mid-blue when the host cavity is opened (i.e., when first gets into contact with air), but rapidly (few ten minutes) darkens and finally turns bluish black due to in-situ oxidation.

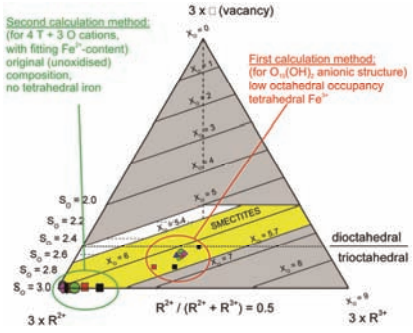

Fig. 1: Ternary diagram showing the composition of the octahedral sheet of the studied smectite. S_O = octahedral site occupancy; X_O = octahedral cation charge; R^{2+}, R^{3+} = octahedral cations.

The subhedral crystallites are up to 500 nm wide and a few nm thick, and exhibit the typical ring-like diffraction pattern of smectites. Mössbauer spectroscopy revealed that 90% of the iron content is Fe^{3+}. Tetrahedral Fe^{3+} was excluded. Calculating the crystal chemical formula from TEM-EDX data and 10% Fe^{2+}, for $O_{10}(OH)_2$ anionic structure, octahedral occupancy was found to be low (2.6 *a.p.f.u.*) and the tetrahedral sites had 0.2 *a.p.f.u.* Fe^{3+}, contradicting Mössbauer data. If modelling the original, unoxidised state of the mineral, calculating the formula for 4 tetrahedral + 3 octahedral cations, fitting iron oxidation state to retrieve an electrostatically neutral formula, 90-97% of Fe is Fe^{2+}, and there is no iron in the tetrahedral positions. It is suggested that the iron-rich trioctahedral smectite has originally around 90% of its iron content in the divalent form, which is mostly oxidised to Fe^{3+} in contact with air, accompanied by the deprotonation of the OH groups. The original (unoxidised) formula is approximately $Ca_{0.15}K_{0.04}(Mg_{1.5}Fe^{3+}{}_{0.14}Fe^{2+}{}_{1.37}Al_{0.1})[Si_{3.5}Al_{0.5}O_{10}](OH)_2$, while the oxidised one is approximated as $Ca_{0.15}K_{0.04}(Mg_{1.5}Fe^{3+}{}_{1.37}Fe^{2+}{}_{0.14}Al_{0.1})[Si_{3.5}Al_{0.5}O_{10}]O_{1.23}(OH)_{0.77}$. Based on the calculated chemical formula, the oxidised form and partly the unoxidised form (where Fe^{2+} > Mg) can be regarded as new smectite species.

Structure modeling and its application to the analysis of crystal-chemical variations in dioctahedral micas

Zviagina, B.B[*] & Drits, V.A.
Geological Institute RAS, Moscow, Russia
([*]zviagina@ginras.ru)

An improved structure modeling procedure has been elaborated for the calculation of atomic coordinates in dioctahedral micas from the experimental data on cation composition and unit-cell parameters. The algorithm is based on regression equations relating the structural features and chemical composition of dioctahedral micas that were obtained from the analysis of published data on refined structures of micas of various compositions. The new technique follows the general approach [1], but in order to account for new high-precision refined structural data on dioctahedral $2M_1$ micas published since 1993 the majority of regression equations were modified. In addition, changes were made in the calculation algorithm.

The empirical relationships used in the algorithm accurately describe the observed structural distortions in dioctahedral micas, such as tetrahedral tilt and rotation, tetrahedral elongation, octahedral flattening; hydroxyl depression *etc.*, and include the following dependences:

mean tetrahedral and octahedral bond lengths, d_T and d(M-O,OH) *vs* tetrahedral and octahedral cation composition, respectively;

differences between non-bridging and bridging tetrahedral bond lengths, d_{nbr} and d_{br} *vs* cation composition;

differences between distances from the octahedral cation to hydroxyl and non-hydroxyl oxygen anions, d(M-O) and d(M-OH), *vs* cation composition;

tetrahedral sheet basal surface corrugation, ΔZ, *vs* d(M-O) and b;

tetrahedral sheet thickness calculated over non-depressed basal O anions, $h_{T,\,max}$, *vs* ΔZ;

tetrahedral mean basal edge length, l_b, *vs* tetrahedral and interlayer cation composition;

tetrahedral elongated basal edge length, l_{bl}, *vs* octahedral cation composition;

tetrahedral ditrigonal rotation angle, α_T, *vs* l_b and b;

mean octahedral sheet thickness, $<h_{oct}>$, *vs* octahedral cation composition and b;

The estimated standard deviations are 0.002-0.007 Å for distance parameters and 0.5° for α_T

Structure modeling was used to deduce atomic coordinates for several low-temperature 1*M* dioctahedral micaceous minerals from solid solutions (Mg, Fe)-free illite-aluminoceladonite via Mg-rich illite and Fe^{3+}-rich glauconite-celadonite, for which structure studies are problematic because of fine dispersion and low structural order. The application of the structure modeling procedure to these samples was based on the assumption that the structural features of the 2:1 layer in 1*M* micas should be similar to those in $2M_1$, so that the structural data modeled for the 1*M* mica structures should have similar reliability. Analysis of the modeled structures revealed the basic factors responsible for crystal-chemical variations in the two sample series.

Excess protons and tetrahedrally coordinated Ni^{2+} in triocta-dioctahedral micas

Robert, J.-L.[1*] & Abs-Wurmbach, I.[2]
[1]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France
([*]jean-louis.robert@impmc.upmc.fr)
[2]Technische Universität, Berlin, Germany

Series of Ni-micas have been prepared by hydrothermal synthesis at 500°C, 1 kbar PH_2O, in the K_2O-NiO-SiO_2-H_2O system. A complete mica solid solution has been obtained under the chosen experimental conditions, between two end-members with the nominal compositions $K(Ni_{2.5}\square_{0.5})Si_4O_{10}(OH)_2$ [A] and $KNi_3(Si_{3.5}Ni_{0.5})O_{10}(OH)_2$ [B]. The [A] phase is a triocta-dioctahedral mica, with 50% OH groups bonded to three Ni^{2+} and 50% bonded to two Ni^{2+} and adjacent to an octahedral vacancy. At the [B] end-member, Ni^{2+} is present in both [6] and [4] coordination numbers, which is an uncommon situation. Along the join, the mica color reflects the evolution of the composition, from pale green for [A], which contains only $[6]Ni^{2+}$, to sky blue for [B].

Both UV-vis and FTIR spectroscopies confirm the presence of $^{[4]}Ni^{2+}$ besides $^{[6]}Ni^{2+}$. In UV-vis, the first transition ν_1(t): $^3T_1$ (F) → $^3T_2$ (F) is outside the observable range. ν_2(t): → 3A2 (F) is at 9078 cm^{-1} and ν_3(t): $^3T_1$ (P) includes two bands at 15280 and 17120 cm^{-1}. CFSE Δ_t and Bt were calculated as 4910 cm^{-1} and 887 cm^{-1}, respectively. From these data, ν_1(t) was derived as 4160 cm^{-1}. FTIR spectroscopy in the antisymmetric T-O-T region, around 1000 cm^{-1}, also demonstrates the presence of $^{[4]}Ni^{2+}$. The [A] end-member shows two bands in this region, a high intensity band at low wavenumber, 970 cm^{-1}, due to the antisymmetric Si-O-Si motion, and a low intensity one, at 1120 cm^{-1}, assigned to the Si-O ⊥ vibration. Towards [B], a second doublet appears, at 1020 and 1080 cm^{-1}, also assigned to T-O-T and Si-O ⊥ vibrations but involving SiO_4 adjacent to NiO_4 tetrahedra.

Along the [A]-[B] join, vacant octahedral sites and NiO_4 tetrahedra, both generating local charge imbalances, are expected to be as far as possible from each other. On the contrary, they are systematically associated which provokes a strong charge imbalance on the apical oxygens of NiO_4 tetrahedra. These local defects are compensated by the incorporation of additional protons, very strongly bonded to the structure. FTIR spectroscopy in the OH stretching region confirms the presence of $^{[4]}Ni^{2+}$ and excess protons. The spectrum of the [A] mica mainly shows two bands, at 3677 and 3543 cm^{-1}, due to OH-groups in trioctahedral (Ni_3) and dioctahedral ($Ni_2\square$) environments, respectively. Along the [A]-[B] join, the IR spectra become more and more complicated in this region, and up to six bands are observed, from 3664 cm^{-1} to 3507 cm^{-1}, corresponding to the different combinations Ni_3-OH, $Ni_2\square$-OH in the octahedral layer plus Si-O-Si and Si-O-Ni in the tetrahedra. This very low wavenumber band is assigned to remaining dioctahedral OH-groups bonded to $2^{[6]}Ni^{2+}$ pointing towards $^{[4]}$Si-O-$^{[4]}$Ni tetrahedral associations. A broad grows at high wavenumber, 3635 cm^{-1}, as $^{[4]}Ni^{2+}$ content increases in the solid solution. It is assigned to the additional OH-groups.

Finally, a clear 1:1 correlation is observed between $^{[4]}Ni^{2+}$ and the additional H^+ content, measured by thermogravimetric analysis. We conclude that the [B] mica is off-composition. The structural formula of the corresponding compound can be written $K(Ni_{2.75}\square_{0.25})(Si_{3.5}Ni_{0.5})O_{9.5}(OH)_{2.5}$.

Characterization of the interlayer space of synthetic micas by far infrared spectroscopy

Robert, J.-L.[1*], Diaz, M.[2], Laperche, V.[3] & Prost, R.[2]
[1]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France ([*]jean-louis.robert@impmc.upmc.fr)
[2]INRA, Unité de Sciences du Sol, Versailles, France
[3]BRGM, Service EPI, Orléans, France

Series of synthetic mica solid solutions, related to phlogopites, have been characterized by far infrared absorption spectroscopy in order to derive the influence of octahedral, coupled tetra- and octahedral, and anionic substitutions on the properties of the interlayer site and specially on the interactions between the compensating cation and the basal oxygens of the tetrahedral layers.

In the far infrared region (wavenumbers < 200cm^{-1}), three main groups of bands can be observed: (1) a band at ν > 150 cm^{-1}, frequently broad with several shoulders, and sometimes well resolved, like in talc with a doublet at 177 and 166 cm^{-1}. The wavenumber of this band, or doublet, is sensitive to the nature of the octahedral cation and its assignment is beyond the scope of this work. (2) a plus or minus broad band, in the range 140-130 cm^{-1} and (3) a low-wavenumber band, with ν < 110 cm^{-1}. The last two bands evidently involve the interlayer cation C, first because they are absent in talc and second because they shift as a function of the nature of this cation (mass and charge effect). Previous measurements on oriented single crystals led to assign the first band(s) to out-of-plane C-O motions, roughly along the c* direction, and the low-wavenumber band(s) to in-plane C-O vibrations.

The micas investigated belong to the joins phlogopite $KMg_3(Si_3Al)O_{10}(OH)_2$ - $KM^{2+}{}_3(Si_3Al)O_{10}(OH)_2$, with M^{2+} = Fe^{2+} , Co^{2+} and Ni^{2+}, phlogopite - eastonite $K(Mg_{2.5}Al_{0.5})(Si_{2.5}Al_{1.5})O_{10}(OH)_2$, phlogopite - tetrasilicic Mg mica (TMM) $K(Mg_{2.5}\square_{0.5})Si_4O_{10}(OH)_2$, and their OH^- - F^- substituted equivalents, plus trioctahedral Na-micas along the join aspidolite $NaMg_3(Si_3Al)O_{10}(OH)_2$ - preiswerkite $Na(Mg_2Al)(Si_2Al_2)O_{10}(OH)_2$.

The low-wavenumber band (in the range 110 - 80 cm^{-1}) is particularly sensitive to variations of crystal-chemical features. A systematic correlation is observed between the geometry of the interlayer site and the position of this band. The main factor is the ditrigonal distorsion of the tetrahedral layer, measured by the α angle. This distortion is required to compensate the misfit between tetrahedral and octahedral layers and can be measured by XRD. It depends on the tetrahedral and octahedral occupancies: $^{[4]}$(Si,Al) proportion and ionic radius of the $^{[6]}$M cation(s) and varies from ≈ 1° in annite (the Fe^{2+} equivalent of phlogopite), to 20° in preiswerkite. In all series, the wavenumber of the in-plane C - O vibration increases with α, indicating higher C - O bond strengths, and a better retention of the interlayer cation.

The evolution of out-of-plane vibration(s) with composition is less clear. Generally the trend is in the reverse way, and frequently this band overlaps with the higher wavenumber ones, see (1). Nevertheless their evolution also reflects crystal-chemical modifications in the interlayer space.

Application of XANES experimental and theoretical studies to high-coordination cations. The case of potassium in micas

Polarized synchrotron radiation allows recording angle-dependent XANES (AXANES) spectra of layered minerals, such as trioctahedral 1*M*-micas [1,2]. The experimental spectra can be evaluated for both their in-plane and out-of-plane component fractions of the electric dipole contribution, so that the related multiple-scattering pathways can be extracted. Most contributions arise from multiple-scattering interactions of the photoelectron ejected from the absorber (K in the interlayer *I*) colliding with other coplanar K and/or alkali atoms, and also with facing oxygen atoms that lie on the basal planes of the tetrahedral *T* sheets [3]. By contrast, the out-of-plane component fractions arise from multiple-scattering pathways that cross the energetic and structural barrier represented by the *T* sheets and reach the *W* anions that are located on the upper level of the octahedral *M* sheets and also the metal cations centering the *M* sheet itself. *Ab initio* calculations help to further interpolate experimental angle-dependent XANES work and to deduce from it the related physical/chemical effects. Calculations show that there are unexpected, large distortions in the mica local structure around the K atoms of the interlayer *I*. Such structural distortions are highly correlated with the compositional disordering that arises from electronic interactions between anions and cations, and extend far away *I* entering deep into the nearby *T* and *M* sheets [4].

Kaolinite and dickite behaviour after deformation by compaction and shear

Aparicio, P.[1*], Johnston, C.[2] & Valdrè, G.[3]
[1]Dpto. Cristalografía, Mineralogía y Q. Agrícola, University of Seville, Spain (*paparicio@us.es)
[2]Crop, Soil and Environmental Sciences, Purdue University, West Lafayette, USA
[3]Dept. of Earth and Geo-Environmental Sciences, University of Bologna, Italy

The structural changes produced on commercial powdered kaolin deformed by compaction and shear was investigated by X-ray diffraction (XRD), low temperature FTIR, differential thermal analysis and thermogravimetry (DTA/TG). Kaolin is composed by 40% of well orderered kaolinite, 18% of dickite and 42% of quartz. The deformation was induced through a specifically built planetary ball milling working in a controlled thermodynamic environment at room temperature and at a vacuum of 0.13 Pa (10^{-3} Torr). In this controlled environment the mechanical apparatus induces simultaneous compaction and shear stress to the material as described in detail by [1]. Kaolin samples were milled for 1, 5, 10 and 20 hours.

The deformation treatment produces a kaolinite structural order decrease, from a low-defect kaolinite to a high-defect kaolinite according to the AGFI index determined by XRD [2]. An index to evaluate the changes produced on dickite was determined following the fitting procedure described in [2]. The results indicated that dickite is apparently less affected by the deformation than kaolinite. A structural order was defined by FTIR and the results were correlated with AGFI results.

Low-temperature FTIR spectral analysis of kaolin group minerals provides a sensitive method for detecting the presence of kaolinite, dickite and nacrite [3]. Using this technique it was confirmed that dickite is more resistant to the deformation process than kaolinite. This technique indicates also that the deformation process produces a hydrous phase which increases with the time of the treatment and, at the same time, that kaolin minerals decrease (Fig.1). The presence of this hydrous phase was also confirmed by DTA/TG, which indicates that its percentage increases especially after 5 hours of treatment.

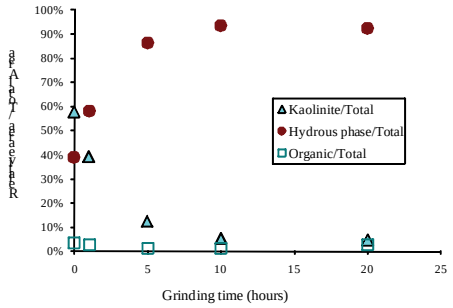

Fig. 1: Evolution of kaolinite and hydrous phase, determined by low temperature FTIR, versus time of deformation process.

In summary our peculiar milling induced a structural change to the octahedral sheets of kaolinite and subsequently to the tetrahedral ones. A progressive reduction of the stacking layer coherence is observed, although the complete amorphisation was not induced even after prolonged milling for 20 hours. Dickite remains after the deformation treatment by compaction and shear even for long times.

Synthesis and degradation mechanism of a swelling fluoromica

Cota, A.[1*], Alba, M.D.[2], Castro, M.A.[2], Pavon, E.[2], Naranjo, M.[2], Orta, M.M.[2] & Pazos, M.C.[2]
[1]Laboratorio de Rayos-X, CITIUS, Universidad de Sevilla, Seville, Spain (*acota@us.es)
[2]Instituto Ciencia de los Materiales de Sevilla, CSIC-Universidad de Sevilla, Seville, Spain

Na-2-mica, a synthetic swelling fluoromica, has recently attracted much attention for its unique combination of high charge (2 charges per unit cell) and its capacity to expand and exchange cations from the interlayer space. A variety of studies regarding the exchange and retention properties of those fluoromicas have been published, as well as their applications in the decontamination of soils [1,2]. However, few studies have been devoted so far to clarify key aspects such as the formation mechanism, the local order of the tetrahedral cations and the arrangement of interlayer species [3-5].

It is well-known that the distribution of aluminum in the framework, and thus the local framework negative charge, would have a dramatic effect on the properties of aluminosilicates [6,7]. If Al distribution in synthetic aluminosilicates could be adjusted, it would offer a way to control their properties. To achieve an exhaustive control of Al distribution through the conditions of synthesis, an experimental method for the determination or, at least, for indirect estimation of the distribution of aluminum in the aluminosilicate framework should be available.

The objectives of this research were to synthesize fluoromica at variable reaction times between 0 and 600 hours. That could enable us to determine the optimum reaction time for the process and identify the appearance of intermediate species which inform of the reaction mechanism. At the same time, the local order changes accompanying the synthesis process, which influence the final physico-chemical properties of the product, could be analyzed.

With the combined use of techniques that inform of both the long and short range structural order, we have shed a light on the synthesis mechanism of high-charge swelling mica and its stability range. The precursors are rapidly transformed into intermediate phases such as tectosilicates and 2:1 phyllosilicate. The precursors are transformed into fluoromica which remains stable for a period of time. Finally, the fluoromica starts to decompose and only the firing products are present.

Surface structure of natural muscovite

Elmi, C.[1*], Brigatti, M.F.[1], Malferrari, D.[1], Castro, G.R.[2] & Ferrer Escorihuela, P.[2]
[1]Dipt. di Scienze della Terra, Università di Modena e Reggio Emilia, Modena, Italy ([*]chiara.elmi@unimore.it)
[2]SpLine at European Synchrotron Radiation Facility, Grenoble, France

The aim of this project is to study the atomic surface structure of a natural muscovite crystal by means of the synchrotron radiation light and the grazing incidence X-ray diffraction (GIXRD).

The muscovite studied [$(K_{0.92}Na_{0.08})$ $(Al_{1.86}Fe^{3+}_{0.01}Mg_{0.07}$ $Fe^{2+}_{0.06}Ti_{0.02})$ $(Si_{3.03}Al_{0.97})$ O_{10} $F_{0.09}$ $(OH)_{1.91}$] is monoclinic, $2M_1$ polytype, with space group $C2/c$ and unit cell parameters: a = 5.19690(10), b = 9.0138(3), c = 20.0835(7) Å, β = 95.763(2)°.

The muscovite structure was refined by single crystal X-ray diffraction and the final refinement yielded the agreement factor R = 0.0299. The difference Fourier map shows a significant residual electron density (2.2 e^-) close to the position related to the M1 site, thus indicating that the excess of octahedral cations is located at M1. The <M1-O> mean bond distance is 2.247(9) and the <M2-O> distance is 1.929 Å.

Grazing incidence X-ray diffraction (GIXRD) was recently performed at SpLine at the European Synchrotron Radiation Facility (ESRF). This type of analysis is very useful to identify typical structural features of the surface, such as possible imperfections, relaxations or reconstructions [1]. Usually, the atoms on surfaces, and sometimes those as deep as several layers down, assume positions different from their equilibrium positions in the bulk. Generally mineral surfaces will not be reconstructed unless they have been heated to temperature higher than 100°C [2]. In our case, the muscovite surface has been exposed to a delay of the first layer in order to study a freshly cleaned surface and data collected by GIXRD confirm that on muscovite surface only a relaxation occurs from an equivalent plane in the bulk. This is a common case for minerals with a low-symmetry structure, e.g. for feldspar [3].

Preparation of homoionic exchanged smectites in bentonites: influence of cation valence and soluble minerals on the success of exchange

Emmerich, K.[*] & Steudel, A.
Karlsruhe Institute of Technology (KIT), Competence Center for Material Moisture (CMM) c/o Institute for Functional Interfaces (IFG), Eggenstein-Leopoldshafen, Germany ([*]katja.emmerich@kit.edu)

The interlayers of natural smectites are commonly occupied by a mixture of Na^+ and/or Ca^{2+} and Mg^{2+}, respectively, and to less extent by K^+. Many chemical, mechanical and thermal properties of smectites and smectite-rich materials depend on the interlayer cations. Therefore, homoionic exchanged materials are prepared to investigate reaction mechanism as function of the interlayer cation or as function of the layer structure with uniform interlayer occupation. 54 publications from different journals from 1950 to 2009 were reviewed with respect to the applied homoionic exchange procedure. Only 6 papers [1-6] reported on the success of homoionic exchange. Up to now there exists no general instruction to prepare homoionic exchanged smectites in dependency of layer charge, cation exchange capacity (CEC) and the obtained level of homoionic interlayers. The aim of the present study was to create a general instruction based on smectite properties, overall phase content and experimental conditions.

For the research three natural bentonites were applied, which differ in content of calcite, dolomite, and gypsum and whose smectites differ in layer charge, CEC and interlayer composition. The homoionic exchange was achieved by repeated reactions of air dry clay aliquots with suspensions of readily soluble chlorides of different cations (Na, Li, K, Mg, Ca, and Cu). The concentration of the chloride solutions was equal to 1x CEC, 5x CEC, 10x CEC and 20x CEC of each material. The solid-liquid ratio averaged 4.4%. The success of homoionic exchange was monitored by exchange of interlayer cations with Cu-Trien and subsequent analysis of the cations in the supernatant exchange solution by ICP-OES.

As expected from charge, size and hydration properties of the cations the homoionic exchange with bivalent cations (Mg, Ca, and Cu) was more effective compared to that with monovalent cations (Na, Li, and K). In addition the exchange of monovalent cations was strongly inhibited or even prevented during exchange experiments with low salt concentrations (1-5x CEC) by present carbonates and sulfates that were dissolved during the exchange reactions. The released Ca or Mg replaced the monovalent cations in the interlayer, thus, the amount of Ca and Mg increased compared to the starting material.

The homoionic exchange was regarded successful if more than 95% of the interlayer consists of a single type of cation. To reach this occupancy rate, 20x CEC (three times exchange) was necessary for monovalent cations and 5x CEC (three times exchange) for bivalent cations. Purification improved the uptake of monovalent cations (reduced concentration of exchange solution, e.g. 5x CEC for K).

Our results briefly indicate that the following information: layer charge, CEC, solid-liquid ratio, concentration of salt solution, type of salt, reaction time, repetitions, and success of exchange should be reported as exchange procedure differs for materials in dependence of material properties, pretreatment and experimental conditions to enable comparison of different studies.

Structural and crystallochemical characterization of sepiolites

González, N.[1], Cuevas, J.[2] & Ruiz, A.I.[2*]
[1]RTL Laboratorio DRX Policristal, Universidad Autónoma de Madrid, Spain
[2]Dept. de Geología y Geoquímica, Universidad Autónoma de Madrid, Spain ([*]anai.ruiz@uam.es)

Sepiolite is a hydrous Mg-rich silicate clay mineral with fibrous morphology that typically occurs as fine-grained, poorly crystalline masses. It is an important industrial mineral with more than 100 commercial uses today in the pharmaceutical, fertilizer, and pesticide industries [1].

In this study, we report the structural and crystallochemical characterization of two sepiolite locations in the same geological context. This is in order to establish structure-properties relations of these clays. The materials came from a lacustrine environment in the Intermediate Unit of Miocene sediments of the Madrid basin (Spain), specifically located in the East of Madrid, Barajas - Vicálvaro.

The crystal structure of four samples of sepiolite was analysed using X-ray diffraction technique and the Rietveld structural refinement method. Sepiolites from Barajas show dolomite and quartz as accessory minerals. Crystal parameters obtained by Rietveld refinement are different depending on the origin, Barajas or Vicálvaro and are attributed to different hydration states.

Structural formulae of sepiolite samples calculated from the results of the chemical analysis, corrected by using the quantification of secondary mineral phases by Rietveld refinement, were close to the ideal formula based on the literature [2].

On the other hand, the X-ray thermodiffraction study revealed zeolitic H_2O is lost during heating from 25 to 200ºC; bound H_2O molecules are released completely at 750ºC; and hydroxyl groups are lost above 850ºC. However, the more ideal sepiolite composition is related to significant better thermal properties characterized by the maintenance of the dehydrated sepiolite structure unchanged up to 350ºC. Above this T a similar evolution can be followed for the several sepiolites, ending with a phase transformation to enstatite mineral.

Characterization of clay material from chalk reservoirs in Denmark

Hem, C.[1*], Skovbjerg L.L.[1], Andersson, M.P.[1], Balogh, Z.[1], Makovicky, E.[2] & Stipp, S.L.S.[1]
[1]Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Denmark ([*]hem@nano.ku.dk)
[2]Dept. of Geography and Geology, University of Copenhagen, Denmark

The presence of clay in reservoir chalk has an effect on calcite recrystallization [1]. It has been suggested that a high clay content enhances chalk dissolution and hence calcite recrystallization [2,3]. Clay could also inhibit recrystallization when it nucleates and grows over the chalk particles. Therefore, although chalk might only contain a few percent of clay, its mineral composition, morphology, size and structure can play an important role in the properties and behaviour of the reservoir. In this study, we examined Maastrichtian age samples from the Aalborg Portland pit (Jutland, Denmark) and from a shallow borehole at Klintholm (Fyn) as well as from the North Sea basin.

Clay was separated from the chalk and analyzed using X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM), atomic force microscopy (AFM) and infrared spectroscopy (IR). The clay types varies from sample to sample, but there is little variation among samples from the same location. SEM and AFM show that there are two distinctly different morphologies of clay. By volume, the major part consists of detrital larger grain smectite or mixed layer smectite/illite but we also find smaller particles of clay, sometimes single layers, which have grown in pore spaces and on the surface of other chalk particles.

[1] Baker, P.A. et al. (1980) *Mar. Geol.*, **38**, 185-203. [2] Fabricius, I.L. (2007) *Sedimentology*, **54**, 183-205. [3] Hardman, R.F.P. (1982) *Bull. Geol. Soc. Denmark*, **30**, 119-137.

Crystal chemistry and thermodynamic properties of kerolite-stevensite mixed-layer minerals

Krupskaya, V.V.[1,2*], Vigasina, M.F.[2], Melchakova, L.V.[2], Ogorodova, L.P.[2] & Kiseleva, I.A.[2]
[1]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry, Moscow, Russia
[2]Dept.of Mineralogy, Geological Faculty, M.V. Lomonosov Moscow State University, Moscow, Russia (*vi_kru@bk.ru)

Two kerolite-stevensite mixed-layer minerals from residual soils of serpentinized ultra basic rocks (Ural, Russia) are studied by X-ray diffraction (XRD), infrared spectroscopy (FTIR), differential thermal (DTA), thermogravimetric (TG, DTG), electron microprobe, and thermochemical analyses. The FTIR-spectra of both air-dried samples indicate that these belong to kerolite-pimelite-trioctahedral smectite minerals with different levels of Ni for Mg substitution [1-3]. This is confirmed by XRD modeling, which additionally shows a mixed layer structure with ca. 30-40% expandable layers. Both samples in air-dried state exhibit the 001 reflection at 11.6 Å shifting to 9.7 Å upon heating at 550-600°C. The corresponding patterns of the ethylene-glycolated samples depend on Ni content (25.0, 13.0, 9.3, 5.3 Å and 24.0, 17.0, 9.0, 5.3 Å for the Ni-poor and Ni-rich samples, respectively).

The TDA and TG curves of both samples are similar and show three steps of water loss: 100-200°C – adsorption water (7.5 and 7.7%) with t_{max} = 100°C, 200-780°C – structural water (2.8 and 3.5%) with $t_{max} \approx 380^oC$, and 780-1050°C – dehydroxylation (4.3 and 3.8%) with t_{max} = 850°C, for the Ni-poor and Ni-rich samples, respectively. Chemical formulas calculated on the basis of a +22 total cation charge were:

$[(Mg_{2.91}Ni_{0.02}Fe_{0.02}Al_{0.01})Si_4O_{10}(OH)_2][Na_{0.02}Ca_{0.02}] \cdot 0.7H_2O$ (I), $[(Mg_{2.07}Ni_{0.87}Fe_{0.08}Al_{0.04})\ (Si_{3.76}Al_{0.24})\ O_{10}\ (OH)_2]\ [Na_{0.02}Ca_{0.03}]\cdot 0.9H_2O$ (II).

Thermochemical investigations by "transposed temperature drop solution calorimetry" are performed in molten $2PbO\cdot B_2O_3$ at T=973 K with a Tian-Calvet high-temperature heat-flux calorimeter. The calibration of the calorimeter was performed by dropping pieces of platinum wire with known enthalpy increments, and the sum of the heat of solution and the heat content of the sample was measured: $\Delta H = [H^o(973\ K) - H^o(298.15\ K) + \Delta H_{sol.}973\ K)]$. The enthalpies of formation from the elements of the kerolite-stevensite mixed-layer minerals were determined after corrections for adsorbed water and by employing reference data for the constituent oxides according to the equation: $\Delta_f H^o_{el}(298.15\ K)_{min.} = \sum \nu_i \Delta H_{oxi} - \Delta H_{min.} + \sum \nu_i \Delta_f H^o_{el}(298.15\ K)_{oxi}$, where ν_i are the stoichiometric coefficients in the reaction of mineral formation from the oxides. The resulting $\Delta_f H^o_{el}$(298.15 K) values are -6018.4±8.5 kJ·mol^{-1} for the Ni-poor sample (I) and -5823±14kJ·mol^{-1} for the Ni-rich sample (II). These values suggest that the Mg-rich members of the kerolite-stevensite mixed-layer minerals are more stable than their N-rich analogs.

Crystallization of natural montmorillonite applying very-high pressure and temperature

Nakazawa, H.* & Taniguchi, T.
National Institute for Materials Science, Tsukuba, Japan
(*nakazawa.hiromoto@nims.go.jp)

Clay minerals of the smectite group are inorganic materials with ability to react with organic compounds. For this reason, they attract particular attention for their application as nanohosts for organic guest molecules. However, smectite occurs usually as a poorly crystallized fine powder. Their characterization and application have been hindered by a lack of large single crystals.

An entropy consideration suggests that a 3D-ordered smectite, if it would exist, might be stable under higher pressure than smectite with a turbostratically disordered structure. Previously, one of the authors has been successful in synthesis of smectite crystals using a silica-alumina glass as starting material by applying 5.5 GPa and 1600°C [1]. However, their crystal sizes were still insufficient for an X-ray structure analysis and nothing was known about their stability relations at very high pressures and temperatures.

In this contribution, similar pressures and temperatures were applied to natural montmorillonite and a highly purified bentonite from Yamagata, Japan, as starting materials. The purification procedures and characterization have been reported in detail elsewhere [2].

The montmorillonite was placed in 100% of humidity for 24 h before the experiment and was encapsulated in a Pt tube with water of about 15 wt.%. Very high pressures and temperatures were applied to the sample by using a belt-type apparatus, e.g. 5.5 GPa and 1500°C for 1 hr [3]. A series of runs under 5.5 GPa were carried out at different temperatures in the range from 1700 to 1000 °C and for durations from 1 to 25 h.

The high pressure product was lightly crushed, mounted on a glass slide, observed by optical microscope and studied by X-ray diffraction for identification. The sample was then exposed to ethylene glycol vapour for one night and investigated again for confirmation of characteristic expansion of smectite. Its morphology was observed by electron microprobe analyzer (JEOL, JXA-8500F) and transmission electron microscope (JEOL, JEM 2000EX).

X-ray diffraction (XRD) study showed that the products consist mostly of montmorillonite with small admixture of kyanite. All the XRD peaks of montmorillonite were extremely sharp. Morphologies of particles revealed in the SEM and TEM images corresponded to long euhedral laths and rare hexagonal thin plates.

Because the starting montmorillonite was extremely fine nanometer-scale powder and completely disordered from structural viewpoint, the euhedral morphology of the high pressure montmorillonite and its size of some tens of micron meter indicate that they were surely grown under high pressure and temperature, probably by the Ostwald ripening mechanism. This suggests that there may be a stable phase of 3D-montmorillonite at very high pressure and temperature around 5.5 GPa and 1700°C. The synthesis of large single crystals of montmorillonite is therefore not entirely impossible and seems to be rather realistic.

How to calculate mineral formula for 3-members mixed layers from EDX-analysis by Transmission Electron Microscopy: example – kaolinite-smectite-vermiculite mixed layers in Friedland Clay (Germany)

Nguyen, T.L.[1*], Kasbohm, J.[2] & Hoang, T.M.T.[3]
[1]Inst. of Geography and Geology, University of Greifswald, Greifswald, Germany (*thanhlangeo@googlemail.com)
[2]GeoENcon Ltd., Greifswald, Germany
[3]Fac. of Geology, Hanoi University of Science, Hanoi, Vietnam

Transmission electron microscopy (TEM) is a very sensitive tool to recognize alteration processes of montmorillonite or other clay mineral phases. The variability of chemical composition of interlayer space, octahedral as well as tetrahedral sheets of each TEM-EDX investigated particle is mirroring this process of alteration.

The contribution offers a methodology to calculate the mineral formula also from particles, which represents e.g. irregular interstratified mixed layer structures with three end members composed by kaolinite, smectite and dioctahedral vermiculite (KSV-ml).

For the calculation of a model mineral formula of KSV-ml it was developed a series of equations to convert the TEM-EDX-analysis of each particle. This conversion is controlled by three parameters: (i) total charge (22 ... 28 per $(OH)_n$ O_{10}), (ii) Si-amount in tetrahedral sheet and (iii) numbers of atoms in octahedral sheet (2 ... 4 per $(OH)_n$ O_{10}).

The contribution contains also an approach of this methodology for the German Friedland clay. Friedland clay is composed mainly by Fe-rich illite-smectite mixed layer (IS-ml), kaolinite (15 wt.%), mica, quartz. KS-ml or KSV-ml could be not detected there before by XRD. After deconvolution of XRD-traces (oriented mounts: air dried, ethylene-glycol saturation) by BGMN-Rietveld technique X-ray diffraction of Friedland clay confirms now also the occurrence for KSV-ml.
Applying presenting TEM-EDX-methodology following different compositions of KSV-ml were calculated in three different samples of Friedland clay. Each analysed sample of Friedland clay is representing a different geological history.

KSV-ml in Friedland Clay 1 *(%K 60%, %S 25%, %V 15%)*
$Mg_{0.01}Ca_{0.02}Na_{0.05}K_{0.08}Al_{2.96}Fe^{3+}{}_{0.13}Mg_{0.08}Ti_{<0.01}(OH)_{5.54}$
$Si_{3.90}Al_{0.10}O_{10}]$
KSV-ml in Friedland Clay 2 *(%K 45%, %S 40%, %V 15%)*
$Mg_{0.03}Ca_{0.01}Na_{0.03}K_{0.06}Al_{2.76}Fe^{3+}{}_{0.11}Mg_{0.03}Ti_{<0.01}[(OH)_{4.72}$
$Si_{3.88}$ $Al_{0.12}O_{10}]$
KSV-ml in Friedland Clay 3 *(%K 50%, %S 35%, %V 15%)*
$Mg_{0.02}Ca_{0.02}Na_{0.00}K_{0.06}Al_{2.64}Fe^{3+}{}_{0.24}Mg_{0.03}Ti_{<0.01}[(OH)_{4.79}$
$Si_{3.89}Al_{0.11}O_{10}]$

Friedland Clay 1 represents the original composition located in the core of ore body. Friedland Clay 2 shows alterations by interaction with glacial water in a closed system. Friedland Clay 3 mirrors the effect of rain to the clay mineral matter (Clay 2) at the surface of open cast mine (= open system).

The differences between Clay (1) and (2) are comparable with smectitization. The differences between Clay (2) and (3) are pronounced by higher octahedral Fe3+ in substitution of octahedral Al. The origin of Fe is the result of degradation processes of Fe-rich IS-ml phases and oxidation of pyrite.

KSV-ml structures in Friedland Clay undergo similar processes of alteration in closed and open systems like described for smectite by Herbert et al. (2008) [1] from batch experiments with bentonites.

The kaolinite-dickite relation by thermodynamic data

Ogorodova, L.P.[1*], Vigasina, M.F.[1], Melchakova, L.V.[1], Kiseleva, I.A.[1], Krupskaya, V.V.[1,2], Luse, I.V.[3] & Randers, M.A.[3]
[1]Dept. of Mineralogy, Geological Faculty, M.V. Lomonosov Moscow State University, Moscow, Russia
(*logor@geol.msu.ru)
[2]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry, Moscow, Russia
[3]Dept. of Applied Geology, Faculty of Geography and Earth Sciences, University of Latvia, Riga, Latvia

The thermodynamic properties of the kaolinite $Al_2Si_2O_5(OH)_4$ and its polymorph dickite were studied on natural samples of kaolinite from the Glukhovetskoye (Ukraine) and dickite from Tibskoye deposits (Russia). Samples were characterized by optical microscopy, X-ray diffraction, electron probe microanalysis, infrared spectroscopy (FTIR) and differential thermal and thermogravimetric analyses. The XRD data refined by Rietveld method with QUANTO software [1] showed rather purity of both studied samples (kaolinite – more 96%, dickite – more 92%). They were well-crystallized, the IR-absorbance spectra and the thermal curves correspond to pure minerals. All thermodynamic investigations were performed with a Tian-Calvet high-temperature heat-flux calorimeter ("Setaram", France). The enthalpies of formation from the elements were determined by "transposed temperature drop solution calorimetry" in molten $2PbO{\cdot}B_2O_3$ at T=973 K. The sum of the heat of solution and the heat content of the sample was measured:

$$\Delta H = H^o(973\ K) - H^o(298.15\ K) + \Delta H^o_{solution}(973\ K).$$

Before experiments, all samples were heated at 200°C for 1.5 hours to remove minor amount of low-temperature water. Calibration of the calorimeter was performed by dropping pieces of platinum wire with known enthalpy increments [2]. With the calorimetric data obtained and needed thermochemical [3, 4] and reference [2] data for pyrophyllite, corundum and quartz the standard enthalpies of formation of natural minerals of kaolinite group from the elements were calculated on the basis of reaction:

$$2Al_2Si_4O_{10}(OH)_2 = Al_2Si_2O_5(OH)_4 + Al_2O_3 + 6SiO_2.$$

For the calculation the following equation was used:

$$\Delta_f H^o_{el}(298.15\ K)_{mineral} = 2\Delta H_{pyrophyllite} - \Delta H_{mineral} - \Delta H_{corundum} - 6\Delta H_{quartz} + 2\Delta_f H^o_{el}(298.15\ K)_{pyrophyllite} - \Delta_f H^o_{el}(298.15\ K)_{corundum} - 6\Delta_f H^o_{el}(298.15\ K)_{quartz},$$

where ΔH – calorimetric data for all constituent minerals. The resulting values of $\Delta_f H^o_{el}(298.15\ K)$ are -4118±10 kJ mol^{-1} for kaolinite and -4127±10 kJ mol^{-1} for dickite. Taking into account the reference data on their entropies [2] the Gibbs energies of formation from the elements were calculated: -3796±10 kJ mol^{-1} and -3805±10 kJ mol^{-1}, respectively. These results show that kaolinite is metastable relative to dickite and agrees with data from [5]. The more widespread natural occurance of kaolinite vs. dickite is due to kinetic factors rather than thermodynamics.

Theoretical study of one-layered kaolinite polytypes

Orbán, R.[*] & Dódony,I.
Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary ([*]orban.richard@gmail.com)

The stacking of adjacent kaolinite-type structural layers with one-layer periodicity is studied using **R** vector and „+", „–" notation introduced by Dódony [1] for trioctahedral TO phyllosilicates. In this notation, **R** is the projection of the **c** axis onto the **ab** plane and „+" or „–" signs the slant of octahedral sheet. The length of **R** can be 0, **a**/3 and **b**/3, with directions of <100>, <110> for **a**/3 shifts and <010>, <310> for **b**/3 shifts, relating subsequent layers.

In the present work, all the twenty crystallographically different one-layer kaolinite polytypes allowed by H-bonding are derived as a result of possible combinations of **R** and slant of octahedral sheet („+", „–"). The number of polytypes, which is 20 (including 8 enantiomorph modifications), is in disagreement with previosuly reported 6 one-layered polytypes [2,3].

Each polytype is characterized by simulated X-ray powder diffraction pattern, [001] selected area electron diffraction (SAED) pattern and [001] projected charge density map. All simulations were calculated for the chemical composition of $Al_2Si_2O_5(OH)_4$, and with the structural dimensions of a = 5.023 Å, b = 8.700 Å, the *layer thickness* ($d_{(001)}$) = 7.000 Å and γ = 90°.

Patterns of the [001] projected charge density map of non-enantiomorph polytypes (12) differ from each other, because they are crystallographically different. By comparison of simulated data, every non-enantiomorph polytype can be identified by combination of intensity distributions and geometry of XRD and [001] SAED patterns.

Molecular simulations of layered double hydroxides (LDHs) by various porphyrine molecules

Pospíšil, M.[1*], Kovář, P.[1], Kovanda, F.[2], Káfuňková, E.[3] & Lang, K.[3]
[1]Faculty of Mathematics and Physics, Charles University in Prague, Czech Republic ([*]pospisil@karlov.mff.cuni.cz)
[2]Dept. of Solid State Chemistry, Inst. of Chemical Technology, Prague, Czech Republic
[3]Inst. of Inorganic Chemistry, v.v.i., Academy of Sciences, Řež, Czech Republic

Molecular simulations were applied for structure analysis of Mg_2Al LDH (original nitrate form) intercalated with [5,10,15,20-tetrakis(4-sulfonatophenyl) porphyrin (TPPS)] [1] and Pd-TPPS. LDH was prepared with an Mg/Al molar ratio of 2. The results are supported by experimental methods like powder X-ray diffraction (XRD) analysis, infrared (IR) spectroscopy and thermogravimetry.

In the case of TPPS, three different types of structures were modelled. The experimental XRD patterns of LDH intercalated with TPPS show 70–80% loading with respect to the theoretical anion exchange capacity (AEC). Type 1 model represent single-phase systems with a 100% TPPS loading in the interlayer space, type 2 show the coexistence of two separate phases, the first phase has interlayer saturated with TPPS anions and the second phase has interlayer fully occupied with NO_3^- anions. Total loading of TPPS in type 2 models was in the interval of 75 – 92 %. Type 3 model represent a structure with the coexistence of both TPPS and NO_3- anions in the same interlayer space. The agreement between experimental and calculated X-ray diffraction patterns and energy characteristic of models show type 2 as most probable.

In the case of Pd-TPPS two models with various loadings (10% and 100%) were investigated. Geometry of Pd-TPPS was optimized by *ab initio* calculations. Optimized geometry of this molecule was inserted into interlayer space from parallel to nearly perpendicular arrangement. The resultant position of Pd-TPPS in the interlayer depends on the degree of intercalation and is related to AEC.

Sonication induced reduction reactions of the Ojén (Andalucía, Spain) vermiculite

Poyato, J.[1*], Pérez-Rodríguez, J.L.[1], Lerf, A.[2] & Wagner, F.E.[3]
[1]Instituto de Ciencia de Materiales de Sevilla, Consejo Superior de Investigaciones Científicas, Universidad de Sevilla, Spain ([*]jpoyato@us.es)

[2]Walther-Meissner-Institut, Bayerische Akademie der Wissenschaften, Garching, Germany
[3]Physik-Department, Technische Universität München, Germany

Sonication produces a delamination and a reduction of the particle size without the significant destruction of the vermiculite structure that is caused by grinding [1]. The extent of particle size reduction and the closely related increase of the surface areas (S_{BET}) are almost independent of the choice of the transfer medium (water or a water/H_2O_2 mixture) [2]. However, chemical analysis, Mössbauer spectroscopy and infrared (IR) spectroscopy show clearly that the choice of the transfer medium can affect the structure of a particular material on a more local scale [2].

More puzzling than the oxidation in presence of hydrogen peroxide was the reduction of the Ojén vermiculite observed during sonication in pure water. Water itself does not reduce the Ojén vermiculite. Interlayer water does not play a role in the reduction of the Ojén vermiculite, since the extent of reduction is roughly the same when the potassium-exchanged Ojén vermiculite, where K^+ is almost unhydrated, is sonicated in water.

Possible reducing agents could be the $H^\bullet$ or the $HO_2^\bullet$ which are formed as an intermediate product in the sonication of (aerated) water or subsequent reactions products like H_2. Especially interesting is the $HO_2^\bullet$ radical because solid surfaces can trigger its formation [3]. Furthermore, it is well documented that these hydroperoxyl radicals react in Fenton systems even in the presence of hydrogen peroxide as a reducing agent [4,5].

To get more insight in the reduction mechanism we carried out sonication in water under air and under nitrogen. By means of Mössbauer spectroscopy we observed a significant difference: the Fe^{3+}/Fe^{2+} + Fe^{3+} ratio amounts to 0.59 under nitrogen and to 0.39 under air (cf. for untreated vermiculite it is 0.73). Though under air the influence of oxygen and, thus, the contribution of $HO_2^\bullet$ cannot be neglected. Under exclusion of oxygen gaseous hydrogen cannot be the reducing agent because it does not react with the Ojén vermiculite at temperatures below 400 °C. The only other choice is the $H^\bullet$. For this radical to act on the clays as reducing agents the cavitation bubbles must be closely attached to the vermiculite surface and they have to reduce the structural iron ions prior to the recombination/decomposition to H_2 or H_2O (together with $OH^\bullet$).

Influence of interlayer charge and water mobility on ^{29}Si NMR chemical shift of 2:1 phyllosilicates

Sanz, J.[1], Sobrados, I.[1] & Robert, J.-L.[2*]
[1]Instituto de Ciencia de Materiales de Madrid, CSIC, Madrid, Spain
[2]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France ([*]jean-louis.robert@impmc.upmc.fr)

A series of synthetic sodium-rich saponites $Na_xMg_3(Si_{4-x}Al_x)O_{10}(OH)_2.nH_2O$, with $0.33 \leq x \leq 1$ and trioctahedral Na-micas $Na(Mg_{3-y}Al_y)(Si_{3-y}Al_{1+y})O_{10}(OH)_2.nH_2O$, with $0 \leq y \leq 1$ have been investigated by ^{29}Si magic angle spinning nuclear magnetic resonance (MAS-NMR) spectroscopy. The salient result is the major effect of the interlayer charge on ^{29}Si chemical shift of four detected NMR components ascribed to Si_3, Si_2Al, $SiAl_2$ and Al_3 environments. The contribution of the interlayer charge is much more important than the previously reported contribution of the ditrigonal distortion of tetrahedral layers, generated by the misfit between tetrahedral and octahedral layers. This observation derives from the peculiar disposition of tetrehedra in phyllosilicates, with three out of four oxygen atoms exposed to the interlamellar space. In saponites with $x < 1$, ^{29}Si MAS-NMR spectra change considerably with the amount and mobility of adsorbed water, indicating that for a given tetrahedra, chemical shift depends on the proximity and amount of interlayer charge seen by this tetrahedron. In dehydrated saponites, where Na^+ cations are disposed in ditrigonal cavities, NMR components split as a consequence of the partial occupancy of three neighbouring cavities. In hydrated saponites, chemical shifts of splitted components are averaged as a consequence of interlayer water and cation mobility. In this analysis, the effect of the increasing octahedral charge of micas is considerably lower than that of interlayer charge. In micas, chemical shift discontinuities detected near $y = 0.5$ are discussed in terms of distortions and relative disposition of contiguous layers.

Computational study of TMA^+ fluorohectorite intercalate

Scholtzová, E.
Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovak Republic (uacheva@savba.sk)

The structural data of TMA^+ fluorohectorite intercalate (TMA-H) into 2:1 layer silicates suggest two possible orientations of TMA^+ cations with low occupancy (~0.9) [1]. The TMA^+ atoms could only appear in any of the positions constrained in the original space group (*C*2/*m*) to the 8*j* Wyckoff position. In the triclinic space group *P*1, TMA^+ cations are free to translate and rotate, though all the movements are restricted by the potential field generated by surrounding atoms. The 64 computational models of mutual orientation of TMA^+ cations were based on this assumption. The primary aim of this study is to find the energetically most favorable arrangement of the TMA^+ cations in fluorohectorite interlayer space. The second task is to identify whether a particular configuration can be detected using X-ray powder diffraction and/or vibration spectroscopy. The main tool in this study is a density functional (DFT) method as applied for the solid state in the VASP program [2]. The analysis of total energies of the models shows that approximately 70% of models fall to the region with very close energies. Hence it is very difficult if ever possible to distinguish the mutual orientation of the TMA^+ cations in these models. The calculated powder diffraction patterns for model with the lowest (BEST) and with the highest (WORST) energy confirm this result. The differences in the intensities of both patterns are almost negligible. The analysis of the calculated vibrational modes for BEST, COMMON (representing group of models with close energies) and WORST models were done in details (Fig. 1). The minimal changes in the position of the C-H stretching modes are caused by changes, formation and/or interruption of the weak C-H…O hydrogen bonds according to mutual orientation of TMA^+ cations in the models.

It can be concluded that experimental distinguishing of mutual orientations of TMA^+ cations in the fluorohectorite interlayer space by the methods discussed above is not possible.

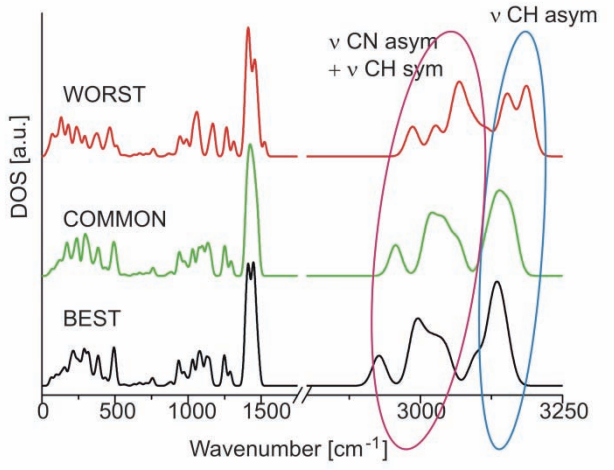

Fig. 1: The calculated vibrational density of states for selected models.

Occlusion of sulphate salts into the Mg-Al-SO_4 hydrotalcite

Stanimirova, Ts.
Sofia University "St. Kliment Ohridski", Sofia, Bulgaria (stanimirova@gea.uni-sofia.bg)

Occlusion of the different salts or molecules into the layered minerals (clays, mica), zeolites, etc. is a well known phenomenon [1]. However, there are only a few papers describing an occlusion of sulphate salts in the natural layered double hydroxides, which are also known as anionic clays or hydrotalcite-like minerals (HTs) [2-4].

This contribution presents the results of experimental investigations of occlusion (possibilities, conditions and peculiarities) of sulphate salts in the interlayer space of Mg-Al-SO_4 hydrotalcite.

Occlusion was obtained by two main ways:

1) During syntheses of the Mg-Al-SO_4 hydrotalcites (Mg:Al =2:1) by co-precipitation of mixed acid solution ($MgCl_2$ and $AlCl_3$) with mixed alkali solution (NaOH and Na_2SO_4 or K_2SO_4 in 5-fold excess). 2) Through post-synthetic reactions (sulphate solution treatment and anion exchange) of dried samples (Mg-Al-SO_4, Mg-Al-NO_3 and Mg-Al-$B_4O_5(OH)_4$ HTs) dispersed in water solutions of Na_2SO_4, K_2SO_4 or $MgSO_4$ with 5-fold excess of SO_4^{2-} anions. All obtained samples were characterized by X-ray powder diffraction (XRD) and Fourier-transform infrared spectroscopy (FTIR).

According to the literature data, lattice parameters of natural and synthetic Mg-Al-SO_4 (Mg:Al=2:1) HTs are a = 0.3044 nm and c = 2.667 nm. Table 1 lists values of the d_{003} and d_{110} reflections, which correspond to the lattice parameters $c = 3 \cdot d_{003}$ and $a = 2 \cdot d_{110}$, respectively.

Table 1: Chemical composition and cell parameters of the materials

Sample	Chemical formula	d_{003}, nm	d_{110}, nm

In the XRD patterns of the products obtained by all three types of occlusion of Na and K sulphate, the MgAl-SO_4 HTs with d_{003} = 1.12 nm were registered. These values are in agreement with previously published d_{003} values of natural MgAl-SO_4 HTs with high content of interlayer water molecules and occluded Na_2SO_4 [3]. However, after additional washing of the occluded samples, in the XRD patterns the phase with d_{003} = 0.889 nm only was observed. It can be concluded that the occlusion and extraction of the sodium and potassium sulphate salts are reversible processes and depend on the concentration of sulphate salts in the solutions and on the washing process.

In the case of occlusion of the sulphate salts of divalent cations (Mg, Ni, Zn, Co, Cd, Mn etc.) it should be taken into account the order of selectivity of divalent cations in the hydrotalcite: Mg<Mn<Cd<Co≈Ni<Zn, because the occluded cations may affect the composition of the host structure [5].

Thermal transformation of chrysotile asbestos

Uehara, S.[1*], Takai, Y.[1] & Mashima, H.[2]
[1]Dept. of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, Fukuoka, Japan
([*]uehara@geo.kyushu-u.ac.jp)
[2]New Material Research Institute Co. Ltd, Tokyo, Japan

Chrysotile is a fibrous form of serpentine. Thermal reactions of chrysotile have been extensively investigated (see, e.g. [1]), and thermal treatment is a possible method of converting the material into less hazardous form [2].

Differential thermal (DTA) and thermogravimetric (TGA) analyses were made simultaneously on a SII NanoTechnology SSC/5200 thermal analyzer using 20 mg samples. A JEOL JEM-3200FSK instrument was used for transmission electron microscopy (TEM), scanning electron microscopy (STEM) and electron diffraction analysis. Thermal transformation of chrysotile from Thetford Mines-Black Lake, LAB Chrysotile Mine, Quebec, Canada, were heated to 1000ºC in dry conditions (N_2) at a rate of 10 º/min for DTA/TG analysis was studied by TEM, STEM with EDS and selected area electron diffraction (SAED).

Morphological changes of many fibrils were observed (Fig. 1). The dehydration products have generally irregular to granular shape and a few other grains show fibrous morphology. Chemical analysis of the thermal products show intermediate compositions of forsterite and enstatite, which means that very tiny grains of enstatite were formed together with forsterite (Fig. 2). The SAED pattern is complex due to the coexistence of forsterite, enstatite, and amorphous areas.

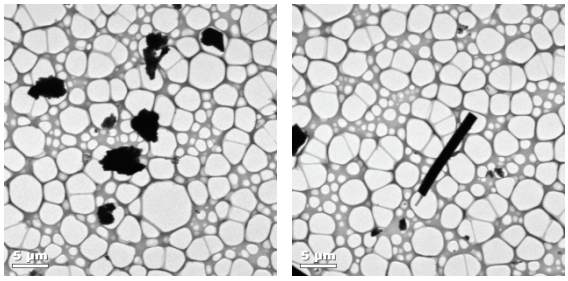

Fig. 1: TEM images of chrysotile asbestos after DTA/TG analysis. (a) granular shape grains. (b) fibrous morphology.

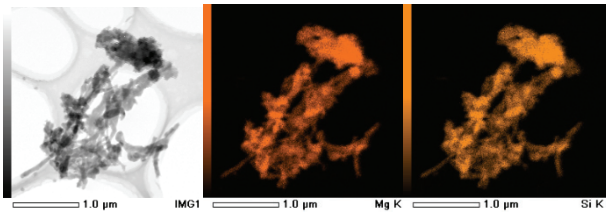

Fig. 2: STEM image (a) of chrysotile asbestos after DTA/TG analysis up 1000ºC and X-ray mapping images for Mg*K*α (b) and Si*K*α (c).

Globular phyllosilicates of the Lower Riphean Ust'-Il'ya Formation, Anabar Uplift, Northern Siberia – crystallochemical and isotope data

Zaitseva, T.S.[1*], Gorokhov, I.M.[1], Ivanovskaya, T.A.[2] & Melnikov, N.N.[1]
[1]Institute of Precambrian Geology and Geochronology, RAS, St. Petersburg, Russia ([*]tatiana.s.zaitseva@gmail.com)
[2]Geological Institute, RAS, Moscow, Russia

Geological interpretation of K-Ar and Rb-Sr dates for globular phyllosilicates has been an important task since the 1950s, when these minerals have received wide acceptance as isotopic geochronometers. In many cases, the results agreed well with biostratigraphic data or with the ages of associated igneous rocks. But along with such data, there were overestimated or "rejuvenated" age values, and it was necessary to explain them and find criteria assuring suitability of globular phyllosilicates for dating. The structural simulation together with the Mössbauer data for globular phyllosilicates enables to estimate, whether the cation distribution in their crystal lattice is primary or resulted from post-diagenetic transformation of the mineral structure. The efficiency of such approach has been demonstrated by the examples of globular phyllosilicates of the Lower Riphean Ust'-Il'ya Formation, Anabar Uplift.

The modeling is based upon the following concept of glauconite formation. It is supposed [1,2], that an unordered distribution of the octahedral cations is typical for the newly formed glauconite. At this point atoms of the ^{40}Ar and ^{87}Sr inherited from a mineral-precursor do not leave glauconite structure yet. Only at the final stages of glauconite formation involving significant increase of the K content, the cation ordering occurs in the octahedral layer. The ordered distribution appears to result from a layer-by-layer dissolution-precipitation process. The redistribution of the cations in all glauconite layers should result in expulsion of radiogenic ^{40}Ar and ^{87}Sr alien to the mineral structure and in startup of the "radioactive clock", based on the decay of ^{40}K and ^{87}Rb. If such a glauconite is free from secondary alteration, its isotope date should correspond to the timing of early diagenesis, i.e. should be close to the stratigraphic age.

Globular phyllosilicates of the Ust'-Il'ya Formation are characterized by the ordered cation distribution in the structure formed at the stage of early diagenesis of the sediments. This means that the Ust'-Il'ya globular phyllosilicates appeared to undergo no important chemical and structural transformations which could result in loss of radiogenic ^{87}Sr and ^{40}Ar. The Rb-Sr isochron age (1483±5 Ma) and K-Ar dates (1459±10 Ma) of these minerals [3] do correspond to the Lower Riphean. An agreement between the stratigraphic position of glauconites and their isotope ages suggests that the Rb-Sr and K-Ar systems of minerals were not seriously distorted since the early diagenesis.

Historical minerals from the Evje-Iveland pegmatites at the Natural History Museum in London

Müller, A.[1*], Rumsey, M.[2] & Ihlen, P.[1]
[1]Geological Survey of Norway, Trondheim, Norway
([*]Axel.Muller@ngu.no)
[2]Natural History Museum, London, UK

The granitic pegmatites of Evje-Iveland in southern Norway have attracted the attention of mineralogists for more than a century due to the large number and extraordinary crystal size of rare metal-containing minerals. Many of these, such as the scandium-bearing mineral thortveitite, were first discovered and described from localities in this district. Mineral collectors became fascinated by exotic minerals, such as thortveitite and the local farmers, who mined the pegmatites for feldspar, soon realised an opportunity to improve their income by selling specimens. Through farmers and then more professional mineral dealers, it was not long before these rare minerals began to appear in both public and private mineral collections worldwide. As part of the EU Synthesys project GB-TAF-5516 – a collaboration project between the Geological Survey of Norway and the Natural History Museum (NHM) in London – the mineral specimens from Evje-Iveland in the NHM collection and their history were studied. About one hundred high quality mineral specimens from the Evje-Iveland pegmatite district are registered in the collection, including specimens of beryl (n=15), thortveitite (12), aeschynite-(Y) (12), gadolinite (8), ilmenorutile (8), monazite (7), euxenite (4), columbite (3) and tveitite-(Y) (2) and other more common minerals.

The oldest mineral specimen from Evje-Iveland is a giant topaz crystal that weighs about 60 kg and is ca. 48 x 33 x 20 cm in size. It was purchased from Christiania Bergbureau of Norway in 1901 for 27 pounds 11 shillings and 11 pence, which was a considerable amount of money at the time. It is remarkable that even before the first scientific description of the Evje-Iveland minerals by Brøgger [1], the NHM collection had already obtained a beautiful topaz specimen from the region.

Besides interesting early Evje-Iveland specimens, the NHM collection also contains some important scientific specimens, including sample BM 1908,74 registered as an ilmenorutile which was described and analysed by W.C. Brøgger in 1906 [1]. In his article, Brøgger used the specimen to determine that ilmenorutile was distinct from rutile and at that time should be considered a separate species. Since this time, there has been much controversy over the classification of ilmenorutile which was eventually concluded in its discreditation as a mineral species in 2006.

One of the most famous minerals of the region is thortveitite, which is one of only three terrestrial minerals known to contain a large quantity of scandium (>20%). It was first described by Jacob Schetelig in 1911 [2] from the Ljosland mine in Iveland and is named after the Norwegian feldspar trader Olaus Thortveit who operated this pegmatite mine. The first two thortveitite specimens obtained by the NHM were purchased in 1914. It should be noticed that only three years after the first description of thortveitite, two high quality specimens had already been purchased by the museum in London.

These and other examples illustrate the historical and scientific importance of the rare minerals from Evje-Iveland pegmatite district.

Early 19th century scientific networking – a study in Jacob Berzelius' mineral collection

Langhof, J.
Dept. of Mineralogy, Swedish Museum of Natural History, Stockholm, Sweden (jorgen.langhof@nrm.se)

Jacob Berzelius (1779-1848), one of the most renown chemists of all times, is credited, among others, for the discovery of four new elements (Ce, Se, Th, and Si), establishing the today-used chemical symbols system, and coining chemical terms such as catalysis, protein, isomerism etc. But not to forget, he is also the founder of modern systematic mineralogy, introducing a chemical classification of minerals in 1814.

From the early 1800's up to his last year of life, he accumulated a mineral collection of nearly 2,400 specimens from all over the world. His mineral collection was donated to the Swedish Museum of Natural History (SMNH) in 1848, then a part of the Royal Swedish Academy of Sciences in Stockholm, were he acted as Secretary for 30 years. This is today part of the museums' vast systematic mineral collection and it is kept with the original hand written labels of Berzelius. His collection contains the holotypes of acmite, aeschynite-(Ce), thorite (and hence of the element thorium!), and the "proto-holotype" of xenotime-(Y). Also many of his original published mineral analyses are based on specimens from his own collection.

Berzelius was a prolific correspondent and wrote and received thousands of letters from several hundreds of scientists, industrialists, physicians, politicians etc. Many of the important correspondences have been published over the years (for example with Wöhler, Berthollet, Goethe, Davy, and Rammelsberg). Berzelius field-collected himself and received mineral specimens as gifts or in exchange; he usually documented from whom, on the labels.

During the digitalization of the catalogues at the Department of Mineralogy at the SMNH, a detailed survey on donations of collections has been performed. And by a more thorough study of Berzelius' original labels, we have been able to establish many of his sources for mineral specimens, not always traceable in the preserved letters from archives. Many famous names known from the mineral realm have been thus revealed: Cordier, Zinken, Stromeyer, Haüy, Brewster etc. The work on the important Berzelius mineral collection will continue; we plan to publish the final results in the near future.

The scientific heritage and biography of Friedrich Martin Berwerth (* 16.11.1850, Sighişoara, Romania – † 22.9.1918, Vienna, Austria)

Hammer, V.M.F.[1*], Pertlik, F.[2] & Seidl, J.[3]
[1]Dept. of Mineralogy and Petrography, Museum of Natural History, Vienna, Austria ([*]vera.hammer@nhm-wien.ac.at)
[2]Institute of Mineralogy and Crystallography University of Vienna, Geozentrum, Vienna, Austria
[3]Archive of the University of Vienna, Austria

F. M. Berwerth was born on the 16th of November in 1850 in Sighişoara (former Hung.: Segesvár, Germ.: Schäßburg), Romania, as the son of the pharmacist F. Berwerth. There he visited the protestantic secondary school. In 1869, already one year before school leaving examination, he was graduated an adjunct in pharmacy. Since then he matriculated at the University of Vienna and later on in Graz, where he finished pharmacy in 1872. For postgraduate studies he went to Heidelberg, where he obtained his PhD in chemistry within one year only. His teacher was Robert W. Bunsen (1811–1899).

His scientific career started in 1874, when he became employee of G. Tschermak-Seysenegg (1836–1927) at the University of Vienna and in the same year he became an assistant at the Imperial Mineralogical Cabinet. The following years he chiefly worked as analyst of minerals together with E. Ludwig (1842–1915).

In 1884 he married E. Frankel (1860–1936), a niece of the geologist E. Suess (1831–1914). They raised three children.

The transfer of the mineral collection from the Imperial Royal Mineralogical Court Cabinet – originally hosted by the Imperial Palace to the new Imperial Museum of Natural History building situated on the Viennese "Ringstrasse" – was mainly performed by F. M. Berwerth together with director M. A. Brezina (1848–1909). F. M. Berwerth oversaw the revision and re-numbering of more than 108,000 mineral specimens. In 1888 F. M. Berwerth was nominated as curator I. class and in this function he was the man in charge of the new scientific presentation of the mineral-, the rock- and the meteorite collection. Since 1896 he was the head of the Mineralogical-Petrographical Department of the Imperial Museum but he was designated as the director around the year 1904.

F. M. Berwerth´s research interests changed from mineral chemistry to petrography and geology, followed by the classification of meteorites. His scientific work is reflected in more than 150 scientific papers about regional petrography, geology and about meteorites, as one of the main fields of his personal interest. In this context, he was author of "Fortschritte in der Meteoritenkunde" and "Mikroskopische Strukturbilder der Massengesteine", a benchmark for students.

With the petrographic description of the rocks from Jan Mayen Island collected during the Austrian Polar Expedition he got the postdoctoral lecture qualification for Petrography at the University of Vienna in 1888 and became professor in 1907.

F. M. Berwerth did a lot of collecting field trips; among others he started the geological mapping of the Hohe Tauern in Austria in 1892 while the construction of the Tauern-Railway was in progress.

F. M. Berwerth was honoured by the Austrian Emperor, as well as by the king of Spain and he became elected member of the "Imperial Academy of Science". Berwerth was a founder of the Austrian (former Viennese) Mineralogical Society as well as an originator of the German Mineralogical Society.

F.M. Berwerth died in 1918 shortly after his retirement.

Rock samples from World War I in the collections of the Prussian Geological Survey (PGLA)

Ehling, A.
Federal Institute for Geosciences and Natural Resources, Berlin, Germany (angela.ehling@bgr.de)

When preparing the digital documentation of the non-displayed collection at the German Geological Survey in Berlin, Germany, we came across a sizeable suite of samples (more than 700 pieces) from the Balkan region, which had been collected between 1914 and 1918 by the staff of the Prussian Geological Survey.

This discovery represented the starting point of a study on whether and how these samples reflect the events of World War I (WWI), specifically the activities of German geologists during this historical period.

Some of Germany's objectives during the WWI were the conquest of ore-rich regions of France and Luxembourg, as well as military, political and economic control over Belgium, which would have provided access to its mineral-rich colonies in Africa. At the beginning of WWI, Germany founded a "War Raw Material Department". Its original task was to establish an inventory of mineral deposits in Germany, later on expanded to industrial mineral deposits from regions conquered for war economic purposes, such as phosphate, graphite, fluorite and asbestos.

From the collection of about 700 samples that was under investigation, about one third of the samples originated from abroad: France (Alsace-Lorraine), Belgium, Serbia, Ukraine, Turkey and Congo. These samples partly reflect the period's exploration efforts, including reports documenting the 'usable' deposits in Belgium [1] and Serbia [2], especially coal, phosphor and iron.

This material apparently was of great importance to the military at the time. A new name, *i.e.* "War geology" was thus born, and "War geologists" took part, after the war, to the negotiations from Brest-Litowsk [3] (with the purpose to obtain mineral ores, coal and oil from Ukraine) aimed to establish the damage produced by the German army during the war in mining regions of France [4].

The concept of mineral evolution in Russian mineralogical literature (1979–2008)

Krivovichev, S.V.
Dept. of Crystallography, St.Petersburg State University, St. Petersburg, Russia (skrivovi@mail.ru)

A recent paper on mineral evolution [1] and the subsequent series of papers in the February 2010 issue of 'Elements' [2] attracted considerable attention on this subject from both professional and popular scientific circles.

However, for the sake of historical truth, it is worthy to indicate that the very idea of mineral evolution was under consideration in Russian mineralogical literature as early as 1979 [3], when the late A.G. Zhabin considered different aspects of mineral evolution and subdivided three major periods of this development: "meteoritic", "basaltic" and "corous". He also emphasized the importance of this concept in the elaboration of evolutionary mineralogy of our planet, "…which will be the source of new ideas and predictions in the study of mineralogy of other planets of the Sun System". Later, N.P. Yushkin, D.V. Rundqvist, D.P. Grigoriev and others [4-6, etc.] suggested distinguishing between phylogeny and ontogeny of the mineral world with the note that "ontogeny is a brief repetition of phylogeny". A highly original but rather controversial paper [7], investigated the evolution of minerals from the viewpoint of the evolution of their structure types. A.P. Khomyakov and N.P. Yushkin formulated basic principles of inheritance (or heredity) in the mineral world [8]. Later, N.P. Yushkin (2004-2008) emphasized the importance of coevolution of the biosphere and the mineral world.

It is thus obvious that the concept of mineral evolution did not start in 2008 [1] as announced in the February 2010 issue of "Elements", but was under serious consideration at least 30 years prior to its publication in the Western literature.

Jean-Pierre Alibert (1820–1905): when science becomes art

Touret, L.
Musée de Minéralogie, Mines-ParisTech, Paris, France (lydie.touret@mines-paristech.fr)

In the early XIXth century, a French fur merchant at the court of the Russian tars, Jean-Pierre Alibert (1820–1905) was given the permission to prospect for new mines in Siberia. He was first looking for gold, with significant results, but found in 1840 traces of graphite. He was already aware of the fact that Cumberland mines, since 1550 the only producer of quality graphite for art pencils, were close to exhaustion. He then engaged all his strength, as well as a considerable amount of money, for finding the graphite source. After several frustrating years, excavating thousands of cubic meters of hard rock, he finally discovered an incredible graphite seam occurring in alkaline syenite on the top of the remote Mount Botogol, roughly 500 km west of Irkutsk. With the help of the local Saïoute people, he opened a mine, "Siberian graphite" becoming soon a reference for the rest of the world. He also found nearby huge boulders of nephrite, this being the first discovery of this jade variety outside of China.

Alibert left abruptly Siberia in 1865, having secretly sold his mine and related rights to the German Faber who, together with few other competitors, notably Hardtmuth from Austria, became the best specialists in quality pencils. Botogol was at this time very close from the Chinese border, and names like Koh-I-Noor, or pencils painted in yellow, as Hardtmuth did in 1889, were clear references to the "Siberian (or Chinese) graphite". Still to-day, 80% of all pencils sold in the USA are yellow.

Alibert took to Paris the best pieces of graphite, carefully selected during the 10 years of his mine management, together with a number of minerals or animals, all representative for Siberia. Being an admirer of Napoleon III and Alexandre II, he produced in their honour elaborate, very artistic trophies, mainly made of exquisitely carved graphite. These trophies were exhibited (and awarded) at several World Exhibitions, then presented to the most famous educational institutions: in Paris, to Conservatoire des Arts et Métiers, Museum d'Histoire Naturelle, Sorbonne university and, finally, Ecole des Mines. He left behind also a unique book, "Souvenir de Sibérie", containing 146 aquarelles depicting all the stages of his travel between Saint-Petersburg and Mount Botogol, and the most spectacular aspects of Siberian life style.

Incidentally, the Botogol deposit has proven to be not only of best quality ever, but also to contain a number of interesting trace elements (germanium, silicon). Former Soviet authorities did classify this deposit as having strategic importance; its location and existence were thus almost forgotten, but not the name of Alibert by local people, who, hoping on his return, maintained the Botogol village until the beginning of the XXth century. Alibert is now considered as a national hero in the newly independent Bouriatian republic, being also rediscovered in his own home country after a long period of oblivion.

CSI mineralogy: fakes, frauds and shoddy science

Kampf, A.R.
Mineral Sciences Dept., Natural History Museum of Los Angeles County, Los Angeles, California, USA (akampf@nhm.org)

Minerals are, by definition, naturally formed. Their distinctive properties, appearances and modes of occurrence have made them objects of both wonder and scientific interest. As collectables, they formed an important component of the cabinets of curiosities of Renaissance Europe that eventually morphed into today's natural history museums. It is the fascination with the natural beauty of minerals that has ironically tempted some to use unnatural means to enhance that beauty.

The fakery of mineral specimens, including attaching crystals to matrix, cutting and polishing faces, adding color, bending and shaping wires, synthesizing crystals, and ascribing incorrect locality information has been going on for hundreds of years and there is certainly not a major mineral collection in the world that contains no fakes. Of course, there are a variety of motives for faking specimens, some perfectly ethical, but when the motive is to deceive, especially for personal gain, the practice becomes fraud.

Mineralogical fraud is most dangerous when it directly enters the scientific arena, where it is manifest as manufactured minerals and manufactured or intentionally mishandled data. An important rationale for requiring the deposition of type specimens in institutional collections is that they allow others to corroborate the physical existence, natural occurrence and described properties of the minerals. Unfortunately, it is sometimes the case that researchers are not meticulous in their designations of type specimens and deposit specimens that they merely sight-identified and, in the worst case, that don't even contain the described minerals.

Natural history museums are, first and foremost, repositories for natural objects. It is the responsibility of museum curators to uncover mineral fakery, fraud and shoddy scientific practice in order to maintain the integrity, authenticity and scientific reliability of their collections.

Winestone, limestone and rhinestone – examples of low-budget educational museum projects

Schumacher, R.
Mineralogisches Museum, Steinmann-Institut, University of Bonn, Germany (R.Schumacher@uni-bonn.de)

The following are examples of museum projects that were carried out on a minimal budget and – at the same time were meant to educate lay people about and fascinate them with geoscientific topics. The two most common winestone crystals, potassium hydrogen tartrate ($KHC_4H_4O_6$) and calcium tartrate tetrahydrate ($CaC_4H_4O_6 \cdot 4H_2O$) are well-known to the wine connoisseur: they appear like small pieces of broken glass in the "last drops" of a bottle of good quality wine. This project combined crystallographic research [1] with a museum exhibit, thus using an object encountered in daily life to introduce mineralogical themes like crystal structures and chemical reactions.

In a project within the German network "Steine-in-der Stadt" ("Rocks in the city") [2], the building stones of the cathedral of Bonn were presented to the public on the nationwide "Day of the building stone". On demand, tours were offered from a booth in front of the cathedral. Participants learned about traditional regional building stones and their geological history. One of these building stones is a limestone; the quarried material used to be deposited in a Roman aqueduct leading from the northern Eifel to Cologne. Among other rocks, this local limestone was used in the project to build a "bridge" between geology and local history.

A rhinestone is a simulated diamond made of quartz, glass or plastic. Rhinestone is also known as strass, named after the Alsatian jeweler Georg F. Strass, who imitated diamonds by coating the lower side of glass with metal powder. In an exhibit on "Real or fake" presented on the Gem and Mineral shows in Denver, Colorado and Tucson, Arizona, a replica of the Bavarian crown (Fig. 1) with rhinestones and other imitations of gemstones was the center piece of an exhibit with various real gemstones and their "fake" equivalents and helped to explain imitations of gemstones and artificial/synthetic products.

Fig. 1: Replica of the Bavarian Crown.

The Teck Suite of Galleries: Earth's Treasures at the Royal Ontario Museum, Toronto, Canada

Tait, K.T.
Dept. of Natural History, Royal Ontario Museum, Toronto, Canada (ktait@rom.on.ca)

The Royal Ontario Museum (ROM) opened in 1914 and is located in Toronto, Ontario, Canada. It is Canada's largest museum of world culture and natural history objects, with over 6 million objects and over 40 galleries. Showcasing exceptional mineral, gem, rock and meteorite specimens, the Teck Suite of Galleries: Earth's Treasures is one of the ROM's newest galleries. The 2,100 m^2 combined gallery space is divided into the Vale Inco Limited Gallery of Minerals, the Canadian Mining Hall of Fame Gallery and the Gallery of Gems and Gold.

The Vale Inco Limited Gallery of Minerals**,** the largest gallery in the Teck Suite of Galleries, presents the ROM's exceptional specimens of minerals, meteorites and rocks, exploring such areas as the classification of minerals, their physical and scientific properties, causes of mineral colour and the geological environments necessary for mineral growth. This gallery features the ROM's renowned meteorite collection, including one of the biggest lunar meteorites on display in the world, as well as the Tagish Lake meteorite, a rare carbonaceous meteorite that fell in Canada in 2000.

This gallery employs a new interactive touch-screen labeling system in lieu of conventional printed specimen labels. Each case is flanked by computer kiosks, 42 stations in total, containing high resolution images of the minerals and detailed information about the items displayed in the case or elsewhere in the gallery. This sophisticated labeling technology allows visitors to pinpoint where specimens are located within each case as well as in the gallery. The label script can also be enlarged for ease of reading and is in French and English. The high resolution photography of each of the minerals, combined with the zoom-in feature of the system, allow visitors to appreciate each item's intricate details. This kiosk system also allows us to present different layers of information to the visitor. The casual visitor who is only interested in the aesthetics of the minerals, can casually walk through the gallery, taking in the beauty of minerals without being bombarded with information. Whereas the more inquisitive visitor can spend time on each mineral, learning such information as the locality where it was discovered, its chemical formula, crystal structure and any other information and quick facts we would like to highlight.

The Gallery of Gems and Gold is a 245 m^2 room specially-designed to highlight gems, crystals and precious metals. Highlighted in the gallery is the 898-carat "Light of the Desert", the largest faceted cerussite gem in the world.

The Canadian Mining Hall of Fame Gallery showcases the importance of the mining industry in our everyday lives and highlights the exceptional contributions of Canadians to this industry. A 4.5 x 1.8 m fully bilingual, interactive video wall controlled by two computer kiosks located in front, dominates this area. Divided into two sections, the left side portrays the biographies and personal stories of the Canadian Mining Hall of Fame inductees. On the right of the screen, a presentation explains how mining touches every part of our lives and short videos explore a variety of minerals such as silver, titanium and zinc.

A new Romanian meteorite, from a museological perspective

Pop, D.[1*], Benedix, G.[2], Ionescu C.[3], Har, N.[3] & Benea, M.[3]
[1]Museum of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania ([*]dana.pop@ubbcluj.ro)
[2]Dept. of Mineralogy, Natural History Museum, London, UK
[3]Dept. of Mineralogy, Babeş-Bolyai University, Cluj-Napoca, Romania

On June 12, 2008 (21:45 hrs local time), a bolide was observed by eye witnesses crossing the skies of 6 counties (spanning along 325 km distance) in south Romania. Locally, the event was accompanied by sonic booms [1]. The fireball was white-green and very brilliant; it had a W-E trajectory, at an angular height of 35–40º above the horizon (report on "Urbi et Orbi" homepage, by V. Ghincolov). A fragment of 6.913 kg landed in a private garden in Pleşcoi village (Buzău County, Romania), at 12-15 m distance from an eye-whiteness. In November 2008, the complete sample was sent by the finder (M. Popescu) to the Museum of Mineralogy at Babeş-Bolyai University. On December 2008, the new fall was announced in specialized circles by the Romanian meteorite collector A. Răzvan.

The specimen shows a dull, black, fusion crust patched by a thin network of cracks. The flat, basal surface exhibits some lighter-coloured strips and parallel thread-like lines marked by drops of melt (Fig. 1). The first investigations on the new meteorite used nondestructive methods, only, *i.e.* tomography and X-ray fluorescence measurements, and additional 3d-modelling techniques. In January 2010, the material was investigated further at the Natural History Museum in London by means of optical microscopy and electron microprobe (EMP), among other thechniques.

Fig. 1: Surface features on the flat base of Pleşcoi meteorite.

These studies showed that chondrule outlines are obscure under the optical microscope, but more discernable in back-scattered electron (BSE) images. Recognizable chondrule types include barred olivine and radiating pyroxene. The fusion crust is up to 2 mm thick; it is enriched in opaque minerals, displayed along fissures and cleavage planes within silicates. The matrix is fully recrystallized; brecciation is not obvious. Fe,Ni metal and troilite (FeS) grains are relatively fresh, sometimes with thin weathering rims. Olivine exhibits undulatory extinction, but no shock veins. The main non-metallic minerals, identified by EMP, are olivine ($Fa_{25.5\pm0.3}$), low-Ca pyroxene ($Fs_{21.4\pm0.1}$; $Wo_{1.3\pm0.2}$), and chromite (Cr/Cr+Al=0.85; Fe/Fe+Mg=0.86). Based on these features, the "Pleşcoi" meteorite, has been classified as an ordinary chondrite (L5-6), with S2 shock stage and W1 weathering grade.

On May 15, on the occasion of the Night of Museums 2010, a new exhibition will be inaugurated, having the Pleşcoi meteorite and its fall and research history as main focus.

Study on digital technology applied to minerals and museums

Yang Liang-Feng
The Geological Museum of China, Beijing, China
(yanglf@mail.gmc.org.cn)

Minerals and museums are two traditional topics of interest; their combination gave birth to mineral museum. As in the case of other similar institutions, mineral museums acquire, preserve, study, communicate and exhibit the tangible and intangible mineralogical heritage of humanity and its environment for purposes of education, study and enjoyment. Digital technology transfers these functions of mineral museums from reality into the immense virtual space. Thus, it brings vitality and intensity of expression to museums, and establishes another type of museums, *i.e.* the digital museum, which exists in the virtual world on the web. Many organizations or museums have been constructing and developing such digital museums, for example the Virtual Heritage Network (USA), the European Cultural Heritage Network, the Globe Digital Museum (Japan), the Platform of Modern Distance Learning (China), the National Infrastructural Natural Resource (China), the China Digital Science and Technology Museum, the National Digital Museum (China), the National Digital Archives Program (China, Taiwan) etc.

For mineral museums, in the real as well as in the virtual world, mineral specimens and knowledge on their mineralogy represents the core of the displays. In a real museum, it is a fact that some minerals might be destroyed due to physical changes triggered by the lightning conditions of the display; some minerals are difficult to display because of their very small sizes; while too many minerals never have a chance to be on display because of the limitations of the display space. Virtual reality technology provides potential powerful solutions to rebuild the appearance and shape of natural specimens in the virtual world, as virtual minerals; thus, these virtual minerals could be displayed with no limits. Nevertheless, because mineral usually are composed of many crystals and one single crystal shows many crystal faces with different orientations, image capture and shape reconstruction may be difficult procedures. The capture manner and the reconstruction technology, as well as the light used for capture are important factors which should be taken into consideration.

Like in the case of museums in the real world, the attractivity of digital museums arises from their content and display manner. The content of a digital mineral museum should be represented by scholarly information data as well as by more practical information for non-specialists. Scholarly information may relate to databases of scholarly knowledge, research results and specimen images. Non-expert information may link to databases of basic professional information on specimens, publicly-intelligible science illustrations, and multimedia courseware. The first data type supplies professionals with systematic mineralogy knowledge in order to assist mineralogical teaching, research and mineral mining, as assistant tools. The language used in this case should be learned, precise and unadorned. The second type of information provides the society with easily-understandable mineralogical knowledge; this should be acquired *via* interactive display systems that allow scientific knowledge to be communicated to the public in an interactive way. In this case, the language has to be popular, accessible, artistic, as well as joyful and playful. These two kinds of information can be transferred by implementing up-to-date information technology which is currently rapidly-developing.

Lorenz Oken and his mineralogical activities in Jena, Germany

Kreher-Hartmann, B.
Mineralogical Collection, Dept. of Geoscience, Friedrich-Schiller-University of Jena, Germany (cbk@uni-jena.de)

Lorenz Okenfuß (1779-1851), known as Lorenz Oken, was notorious as physician and philosopher, member of the Leopoldina and first principal of the University of Zürich, Switzerland. He edited the journal “Isis” between 1817 and 1822, which was one of the most significant journals for natural science in the early 19th century. But not much was written about his mineralogical activities, although von Kobell named a mineral - O(c)kenite - after him.

Oken spent in Jena 17 years in total, with the main focus on mineralogy at that time. During the first period, from 1807 to 1819, he had been appointed the position of honorary professor for Medicine and Pharmacy. Due to his scientific work in the field, he was acknowledged as ordinary professor for Natural Science in 1812. He held his lectures in the zoological cabinet because of some dissents with J.G. Lenz, who had been the professor for mineralogy in Jena at that time. The main dissagreement concerned the arrangement and system of minerals. Oken preferred a system of five groups, oriented more on the philosophical side. He considered mineralogy as “Irdlehre” (eng. „understanding of the Earth), while Lenz had been an autodidact, non-critical scholar of the theories of A.G. Werner in Freiberg, Saxony. Oken published only a few books. One was entitled „The natural system of the ores”, another one was dedicated to explaining the concept of Natural Science. He used this concept as the basis for his lectures. As opposed to Lenz, he tried to combine new chemical knowledge with the tradititional describing parts of mineralogy.

But not only mineralogy filled his time. He got involved with the uprising of the students and attended the „Wartburgfest”. Together with his political work, his activities had been no longer tolerated and he had been released in 1819. This was decided by J.W. von Goethe, who acted as a minister at that time and was in response to the request of the University of Jena.

After three years of absence, in 1822 Oken came back to Jena as a private scholar and worked with his system of philosophical aspects on mineralogy. He tried to rename minerals and physical characteristics of minerals based on his views, but in the end he failed. Thus, after another five years, he left Jena for ever.

The rediscovery of the "French Blue" diamond

Farges, F.[1,2*] & Sucher, S.[3]
[1]LMCM, Muséum national d'Histoire naturelle, Paris, France
([*]farges@mnhn.fr)
[2]Dept. of Geology and Environmental Sciences, Stanford University, Stanford, CA, USA
[3]The Stonecutter, Tijeras, NM, USA

Within the collections of the Muséum national d'Histoire naturelle, Paris, an unknown lead cast of the "French Blue" diamond (FB), the mythic-, 69 carats-, deep-blue diamond of the French crown jewels [1] was identified. FB was stolen in 1792, and then set in an amazing jewel, the Golden Fleece. Both had never reappeared.

The lead cast was laser-scanned, in order to reveal details in the precious stone's cut. Based on this 3D information, we have assumed for the first time that FB was subsequently recut into the "Hope" diamond. This lead cast was probably donated around 1815 to Haüy by "Mr Achard", the highest authority in gems from Paris at that time. Achard wrote that "Mr Hoppe of London" possessed the original diamond, i.e., the FB. Would it have been possible that Achard and/or Haüy, the founders of scientific gemmology, had confused the FB with the "Hope" diamond? This second discovery suggested instead unsuspected connections of H.-P. Hope with the FB. This is consistent with historical reports suggesting that one of the 1792 thieves, Cadet Guillot, brought the Golden Fleece to London in 1796, when H.-P. Hope started to inherit his parent's immense fortune. But between 1808–1813 H.-P. Hope had severe financial problems, thus the diamond has most likely been pawned to D. Eliason, a London jeweller, who had it recut in 1812. Nevertheless, the recut diamond reappeared within Hope's collection near 1830 when his fortune was back.

Optical spectroscopy for the "Hope" diamond, kindly provided by J. Post (Smithsonian) was used to virtually recreate the FB, based on its 3D laser data. Remarkably, the brilliance of the FB is accurate at ± 5°. The FB shows a bright "7-fold rose" on its pavilion. This unsuspected, spectacular and complex design was clearly intended to symbolize King Louis XIV [1], the "sun-king", with its "7 planets in the deep-blue universe". FB has been cut in 1673, following the constraints of the "Tavernier Blue" (TB) diamond [2] but not only. The diamond shows intriguing ratios of integers for its dimensions, asymmetry of opposite sides and joint diagonals in front of the culet. These constraints follow the "canon of proportions", defined by architects Vitruvius (Antiquity) and Palladio (Renaissance). Thus, the FB fits Da Vinci's "Vitruvian man", where its "membro virile" points to the FB's culet, i.e., the centre of the square representing "the cosmic world", features which make FB a harmonic allegory of the sun-king of divine rights. Additionally, the natural crystal from which the TB was cut has been predicted based on TB's crystallography [2] and refined using the Bravais–Friedel, and Donney–Harker theories [3]. The refined hypothetical crystal, a rhombicuboctahedron, was so thick that its colour was almost black. Cleavages along (111) were thus required to make thinner "slices" within the crystal to reveal its greyish-blue colour. This suggests that two other roughs for this diamond must have existed.

The first recreation of the Golden Fleece of King Louis XV, by using the FB, a 107 ct spinel and 490 other diamonds, conducted by Herbert Horovitz, jeweller in Geneva make the subject of a 90 min. documentary that will be broadcasted by the end of 2010 on National Geographic and Arte channels, among others.

Some tools to adapt mineralogical museums to new trends: the example of the UPMC-La Sorbonne collection

Boulliard, J.-C.
Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), Université Pierre et Marie Curie (UPMC), Paris France (jean-claude.boulliard@impmc.upmc.fr)

In 1983, Paul Desautel (a former curator of the Smithsonian) stated that: "the mineral museums are deathly sick… science has moved off and left them." This terrible diagnosis appears to have ended an era, in which institutional collections were, above all, places of science and research.

Since that time, a tremendous interest in minerals has raised from the public. In addition to research and teaching, the mineral museums have to respond to this public demand. The museum of the Université Pierre et Marie Curie de Paris (UPMC) has developed the following tools which will be presented at the conference:

- a CD, edited in 2006, that tries to be a virtual visit of the collection. It contains 450 pictures of specimens. They have been selected among the most beautiful and important (for science and/or industry) specimens on display. One chapter deals with the history of the collection. Other chapters contain answers to the most frequent questions asked by the public;
- an audioguide (to the knowledge of the author the first one for a mineral museum) tells the story of the collection and describes the contents of the show cases;
- a luxurious book, published in November 2010, presents 150 (mainly large) specimens at 1/1 scale. The photographer offers a new, more artistic vision on mineral photography. Short texts describe the minerals and their classification. Longer texts are more epistemological and museological. They are devoted to the history of the UPMC collection, the general history of the mineral collections and criteria that make a specimen a highlight of the legacy of nature.

18th century collections, 21st century audiences

Chambers, S.* & Mitchell, L.
Royal Cornwall Museum, Truro, Cornwall, UK
(*sara.chambers@royalcornwallmuseum.org.uk)

The Royal Institution of Cornwall's (RIC's) collection of South West of England mineralogy is one of the finest in the world. It is housed and managed by the Royal Cornwall Museum (RCM), the main vehicle by which the RIC's extensive collections are made accessible to the public. Our challenge is to re-present this collection to 21st century audiences.

The mineral collection comprises some 15,000 specimens. At its core is the outstanding early collection of Philip Rashleigh (1729-1811); the most famous of Cornish mineral collectors, who lived near Fowey, Cornwall. Rashleigh collected over 3,000 mineral specimens not only from Cornwall but also from around the world, corresponding with dealers and exchanging with collectors throughout Europe.

Years of under-funding and insufficient human resources resulted in the progressive dormancy of the mineral collection. By the end of the 20th century it was in a state of some disorder and had effectively ceased to function as a learning resource and existed only as a group of display items.

Since then much collection recovery work has been undertaken and behind the scenes, these benefits are already apparent. However, the public face of this collection is still seen via a traditional, pseudo-systematic, gallery display, based on creating knowledge through the development and research of collections and disseminating it through formal, passive, displays. Not only is the gallery physically inaccessible to many of its key audiences; it is intellectually impenetrable to all but the most knowledgeable subject specialists.

Learning is at the heart of the RCM, but we need to redefine our role, not only as a result of pressure from government and current funding streams but also in recognition that we have a bigger role to play in society.

The way in which we present collections to the public has shifted; we have recognised the need to see ourselves no longer as simply collections-focussed but audience-centred. This shift is critical when thinking about how we re-present our collections to the discerning, 21st century, visitor. We face challenging times, competing for funding as well as people's leisure time. What is needed is an understanding of audiences and an outward-looking agenda. Visitor expectations have risen dramatically, and so must ours.

Our evidence suggests that the mineral collection's audience appeal is broad in range - including audience groups that might at first appear mutually exclusive: subject specialists and family or younger visitors. As the largest museum in Cornwall, strategically placed within the region, we have a key role to play in helping tell the story of Cornwall and to promote a deeper knowledge and appreciation of its unique landscape and mining heritage. Our world class collection of minerals can help communicate these narratives: effective interpretation strategies can unlock the scientific understanding of the collection as well as revealing the human stories behind how this collection came to be.

Armed with an understanding of interpretation and how this can be used to present and layer information, as well as specialists from all disciplines (curatorial, learning, interpretation and exhibition), the challenge now is to ensure we have the processes in place, as well as the intellectual flexibility, to make these changes.

The 70 years-old mineralogical collection of Comenius University in Bratislava (Slovak Republic)

Ozdín, D.
Dept. of Mineralogy and Petrology, Comenius University, Bratislava, Slovak Republic (ozdin@fns.uniba.sk)

The Faculty of Natural Sciences was established in 1940, as the fourth faculty of the Comenius University in Bratislava. Complicated war conditions and revolutionary changes in 1948 marked the beginning of a 20-year consolidation process of individual institutes and departments, through periodic organizational changes. The collection of the Mineralogical-Petrographical Institute of the Slovak University in Bratislava was established in 1940–1942. Its founder was Prof. R. Lukáč, the head of the institute, but in the same time the curator (May 1939–August 1940) of the Slovak Mining Museum (former Dionyz Štúr Museum) in Banská Štiavnica, as well as the manager of the Mineralogical-Petrographical Institute of the Faculty of Chemical technological engineering of the Slovak Technical University.

For almost 40 years, R. Lukáč has built the basis of the most distinguished academic mineralogical and petrological collections in Slovak Republic. Besides specimens from Slovak and Czech localities, significant collections were represented by minerals from Krantz Company in Bonn, Peschl collection, the collection of Ronge from Broumov, specimens from Freiberg Mining Academy (Mineralien Niederlage), as well as samples originally belonging to the Slovak Mining Museum in Banská Štiavnica. Later on, the collection was enriched through donations, field-collected specimens and acquisitions resulted from scientific research of the faculty staff.

In the following 20 years, the collection was enriched mostly with samples from active Slovakian deposits (*e.g.* Banská Štiavnica, Rudňany). A big expansion of the collection was recorded after 2000, when new collections were established: gemmological collection, collection of meteorites and tektites, and, of special significance, systematic and topographical collections of minerals from Slovakia. At that time, the largest and most complete, still unparalleled, Slovak systematic collection was opened. Several private collectors contributed with many specimens to this exhibition. Additionally, the Department of Mineralogy and Petrology preserves a rich petrographical collection, one of the largest in European Universities.

Inauspiciously, in the last decades a few hundreds specimens were stolen. However, the worst year for the collection was 2006, when the department's storage place, hosting thousands of specimens mostly from Slovakia and Czech Republic was destroyed.

Traditionally, the department had one or two curators as members of the staff: Prof. Rudolf Lukáč (1940–1977), Vlasta Judinová (1961–1982), Daniela Briatková (1979–1989), Ivan Friedl (1989–1991), Viktória Fejdiová (1991–1997), Miroslav Horal (1997–2000) and Daniel Ozdín, PhD. (2000–).

The department is currently dominated by three main exhibitions: the Mineralogical System of Slovakia, the World Mineralogical System and the Petrographical collection. Smaller displays on ore textures, genesis of minerals, gemmology, SiO_2 phases and historical scientific instruments (as the technical museum of the department) have been opened in 2010.

Thus, we consider our exhibition as one of the best among university mineralogical collection in Central Europe.

Between tradition and innovation: the new Mineralogical Section of the Natural History Museum of the University of Firenze (Italy)

Pratesi, G.[1,2*], Bindi, L.[1], Poggi, L.[1], Fantoni, L.[1], Andreani, M.C.[1] & Scali, G.[1]
[1]Natural History Museum, University of Firenze, Italy
[2]Dept. of Earth Sciences, University of Firenze, Italy
([*]g.pratesi@unifi.it)

The Natural History Museum of the University of Firenze was founded, in 1775, by Grand Duke Pietro Leopoldo Lorena. It was located in Torrigiani Palace, near the Pitti Palace, in order to create an ideal connection between art and science. Nevertheless, the earliest collections date back to the 15th century, namely from the times of Lorenzo de' Medici. The Museum has adsorbed, during its long history, many other collections: it is worthy mentioning that Niels Stensen's specimens – as well as the collections of Targioni Tozzetti, Foresi, Roster, Capacci, Ciampi, Ponis, Brizzi – are preserved in this institution. In 1880, the collections moved near the Botanical Garden (named Giardino dei Semplici) and San Marco church where they have remained until now. The mineral collection of the Museum – containing over 50,000 specimens – ranks among the world's finest due to its very broad representation, wealth of rare species and large number of specimens first described in the scientific literature - namely holotypes, the Island of Elba collection, pegmatite minerals from Brazil etc.

In order to allow a greater public visibility to the about 800 mineral specimens on display, the Mineralogical Section deserved a new exhibition which has been projected by architect Piero Roberto Papi and which was recently opened.

Fig. 1: The new entrance of the Mineralogical Section of the Natural History Museum of Firenze.

A cursory review of the exhibited collections reveals world-class specimens of covellite, elbaite, topaz, beryl, sulphur, celestine and dozens of other minerals. At the entrance, the visitors are welcomed by an amazing view of the best specimens from the Ponis collection and an exciting display of back-lighted thin slices of agate and liddicoatite. Showcases on meteorites, lithology, crystal growth, polymorphism, crystal chemistry, crystallography, physical properties, mineral deposits and use of minerals and rocks add to the educational and visual experience. Finally, the systematic display gathers over 200 beautiful specimens from all over the world, grouped according to their chemical classification.

Mineral collections and museums in Germany: past, present, future

Simon, G.[1*] & Schumacher, R.[2]
[1]Museum Mensch und Natur, Staatliche Naturwissenschaftliche Sammlungen Bayerns, München, Germany
([*]simon@musmn.de)
[2]Mineralogisches Museum am Steinmann-Institut, Bonn, Germany

In Germany, minerals' curation has a long tradition, a fact that immediately becomes evident from the history of classical collections, their establishment and the people in charge. University collections like those of the Humboldt University of Berlin (founded 1781), Bonn (1818), Freiberg (1765), Jena (1779), and Marburg (1790), as well as museums like the State Museum of Mineralogy and Geology in Dresden (1587), the Hessian State Museum Darmstadt (1774), the Senckenberg Natural History Museum in Frankfurt (1817) and the Bavarian State Collection of Mineralogy (1803), are only a few among such well-known historical institutions. The people in charge were internationally-known authorities, for instance A. Breithaupt, B. Cotta, V.M. Goldschmidt, P. v. Groth, A. v. Humboldt, F. Mohs, J.J. Nöggerath, H. Rosenbusch, H. Schneiderhöhn, F.A. Walchner and A.G. Werner.

At present, the general situation of mineralogical collections in Germany has become very problematic, financial support and staff having been reduced. In addition, new duties have been imposed upon curators of mineralogical collections. Storing minerals is only one of the activities. Modern collections have to grow, all samples have to be documented in detail, and, finally, the collections have to represent an area of public information and scientific research. Apart from physical geography, geosciences are not taught in German schools. Thus, one of the main tasks of curators in museums and in universities is also to attract school classes and the general public to geosciences.

Curators of German mineral collections are organized in the "Mineralogical Museums and Collections" working group within the German Mineralogical Association (DMG). The working group periodically organizes meetings to encourage communication and cooperation, to initiate and coordinate joint projects, and to arrange mutual support. Actual activities are represented by this contribution, "Mineralogical Collections and Museums in Germany", as poster at IMA2010, an email network, the "Type Specimen Catalogue Germany" and a joint website (http://www.mineralogische-sammlungen-dmg.de).

The poster presents an overview of the most important mineral and rock collections in Germany, together with their major fields of research and interest.

The tradition of Theophrastus' "On Stones" during the early stages of modern mineral science

Mottana, A.
Dipto. di Scienze Geologiche, Università Roma Tre, Rome, Italy (mottana@uniroma3.it)

Theophrastus' περι λιθων (*De lapidibus* = On Stones) reached western Europe *c*. 1413-27, as one of the many Opuscula then being transferred from Byzantium to Italy. Possibly, the original source was a copy of *Vaticanus graecus 1302*, a codex written in Byzantium c. 1300-30 [1]. However, περι λιθων entered the European Latin-speaking learned community only in the second half of the 15th century, via a number of copies carried out in Italy by Greek expatriates after the taking of Byzantium by the Turks (1453). In particular, it was studied by Hermolaus Barbarus (*c*. 1490) while preparing the first corrected edition of Pliny's *Naturalis Historia*, and it was first printed by Aldus Manutius [2]. Aldus' editorial decision of printing only the Greek text hindered the diffusion of Theophrastus' ideas on the formation of stones and also on the names and properties of the 60-odd minerals contained in his book, thus no real progress for the new science of Mineralogy occurred till a selection of περι λιθων was translated to Latin by Georgius Agricola and incorporated into his *Bermannus* (1530). This is the first innovative treatise on mines and ores published in Europe after Albertus Magnus' *De mineralibus* (*c*. 1265). Agricola added more quotations later, in his *De ortu et causis subterraneorum* and *De natura fossilium* (1546), which contain his theoretical resp. descriptive knowledge on stones. Little else he added into *De re metallica* (1555), which is devoted to mining. Two full Italian translations of Agricola's *corpus* (1550, 1556) helped diffusing Theophrastus' work among scientists much more than could two emended printings of the Greek text (1541, 1577) or one Latin full translation of it (1578), all being of interest only to philologists.

A translation of περι λιθων into Italian was carried out by F. Imperato (1599) and introduced by him into *Dell'Historia Naturale* [3]. His translation is the first one ever made into a modern language, but it is partial, as it covers only 48 sections of Theophrastus' text. Imperato's translation did not help spreading Theophrastus' ideas because: a) his book was printed privately in a small number of copies and circulated only among a selected group of colleagues, albeit of high reputation; b) Italian was already fading out as a widely-known international language, particularly among scientists in the protestant country, where science was advancing rapidly.

Theophrastus' name kept being well known among scientists, but not his ideas. These had no impact onto the "scientific revolution" and remained substantially out of reach for most mineralogists till the English complete translation by J. Hill [4] made περι λιθων known at a level beyond superficiality. The translations into French and German that followed immediately afterwards were carried out from Hill's English text and contributed to farther spreading, as well as to accelerate the "industrial revolution". They created the fame of Theophrastus as the "grandfather" of Mineralogy, much as Agricola gained his fame of "father" of Mineralogy. This outcome took place at the same time when Crystallography overcame Mining as the leading branch of the science of minerals by the efforts of J.-B. Romé de l'Isle and R.-J. Haüy and the separation of Mineralogy from Oryktology (= Petrography) due to A.G. Werner.

Sir James Hall's visit in Schemnitz

Rózsa, P.
Dept. of Mineralogy and Geology, University of Debrecen, Hungary (rozsap@puma.unideb.hu)

Sir James Hall of Dunglass (1761–1832) (Fig. 1) is regarded to be the founder of experimental geology. In these experiments he proved that cooling rate affects the texture of molten rocks [1]; demonstrated the stability of limestone under high pressure and temperature [2]; and performed scale models of folding under compression [3].

Fig. 1: Portrait of the young Hall by Angelica Kauffmann (Scottish National Portrait Gallery).

He attended Christ's College, Cambridge, and the University of Edinburgh, where he studied chemistry and natural history under Joseph Black (1728–1799) and John Walker (1730–1803), respectively; however, he obtained no graduation. In 1783–1786 he went on a 'Grand Tour', which was a flourishing custom of the upper-class British young men. He travelled through France, Germany, Austria, Switzerland and Italy. Although he never published any account on this tour, his handwritten diary survived [4]. Thereafter, he lived in Dunglass and Edinburgh, where he became acquainted with James Hutton (1726–1797) and John Playfair (1748–1819); their excursion to Siccar Point, which proved to be a turning point in history of geology, started from Sir James Hall's house in Dunglass.

During his 'grand tour', in the spring of 1784 he made a three-week-trip from Vienna to Hungary. His main aim was to visit the mining-metallurgical region near Schemnitz (Selmecbánya, now Banská Štiavnica, Slovakia). In his diary he gives a detailed description on hydraulic mining machines and metallurgical processes. He visited several times the chemical laboratory of the 'Bergakademie', and met Anton Ruprecht (1748–1814?), who was the professor of chemistry in the Academy. The excellent chemical-metallurgical laboratory developed by Ruprecht as well as his training method, i.e. the student could make experiments by their own, had a deep impact on the young Hall.

This eminent scientist's account also proves that the Begakademie in Schemnitz, and particularly the chemical-metallurgical training belonged to the European forefront in the last decades of the 18th century.

Letters of German naturalists to Domokos Teleki, the first president of the Jena Mineralogical Society

Viczián, I.
Hungarian Institute of Geology, Budapest, Hungary
(viczian@mafi.hu)

Count Domokos Teleki (1773-1798), a young Hungarian aristocrat studied in Vienna University (1789-1793), later he lived in his native district in Transylvania but occasionally he returned to Vienna. He owned a valuable collection of minerals. On a journey in 1795 he visited the Saxonian principalities in Germany. After returning home he received many letters from Germany. Shortly after his visit, in 1797 the Jena Mineralogical Society was founded, probably the first scientific society in mineralogy ever existed. As a result of his visit and correspondence he was elected for first president of the society.

Ten letters of this correspondence addressed to Domokos Teleki were preserved in the archives of the Teleki Library in Marosvásárhely (Târgu Mureş, Romania). They are so far unpublished. Letters sent in the opposite direction by Teleki and other Hungarian members of the Society are preserved mainly in the archives of the Jena University and have been partly published [1,2].

Teleki received letters in the period 1796-1798 from the following persons:

- J. F. Freiherr zu Racknitz, a high standing official and collector of minerals, Dresden,
- August J. G. K. Batsch (1761-1802), professor of botany and founder of the Society of Natural History (1793) in Jena,
- Johann Georg Lenz (1745-1832), professor of mineralogy and founder of the Mineralogical Society (1797) in Jena,
- prince Ernst of Saxony-Coburg (1784-1844), later ruler of the principality as Ernst I (1806-1844),
- prince Ferdinand of Saxony-Coburg (1785-1851), later incorporated into the Hungarian nobility (1827) after marrying the Hungarian duchess Maria-Antonia Koháry (1816).

The letters are dealing with donation and exchange of precious mineral samples, mainly various gold ores and precious opals of Hungarian origin. Another theme is the Jena Mineralogical Society itself, its organisation, members and activity in the first year after the foundation. Persons like Werner, Klaproth, Goethe, Herder, the Hungarian secretary Bredeczky etc. are mentioned. In this respect the letters represent a valuable source of data concerning the contemporary specimens, collections and scientific studies of minerals.

The letters indicate that mineralogy was widely accepted in high social classes and among leading literary persons in Germany around the end of the 18th century.

Minerals from Carpathians Mountains and Transylvania donated by emperor Josef II (1785) to the Museum of Collegio Nazareno, Rome

Mussino, A.[1], Nasti, V.[1] & Mottana, A.[1,2*]
[1]Gruppo Mineralogico Romano, Rome, Italy
Dipartimento di Scienze Geologiche, Università Roma Tre, Rome, Italy ([*]mottana@uniroma3.it)

The mineralogical museum of Collegio Nazareno, the teaching institution of the "Order of Poor Clerks Regular of the Mother of God of the Pious Schools", in short: "Piarists", was founded, *c*. 1760, by Gian Vincenzo Petrini (Lucca, 1725-1814). It included minerals from all over Europe, and also gifts received by various popes. Minerals from Vesuvius and the Latium volcanoes implemented the collection thanks to Petrini himself and Scipione Breislak [1].

On March 24, 1769 the museum was visited by Josef II, emperor and king of Hungary, who was in Rome as an incognito tourist, but, in fact, had been sent by Maria Theresia to organize the election of a pope who would abolish the Jesuit order. Several years later (June 14, 1785), the museum received a large gift from the emperor, which consisted in eight boxes of minerals, mostly from Transylvania, all carefully classified according provenance and morphological characters. This gift is described extensively in the book, in two volumes, written by Petrini [2] to clarify the find of the new mineral species described by foreign scientists visiting the surroundings of Rome (cf. [3]).

Volume 2 (1791) contains, in addition, the description of the Au-bearing minerals of "Beseraw" and "Boiza" mines, in Transylvania, and of specimens of "gold mixed with iron and copper sulphides and manganese" coming from the "rich mine of Nagyag … which produced so much on behalf of the house of Austria". Petrini further states that the imperial collection had been arranged by the "celebrated Baron of Born" (= Ignaz edler von Born: Alba Iulia, 1742-Vienna, 1791), who had also made the description of the specimens (mostly in Latin). Among them, two were considered by Petrini to be especially valuable samples of *gelfertz* (= auriferous and/or argentiferous chalcopyritic viz. pyritic ore: [4] p. 29): one is from Sankta Barbara mine near Fuszerchs (= Füzzérádvany) and the second one from Sankt Anton quarry in the Boiza valley.

The mineralogical museum of Collegio Nazareno has survived and, in particular, most (unfortunately not all) imperial gift is carefully preserved by Gruppo Mineralogico Romano, an association of mineral amateurs and collectors that helps scientists in studying the minerals of this internationally-known volcanic region. The imperial collection in the museum represents a rare set of samples arrived unchanged to us from 18th century Europe. They are organized according to Agricola's principles, i.e., on the basis of his idea of ore mining, slightly modified on a chemical basis. Thus, its organization shows the state of Mineralogy before the change of paradigm induced by J.-B. Romé de l'Isle's and R.-J. Haüy's crystallographic approaches (*c*. 1780-1790).

Some central European geoscientists of the 18th century and their influence on Mozart's music

Whittaker, A.[1] & Tillmanns, E.[2*]
[1]British Geological Survey, Kingsley Dunham Centre, Keyworth, Nottingham, UK
[2]Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria ([*]ekkehart.tillmanns@univie.ac.at)

The lives and contributions of several central European geoscientists of the 18th century, Rudolph Erich Raspe (1736-1794), Ignaz von Born (1742-1791), Karl Ludwig Giesecke (1761-1833), Karl Haidinger (1756-1797), Nicolaus Joseph von Jaquin (1727-1817), Johann Anton Scopoli (1723-1788), Franz Joseph Müller von Reichenstein (1740-1825), Johann Gottlob Lehmann (1719-1767), Anton Ruprecht (1748-1814) are discussed, many of whom had close contact with composer and musician Wolfgang Amadeus Mozart (1756-1791) by contributing either directly or indirectly to some of his musical works, especially "Die Zauberflöte" (The Magic Flute) as well as making significant contributions to various aspects of geoscience and related technology which are still important today. Mozart's "Kantate auf den hochwürdigen Bruder Born" für Solo, Chor und Orchester (KV 471), also known as „Die Maurerfreude" (Masonic Joy), was composed on the occasion of Born's introduction of the amalgamation process in the Habsburg dominions which was a big social event at the time. It seems certain that Mozart used Giesecke to provide the words of this cantata. Born took an active part in the Vienna musical scene, attending Mozart's concerts and recitals. Especially close was Mozart's connection to the Jaquin family after N. J. von Jaquin returned from his professorship at the Mining Academy in Selmecbánya (Banska Štiavnica, Schemnitz) to Vienna as professor of botany and chemistry. Mozart took an active part in the Jaquin family's musical life and in their musical evenings and dedicated several of his works to Jaquin's sons Joseph Franz and Emilian Gottfried. Jaquin's daughter Franziska studied the piano with Mozart who wrote the piano part of the Kegelstatt-Trio (KV 498) for her.

It seems worthwhile to mention that in 1991, 200 years after his death a new mineral $CaMn^{3+}[OH/SiO_4]$ was detected by Italian mineralogists [1] in the Cerchiara manganese mine, near Faggiona, Val di Vara, Liguria, Italy and was named after him, Mozartite.

Also discussed is the connection of these individuals to other European scientists of the time like John Hawkins (1761-1841), Johann Jakob Ferber (1743-1790), Matthew Boulton (1728-1809), Johann Friederich Blumenbach (1752-1840), Abraham Gottlob Werner (1749-1817), Martin H. Klaproth (1743-1817), Robert Townson (1762-1827), Nicolaus Poda (1723-1798), Friedrich Wilhelm Heinrich von Trebra (1740-1819), Johann Friedrich Wilhelm von Charpentier (1735-1805) and the establishment of the Selmecbánya (Banska Štiavnica, Schemnitz) Mining Academy and its important contributions to geoscience and relation to technical mining matters and its particular importance at the time of the Industrial Revolution. Influential in connection with the scientists mentioned were the North American Benjamin Franklin (1706-1790) and the Spanish mineralogist Fausto d'Elhuyar (1755-1833), founder of Mining Academies in Madrid and Mexico.

The discovery of the element tellurium and the relevance of the Academy to major scientific arguments of the day such as the position and status of alchemical theories and the phlogiston theory are also briefly discussed.

On the formation of giant crystals of gypsum: the science behind beauty

Garcia-Ruiz, J.M.[1*], Canals, A.[2], Villasuso, R.[3], Van Driessche, A.E.S.[1] & Otálora, F.[1]
[1]Laboratorio de Estudios Cristalograficos, CSIC-Universidad de Granada, Spain (*jmgruiz@ugr.es)
[2]Universidad de Barcelona, Spain
[3]Unidad Naica, Compañia Peñoles, Mexico

Giant crystals of gypsum are fascinating masterpieces of Nature. Until the development of flat glass technology, they were used as sophisticated building materials as reported by Pliny the Elder who described the existence of large crystals of gypsum -*lapis specularis*- in Segobriga (Spain) renowned for their transparency and size.

Fig. 1: a) Cave of crystals in Naica's mine (Chihuahua, Mexico) Note man on the left for scale;b) Gypsum crystal from Naica showing the non-singular faces {1k0};c) AFM picture of the {010} face showing void formation.

Other localities with even larger crystals were reported during the last century such as the unique Geode of Pulpí (Spain), the giant crystals of El Teniente mine in Chile and the spectacular caves and caverns in the range of Naica (Mexico) [1,2]. Among them, the so-called Cave of Crystals in the Naica mine is one of the most amazing displays of mineral beauty ever created by Nature. In addition to the colossal crystals, which reach up to eleven meters in length and exceed one meter in thickness, the scenery developed by the individual crystalline beams going through the darkness of the cave, from the floor to the ceiling, is a unique example of harmony based on crystal symmetry. But at the same time, deciphering the mechanism of formation of these crystals is a fascinating scientific challenge. We will discuss in this lecture the scientific basis of this remarkable phenomenon of mineralization. The study is supported by data obtained with a number of techniques including fluid inclusions analysis, confocal differential interference contrast microscopy, atomic force microscopy, stable isotopic analysis, as well as experimental and theoretical nucleation and crystal growth studies of calcium sulfate. Our explanation is based on a solution mediated anhydrite-gypsum phase transition occurring in a slow and smooth cooling scenario. Our fundamental studies have also revealed the importance of kinetics of that mineral transition under natural conditions. Finally, we will also offer an explanation for gypsum properties based on their peculiar growth features.

Genesis of amethyst geodes at Ametista do Sul, Rio Grande do Sul, Brazil

Gilg, H.A.[1*], Krüger, Y.[2], Taubald, H.[3], Morteani, G.[4] & Frenz, M.[2]
[1]Lehrstuhl für Ingenieurgeologie, TUM, Munich, Germany (*agilg@tum.de)
[2]Institute of Applied Physics, University of Bern, Switzerland
[3]Lehrstuhl für Geochemie, University of Tübingen, Germany
[4]Gmain No.1, Isen, Germany

Amethyst-bearing geodes in the Ametista do Sul area, RS, Brazil, are hosted by 40 to 50 thick lava flows of the Lower Cretaceous Paraná Continental Flood Basalt province [1]. They show characteristic hydrodynamic shapes, thus the cavities formed by ascending accumulations of magmatic gas bubbles. Geode infill starts with celadonite, pyrite, and chalcedony, followed inwards by colorless quartz, amethyst with goethite and anhydrite inclusions, and locally rare barite and late gypsum. Calcite crystallized throughout the paragenetic sequence. Mineralized fractures and breccia textures indicate repeated tectonic activity before, during, and after geode infill.

New H, O, and S isotope data and microthermometry on monophase aqueous liquid inclusions reveal novel insights into amethyst mineralization. The fluid inclusion measurements were performed after nucleation of a vapor bubble in the metastable inclusions induced by single femto-second laser pulses [2]. The $\delta^{34}S_{VCDT}$ values of pyrite associated to early celadonite and chalcedony range from -25 to -32‰ indicating bacterial sulfate reduction and temperatures of less than 80°C during initial geode infill related to a maximum burial of about 2 km. Monophase pseudo-secondary aqueous fluid inclusion in amethyst have homogenization temperatures of up to 130°C and three distinct salinity modes of 0.7, 3.4, and 5.9 wt.% NaCl-equiv. Formation temperatures of late calcite and gypsum are below 50°C. The sulfur isotope values of sulfates decrease from 9.6‰ (anhydrite) to 5.6‰ (gypsum). The δD values of amethyst-hosted fluid inclusions range between -59 and -51‰. These values are significantly lower than local meteoric waters [3], but within the range of values reported from the Guaraní aquifer [4]. Oxygen isotope values of amethyst scatter between 28 and 34‰. The isotope composition of waters in equilibrium with gypsum water is intermediate between local meteoric waters and waters in equilibrium with amethyst at temperatures of 50 to 130°C.

These new data suggest that meteoric fluids from the artesian Guaraní aquifer underlying the flood basalts were not the sole mineralizing source [1,5], but repeated injection of hot brines from deep parts of the sedimentary basin into a relatively cool wall rock probably during Andean tectonic phases played a significant role in amethyst formation.

Emerald gastropod fossils from the Mantecanã mine (Gachalà district, Colombia): a record of the recipe for Colombian emerald formation

Giuliani, G.[1,2]
[1]IRD, Toulouse, France (giuliani@crpg.cnrs-nancy.fr)
[2]CRPG/CNRS, Vandœuvre-lès-Nancy, France

Colombian emeralds are famous for their colour, clarity and carat value. They continue to set worldwide standards for emerald and still the finest and most spectacular crystals unearthed. Forming in cavities, emerald crystals developed prism and basal faces and reached spectacular size with zoned and clear prisms up to 15 cm long. Some gems from the Gachalá district are unique in the world: El Monstro, 16020-carats; the Emilia, 7025-carats; the Gachalá emerald, 858-ct; the 75-carats square cut Gachalá stone in the Hooker brooch of the Smithsonian collection. The presence of fluid circulation in an extensional vein-system under an impermeable seal is thus the clue for the free-standing crystal growth of Colombian emeralds. In this mine, a remarkable set of fossilized gastropods shells replaced by emerald were discovered in 1994. In 1998, the tunnel collapsed and "mining" of the fossils ceased.

Twenty-four fossils have been studied and three forms of gastropods identified (*Ataphrus, Pseudomelania and Ampullospira*). All are from the mineralized Guavio formation of Berriasian age (135-130 Ma). The gastropod shells were epigenised by emerald following the usual processes of dissolution-substitution. Such processes are well-known for pyrite, carbonates or opal substitution but have never been described for precious gems. After the burial of gastropods at Berriasian time and dissolution of the aragonitic test, the voids corresponding to the shelly test were filled at about 65 Ma by emerald which perfectly replicated the original form of the shells.

In Mantecaña, the emerald-bearing zone now corresponds to a stratiform brecciated level formed of disrupted blocks of albitites, black shales and limestones from the Guavio formation. The emerald-bearing structures (breccia and veins) are on the hanging-wall of the brecciated level which is also mineralized. The brecciated level is an evaporite dissolution residue which acted as a local detachment. The mineralizing fluids expulsed by evaporite dissolution by basinal brines, flowed in the well-developed set of extensional fractures, simultaneously percolating the gastropod-bearing formation. Emerald deposited both in vugs within carbonate veins but also in voids by impregnation of the gastropod shells.

This unique record of emerald in fossils is the combination of different factors: the development of breccias and extensional vein set at the bottom of a fossil-bearing horizon; the presence of highly reactive salty brines resulting from evaporite dissolution; the high permeability of mechanically-induced (breccia) or chemically-induced (voids by dissolution of shells), and the rapid sealing of the structures due to the competent black shales. All of these factors, combined with the particular expulsion of 300°C fluids and the high concentration in beryllium in the brines resulted in this unique occurrence of emerald fossilizing gastropods and the finest and spectacular emerald crystals yet found on the planet.

Is the V/Cr ratio a fingerprint of the geographical origin of 'tsavorite' in the Mozambique Belt?

Feneyrol, J.[1*], **Giuliani, G.**[2,1], **Ohnenstetter, D.**[1], **Galoisy, L.**[3] **& Pardieu, V.**[4]
[1]CRPG/CNRS, Vandœuvre-lès-Nancy, France
([*]feneyrol@crpg.cnrs-nancy.fr)
[2]IRD, Toulouse, France
[3]IMPMC, Paris, France
[4]GIA, Bangkok, Thailand

The green colour of 'tsavorite', a grossular [$Ca_3Al_2(SiO_4)_3$] garnet variety, is due to the presence of vanadium (V) and chromium (Cr) in the garnet structure [1,2]. Vanadium and Cr contents of 'tsavorites' from several deposits in the metamorphic Mozambique Belt (MB) in Tanzania, Kenya, Madagascar and Pakistan are reported in Table 1.

Table 1: Mean range of V and Cr contents (in wt%) in 'tsavorites' from Tanzania (1), Kenya (2), Madagascar (3) and Pakistan (4)

	(1)	(2)	(3)	(4)
Number of deposits/analyses	7/582	6/310	2/210	1/45
V_2O_3 (wt%)	0.08-2.48	0.07-2.69	1.12-4.02	2.74-6.51
Cr_2O_3 (wt%)	0.04-0.35	0.35-1.42	0.17-0.64	0.54-0.82
V/Cr	0.7-10.1	0.2-4.4	5.1-6.7	5.1-7.9

Detection limits of EPMA: V=14 ppm and Cr=14 ppm.

All 'tsavorites' contain V and Cr, but their concentrations in Kenyan 'tsavorites' differ from that in other deposits in the MB (Fig. 1).

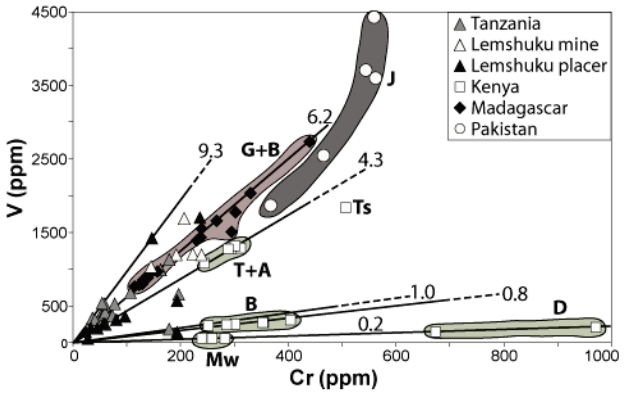

Fig. 1: V vs Cr diagram for the 'tsavorites' of the Mozambique Belt.

Kenyan 'tsavorites' contain more than 240 ppm of Cr and V/Cr is ≤ 4.3. The Baraka (B), Mwatate (Mw) and Dicka (D) deposits can be distinguished by their very low V/Cr ratios. Other Kenyan 'tsavorites' have V/Cr ratios close to 4.3: Tsavo (Ts), Tsavolite and Aqua mines (T+A). 'Tsavorites' from Madagascar and Pakistan display V/Cr ratios higher than 4.3. In Madagascar, the Gogogogo and Behara (G+B) 'tsavorites' contain more than 750 ppm of V and 110 ppm of Cr. Jambil (J) 'tsavorites' from Pakistan have the highest V contents, up to 4500 ppm. Tanzanian 'tsavorites' contain less than 1800 ppm of V and 240 ppm of Cr. Most of them have V/Cr ratios between 4.3 and 9.3. The 'tsavorites' from the Lemshuku placer show a large variability of the V/Cr ratio suggesting: (i) highly variable concentrations of V and Cr in the host-rock, *i.e.* the graphitic gneiss; (ii) variations of the intensity of fluid-rock interactions. In conclusion, the V/Cr ratio can be used to distinguish the geographic origin of most 'tsavorites' from the MB.

Tektites and microtektites Fe oxidation state and water content

Giuli, G.[1*], Eeckhout, S.G.[2], Cicconi, M.R.[1], Koeberl, C.[3], Glass, B.P.[4], Pratesi, G.[5], Cestelli-Guidi, M.[6], Marcelli, A.[6], Carroll, M.R.[1] & Paris, E.[1]

[6]LNF-INFN, Frascati, Italy

Asteroid or cometary impacts onto the Earth surface are known to have played an important role in modifying the composition of the earth crust. Impact glasses, resulting from the rapid cooling of the molten target rock, are clues of the complex melting and metamorphic processes taking place during an impact. Tektites and micro-tektites are a sub class of impact glasses formed during the very first stages of the cratering process by high temperature melting of the target rock. They usually display rounded shapes and can be found over wide areas called strewn fields. As Fe oxidation state could be a useful probe to obtain information on the formation conditions of tektites, it has been the focus of many studies. However, the difficulties in analysing samples with small dimensions and high Fe dilution have so far hindered the possibility to systematically study the Fe oxidation state in these glasses.

To this aim, XANES is an ideal technique as it allows to determine the Fe oxidation state also in small samples even at very high dilution without deteriorating the error in the $Fe^{3+}/(Fe^{2+}+Fe^{3+})$ ratio. Fe K-edge XANES spectra have been collected in fluorescence mode at the ID26 beamline of ESRF using a Si (311) monochromator focusing the X-ray beam down to about 50 x 200 μm. The excellent energy reproducibility (±0.03 eV) allowed to obtain a small error in the determination of the Fe oxidation state. Micro-IR data have been collected in transmission mode at the LNF (Frascati, Italy). Areal analyses (50 x 50 μm) have been collected for 16 moldavites, 7 North American tektites and 5 microtektites.

Tektite glasses display $Fe^{3+}/(Fe^{2+}+Fe^{3+})$ ratios close to 0.05 (±0.03). With few exceptions (moldavites from the Moravian area), no significant variations have been found in the Fe oxidation state of tektite samples according to impact age or target rock composition [1]. Even for very large impacts events, where the target rock presumably displayed a wide range of Fe oxidation states, tektites have been homogeneously reduced to almost exclusively Fe^{2+} [2]. Similar behaviour has been observed in molten rock from the first atomic bomb test (Alamogordo, USA) [3]. Contrary to tektites, North American microtektites show a wide variation in the Fe oxidation state raising the issue of a possible difference with the formation mechanism of tektites [4].

Water content of all the tektites and microtektites are in the range of already published tektite water content data and display no correlation with the Fe oxidation state. The low water content of North American microtektites studied suggests that there has been no sea-water induced alteration in these samples, thus strongly suggesting that the variation of the Fe oxidation state in the North American microtektite samples studied here is not due to secondary alteration. We maintain that the mechanism responsible for NA microtektite oxidation is not sea-water alteration, nor oxidation in air.

Buddha from space – an ancient object of art made of a Chinga iron meteorite fragment

Buchner, E.[1,2*], Schmieder, M.[1], Kurat, G.[3], Kramar, U.[4], Kröchert, J.[1] & Ntaflos, Th.[5]

[1]Institut für Planetologie, Universität Stuttgart, Germany ([*]elmar.buchner@geologie.uni-stuttgart.de)

[2]HNU Neu-Ulm University, Germany

[3]Formerly: Museum of Natural History, Vienna, Austria

[4]University of Karlsruhe, Germany

[5]University of Vienna, Austria

In memoriam Gero Kurat († 27.11.2009)

Meteorites have been regarded as devotional and ritual objects by multitudinous cultures since prehistoric times. Objects of art made of meteoritic iron were found in old Egyptian king tombs and in Mesopotamian sanctuaries. In the Buddhist art in the Middle and Far East (e.g., [1]), meteoritic iron used to be carved but that tradition died out a long time ago, and only ancient artifacts are known. Figurative illustrations or religious sculptures of gods carved in meteorites are not reported in the literature. We here present a sculpture made of an iron meteorite that displays a unique particularity in religious art.

Origin and age of the sculpture, carved from one piece of iron meteorite (now ~10.6 kg and about 24 x 13 x 10 cm) [2,3], is still a matter of speculation. The Swastika on the cuirass of the statue is a minimum 3000 years old Indian sun symbol and is used as an allegory of fortune to date; the scale armor was originally gilded. The sculpture possibly portrays the Buddhist god Vaiśravana (also called Jambhala or Namthöse in Tibet, or Hindu Kubera), either a God of fortune and wealthiness or a God of war (e.g., [4]). The provenance of the meteorite sculpture strongly points to Central Asia.

A plate (~1cm thick, ~500 g) was cut from the base of the sculpture. The texture of the metal is that of a Ni-rich ataxite with streight and curved schlieren bands visible at the etched surface. It fits in detail that of the Chinga (IRUNGR) meteorite. The metal consists of a very fine-grained intergrowth of kamacite and taenite (16 wt% Ni, 0.6 wt% Co), which includes a few daubreelite ($FeCr_2S_4$) crystals of varying size (<1-10 mm) and small (<1 mm) kamacite spindles (5 wt% Ni, 0.6 wt% Co), both rimmed by clear taenite. Clear taenite also forms very long (>10 mm), thin bands, one of which grades into a fissure that contains brecciated taenite, metal, and silicates set in rust.

Detailed geochemical analyses of the iron meteorite revealed mean values for Fe: 84.3 wt% (Chinga: 83.6 wt%), Ni: 15.7 wt% (Chinga: 16.4 wt%), Co: 0.6 wt% (Chinga: 0.57 wt%), and Cr: 897 ppm (Chinga: 810 ppm), as well as a sigificant enrichment of the platinum group elements (PGE) [5-7]. Most of the trace element values analysed (i.e., the PGEs) perfectly fit the geochemical composition of the Chinga iron meteorite. As an exception, the Ge content is significantly higher compared to Chinga. The discrepancy may be caused by analytical imprecision and/or material inhomogeneities.

The data as a whole strongly suggest that the "meteorite man" is the third largest piece from the Chinga strewn field discovered in the border region of Siberia and Mongolia in 1912. One can speculate whether this specimen was discovered earlier as a single find. A part of the cut socket plate is stored at the Museum of Natural Sciences, Vienna. Further geochemical studies are under way.

Origin of strong staining of olivine in the Martian meteorite Northwest Africa 2737

Bläß, U.W.[1*], Langenhorst, F.[2] & McCammon, C.A.[2]
[1]Institut für Geowissenschaften, Friedrich-Schiller Universität Jena, Germany ([*]Ulrich.Blaess@uni-jena.de)
[2]Bayerisches Geoinstitut, Universität Bayreuth, Germany

Intense brown staining of olivine from meteorites is attributed since a long time to shock damage (e.g. [1]). However, the origin of the staining is still not well understood and has been assigned either to shock-induced reduction or oxidation processes. The recently recovered Martian achondrite Northwest Africa 2737 (NWA 2737), which represents the second chassignite ever found, raises these questions again, because it exhibits distinct shock-related features compared to Chassigny, while its mineralogical composition is quite similar [2]. These features comprise essentially the dark appearance of the rock due to an intense olivine staining embedding rectangular sets of bright lamellae [2], a completely different noble gas content similar to shergottites [3] and the exsolution of metallic iron nanoparticles as first published by [4].

In order to gain a better understanding for the physical processes responsible for the formation of these unique shock-induced features and resulting implications to the shock-history of this meteorite, we have investigated in detail the microstructural features of NWA 2737 olivines using transmission electron microscopy (TEM). The trivalent iron fraction has been on average determined by Mössbauer milliprobe spectroscopy and locally by electron energy loss spectroscopy (EELS).

The results reveal that all strongly stained olivine regions are microstructurally characterised by the occurrence of metallic iron nanoparticles and a fine mottled contrast in TEM bright field images, which is due to an extremely high density of polygonised dislocations with Burgers vector [001]. The quantification of EELS-spectra of these regions resulted locally in a high trivalent iron fraction of up to 16 %. In contrast, the bright lamellae contain nearly no metallic nanoparticles, a sufficiently lower trivalent iron fraction and at least one order of magnitude lower density of individual dislocations.

Model calculations confirmed our hypothesis that a sufficient amount of trivalent iron can be incorporated as a laihunite-component into the dislocation core of polygonised dislocations and could therefore be responsible for the intense brown staining. Iron metallic nanoparticles would represent residual disproportionation products and darken the olivine additionally. Resulting spectra are consistent with spectroscopic observations described by [5]. Since the polygonisation of dislocations and the exsolution of metallic iron are both diffusion controlled processes, the meteorite must have remained sufficient time at elevated temperatures. For typical diffusion length of < 10 nm in this meteorite we calculated an annealing time of several days at ~ 500°C or < 1 hour at 800°C.

The different microstructural characteristics of the bright lamellae comprise considerable implications for the shock history of the meteorite. The lamellae are interpreted as regions, which re-crystallised simultaneously during the annealing process. Therefore implemented individual dislocations argue for the occurrence of a second impact event, which likely caused to the ejection of this unique meteorite from Mars.

On the darkening of olivine in Martian meteorites

Mikouchi, T.[*] & Kurihara, T.
Dept. of Earth and Planetary Science, University of Tokyo, Japan ([*]mikouchi@eps.s.u-tokyo.ac.jp)

Olivine is one of the major minerals in Martian meteorites, but their color is sometimes darkened unlike other extraterrestrial olivines. Recent TEM studies on the NWA2737 chassignite revealed that Fe-Ni metal nano-particles in olivine were responsible for the dark color of olivine. Color change of olivine is important to properly understand the remote sensing data and their magnetic signatures. Since similar dark olivine is fairly common among Martian meteorites, especially in shergottites, Fe-Ni metal nano-particles may be widely present in these olivine grains. Here we report TEM observations of olivine in several Martian meteorites and discuss their formation by using the results of shock experiments on olivine.

We found nano-particles in all samples we studied whose sizes range 5-20 nm in diameter. Their abundance appears related to the degree of darkening. ALH77005 and Y000097 contain Fe-Ni metal nano-particles similar to NWA2737. However, magnetite nano-particles were found (5-20 nm) in LEW88516, NWA1950, Dhofar 019, and LAR06319 (Fig. 1). The presence of magnetite nano-particles would be also responsible for the darkening of olivine similar to the case of Fe-Ni metal nano-particles.

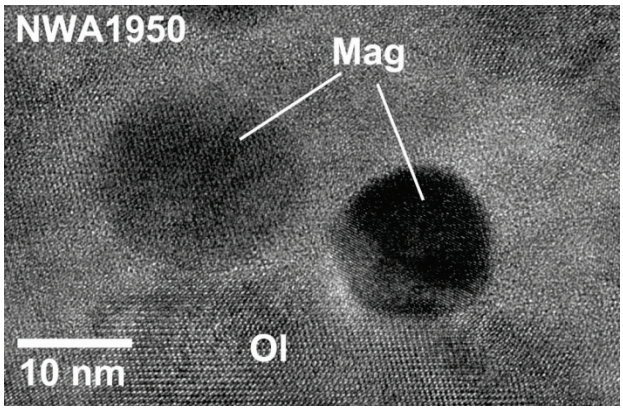

Fig. 1: High resolution TEM image of magnetite nano-particles in olivine from the NWA1950 lherzolitic shergottite.

There has been suggested that Fe-Ni nano-particles have formed by reduction of Fe^{2+} in olivine during heavy shock. Although the formation of magnetite requires oxidation of Fe^{2+}, similar shock metamorphism should be responsible for the formation of magnetite nano-particles. In order to demonstrate the possibility of the nano-particle formation in olivine, we performed shock experiments on San Carlos olivine (Fo_{90}) at 20, 30, 40, and 46 GPa. We found that shock pressure higher than 30 GPa produced magnetite nano-particles in olivine. These shock degrees are consistent with the observation that only highly-shocked Martian meteorites contain dark olivine. It is interesting that both Fe-Ni metal and magnetite coexist in different shergottite samples. The formation of different Fe-rich nano-particles would be explained by the different redox state during shock on (or near) the Martian surface. However, it is unlikely to suppose drastic change of redox state among Martian meteorites because they crystallized under similar conditions (e.g., fO_2, burial depth, crystallization age). Then, temperature difference during shock could be another possible factor. When temperature increase was significant, Fe-Ni nano-particles would be formed rather than magnetite. In fact, we could produce Fe-Ni metal nano-particles instead of magnetite for the preheated (400 and 800°C) San Carlos olivine at 40 GPa.

Soil components in heterogeneous impact glass in Martian meteorite EETA79001

Schrader, C.M.[1*], Cohen, B.A.[2], Donovan, J.J.[3] & Vicenzi, E.P.[4]
[1]NASA-ORAU, Marshall Space Flight Center, Huntsville AL, USA ([*]Christian.M.Schrader@nasa.gov)
[2]NASA, Marshall Space Flight Center, Huntsville AL, USA
[3]Dept. of Chemistry, Univ. of Oregon, Eugene OR, USA
[4]Smithsonian Inst., Museum Conservation Inst., Washington DC, USA

Martian soil composition can illuminate past and ongoing near-surface processes such as impact gardening [2] and hydrothermal and volcanic activity [3,4]. Though the Mars Exploration Rovers (MER) have analyzed the major-element composition of Martian soils, no soil samples have been returned to Earth for detailed chemical analysis. Rao et al. [1] suggested that Martian meteorite EETA79001 contains melted Martian soil in its impact glass (Lithology C) based on sulfur enrichment of Lithology C relative to the meteorite's basaltic lithologies (A and B) [1,2]. If true, it may be possible to extract detailed soil chemical analyses using this meteoritic sample.

We conducted high-resolution (~0.3 µm/pixel) element mapping of Lithology C in thin section EETA79001,18 by energy dispersive spectrometry (EDS). We use these data for principal component analysis (PCA).

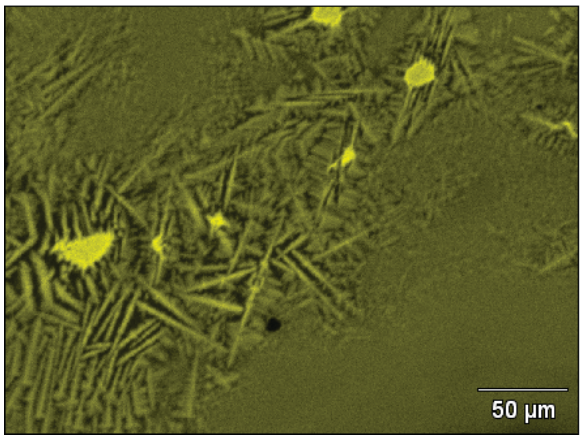

Fig. 1: Magnesium map of EETA79001 Lithology C. Brighter yellow colors correspond to higher Mg contents of pixel. Yellow, sub-angular relict olivine and elongate quench crystals are set in a glassy matrix.

Though visually glassy, EETA79001 Lithology C is heterogeneous. PCA identifies several significant components that may originate either in the basalt or in the soil, but one component with strongly positive eigenvectors for K and Cl likely represents a soluble soil component originating by hydrothermal or evaporitic processes.

We are conducting quantitative beam analysis of the glass to determine minor and trace elements, including halogens. We will compare these to compositions of EETA79001 basalt [5,6] and to MER rock and soil compositions [7,8,9] to constrain the origin of components in EETA79001 Lithology C.

Occurrences and mineral chemistry of chromite and xieite in the shocked Suizhou L6 chondrite

Xie Xiande[*], Chen Ming, Wang Deqiang & Wang Chunyun
Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China (*xdxie@gzb.ac.cn)

Three types of occurrences for chromite were observed in the Suizhou L6 chondrite: coarse chromite, cluster of tiny chromite fragments in molten plagioclase, and exsolution chromite in olivine. All the chromite grains of the first two types are remarkably similar in chemical compositions, no matter how fine the chromite fragments are in molten plagioclase, but the composition of exsolution chromite is variable in Al_2O_3, MgO, Cr_2O_3 and not so homogeneous.

Xieite is a post-spinel CT-phase of chromite firstly found in the Suizhou meteorite [1-3]. Three types of occurrences of xieite have also been revealed in this meteorite: coarse xieite grains, complex three-zone- grains consisting of the inner xieite, the intermediate lamellae-like CF-phase and the outer chromite phase, and two-phase-grains consisting of xieite and one of the high-pressure silicate minerals lingunite, ringwoodite or majorite. The curved boundary between xieite and the silicate half in two-phase grains is indicative of some partial or even full melting of the silicate phase.

EPMA results show that the compositions of xieite inside/contacting the veins are also identical to that of chromite outside the veins. However, some element diffusion appeared in between the xieite and the silicate halves in the two-phase grains. For the xieite + lingunite grains, xieite contains higher content of Al_2O_3 (6.19 *vs* 5.45 wt %) and lower content of Cr_2O_3 (56.48 *vs* 57.98 wt %) than its precursor chromite. On the other hand, the lingunite contains higher contents of Cr_2O_3 (0.32 *vs* 0.03 wt %) and FeO (1.97 *vs* 0.41 wt %), and lower contents of Al_2O_3 (19.98 *vs* 21.73 wt %) than its precursor plagioclase. For the xieite + ringwoodite grains, some of Fe^{2+} from ringwoodite migrated to xieite, and some of Cr^{3+} migrated from xieite to ringwoodite. Majorite garnet in two-phase grains is fully molten and shows remarkable decrease of SiO_2 and MgO, and notable increase of Al_2O_3, CaO and Cr_2O_3. The complexity in mineral chemistry of these two-phase grains can be explained by the much higher shock peak temperature in melt veins (1800-2000°C) than in unmelted chondritic rock (~1000°C)[4], and by the much higher density of xieite (5.63 g/cm^3) than the silicates (<3.80 g/cm^3). Being a refractory and a high-impedance material, xieite is chemically more stable and easier to reflect shock wave into the silicate halves and to cause the partial or even full melting of silicate phases, upon which some diffusion or exchanges of elements between the two phases themselves, or even mixing of molten majorite garnet and the surrounding silicate melt took place.

Carbonate spherules as Chicxulub ejecta in the K-Pg event deposit: detailed characteristics as revealed by micro-chemical and EBSD

Deutsch, A.[1*], Schulte, P.[2] & Salge, T.[3]
[1]Institut für Planetologie, Universität Münster, Germany
([*]deutsca@uni-muenster.de)
[2]GeoZentrum Nordbayern, Universität Erlangen, Germany
[3]Bruker Nano GmbH, Berlin, Germany

New petrographic observations suggest that considerable amounts of carbonate melt were generated and ejected by the Chicxulub impact, and deposited in the Gulf of Mexico region [1]. The amount of carbonate ejecta frequently exceeds that one of silicic melt lithologies in K-Pg event beds. Carbonate and silicic melts were dispersed concurrent but as distinct melt batches that, in part, were mixed as evidenced by emulsion-like bubbly textures and Cc spherules with thin shells of silicic melt.

Carbonate spherules in the Chicxulub ejecta deposits addressed by previous authors [e.g. 2-4] as alteration product of silicic melt droplets display very complicated textures that cannot be understood in terms of pseudomorphic replacement.

Currently we are evaluating the criteria necessary to distinguish primary textures from those grown during alteration and diagenesis using microchemical, cathodoluminescence, and electron back-scatter diffractions techniques.

Shock-metamorphic effects in chert: evidence from the Jebel Waqf as Suwwan impact structure, Jordan

Schmieder, M.[1*], Buchner, E.[2,1], Reimold, W.U.[3], Khirfan, M.[4], Salameh, E.[4] & Khoury, H.[4]
[1]Institut für Planetologie, Universität Stuttgart, Germany
([*]martin.schmieder@geologie.uni-stuttgart.de)
[2]HNU Neu-Ulm University, Germany
[3]Museum for Natural History, Berlin, Germany
[4]University of Jordan, Amman, Jordan

The petrographic study of a chert nodule recovered from the central uplift of the recently discovered ~6 km Jebel Waqf as Suwwan impact structure, Jordan [1,2], revealed - in addition to some well-established shock-metamorphic effects in quartz [3,4] - new potential shock features in crypto- to microcrystalline varieties of silica. The microcrystalline chert groundmass exhibits a dendritic and a superimposed orthogonal fracture pattern at the cm- to mm-scale, commonly associated with microscopic quartz 'recrystallization bands' that intersect the primary diagenetic chert fabric. Aggregates of spherulitic microfibrous silica (first-generation chalcedony *sensu stricto* and second-generation quartzine [5]) in veins are locally of shattered appearance. Quartzine shows conspicuous sets of 'curved fractures' (Fig. 1A) that run perpendicular to the fiber direction (c-axis) and commonly trend subparallel to planar fractures (PF) in neighbouring coarser-crystalline shocked quartz. Quartz exhibits PF, sometimes combined with feather features (FF) [6] (Fig. 1B), and mainly single sets of planar deformation features (PDF) parallel to the basal plane (0001) (Brazil twins) with rare additional PDF in the {10-13} direction.

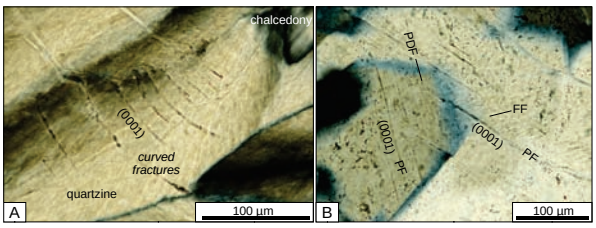

Fig. 1: Microdeformation features in chert from Jebel Waqf as Suwwan, Jordan; **A**: 'curved fractures' in microfibrous spherulitic quartzine; **B**: shocked quartz exhibiting planar deformation features (PDF), planar fractures (PF), and feather features (FF) (A and B cross-polarized light).

Shock petrography indicates shock pressures of ≥10 GPa and high shock-induced differential stresses [4,7] that affected the chert nodule as a whole. The internal crosscutting relationships between primary diagenetic and deformational features suggest that the dendritic-orthogonal fractures in the chert groundmass are post-diagenetic and most likely related to impact-induced shear deformation. Curved fractures in spherulitic quartzine (as possible microstructural equivalents to planar fractures parallel to the basal plane in quartz) might represent particular low- to medium-pressure shock effects in cryptocrystalline fibrous silica, unless noted in rocks not affected by shock metamorphism. Recrystallization bands probably represent healed fractures and cannot be linked with either shock or shear deformation. A systematic comparative study of deformation features in cherts from various terrestrial impact structures and cherts deformed by diagenesis and tectonism is planned.

Feather features as a new low shock pressure feature in quartz

Poelchau, M.H.* & Kenkmann, T.
Museum für Naturkunde, Berlin, Germany
(*michael.poelchau@mfn-berlin.de)

In impact cratering research, the recognition of planar deformation features, (PDFs; sets of 2-3 µm wide, amorphous lamellae), in quartz and other minerals is generally accepted as one of the strongest unequivocal indicators for shock metamorphism, and thus is commonly used to determine if a geological structure is an impact feature. Experimental research has shown that the onset of PDF formation is at >10 GPa. To date, very little systematic research has been done in the shock pressure regime from ~3 to 10 GPa. The recognition of the lowest possible pressures at which unequivocal shock features are induced requires further experimental work and the comparison to natural samples. Feather features (FFs), a recently discovered planar microstructure found in shocked quartz, have the potential to become a standard low-shock pressure indicator.

In the current study, feather features in samples from the Nördlinger Ries (Germany) and the Matt Wilson (Australia) impact structure were microscopically analyzed and crystallographically indexed. FFs occur as short, parallel to subparallel lamellae with a similar spacing as, or sometimes even narrower than, planar deformation features, and are always found in combination with a planar fracture (PF). FFs are crystallographically controlled to a certain degree, with the majority of lamellae oriented parallel to rational low index crystallographic planes. FFs are typically straight and parallel close to their base at the PF and become increasingly curved with progressing length, sometimes even intersecting each other. Angles measured between PFs and sets of FFs average at 50-60°.

Microscopic analysis of quartz grains with feather features show that their formation is linked to shearing along the associated PFs during shock deformation. When the sense of shearing can be determined, FFs are always oriented in the same direction according to the sense of shear. The formation of FFs along sheared PFs implies that high deviatoric stresses in the order of ~5 GPa are necessary, along with elevated confining pressures found in low-pressure shock waves that have progressed further away from the point of impact.

Quartz grains in one thin section of an unoriented sample, MW7, a coarse-grained sandstone, were measured with a U-stage and plotted in stereoplots. PFs in the thin section can be divided into two groups oriented 90° to each other, representing a conjugate set of shear fractures. The majority of sets FFs were all parallel to each other ±~20°. The orientation of PFs and FFs in rock samples is suggested to be controlled by loading along the principle axis of stress in the shock wave, with sheared PFs at ~45° angles to the axis and feather features aligned ±parallel to the axis.

Controlled plane wave shock recovery experiments were performed at the Ernst Mach Institute in Weil am Rhein, Germany, on cylindrical samples of single crystal quartz. Shear fractures with FFs were generated in the pressure range of ~7-10 GPa, thus confirming that FFs are microstructures that can be induced by low-pressure shock waves.

Experiments and FFs found in natural samples that lack PDFs show that FFs can be defined as microstructures that have a lower formation limit at shock levels <10 GPa. Based on their appearance in shocked quartz grains in an increasing number of impact craters (25 so far) and the current lack of reports of these features in endogenically deformed crustal rocks, their uniqueness as a new type of impact-induced planar microstructure alongside PDFs and PFs is proposed.

Geochemical characterization of a large collection of moldavites by neutron, photon, and prompt gamma activation analyses

Mizera, J.[1*], Řanda, Z.[1], Tomandl, I.[1], Skála, R.[2] & Žák, K.[2]
[1]Nuclear Physics Inst., Academy of Sciences of the Czech Republic, Řež, Czech Republic (*mizera@ujf.cas.cz)
[2]Institute of Geology, Academy of Sciences of the Czech Republic, Praha, Czech Republic

The study presents geochemical characterization of a large collection of more than one hundred moldavites based on determination of about fifty major and trace elements using various modes of instrumental neutron activation analysis, supplemented by instrumental photon activation analysis and prompt gamma activation analysis (INAA, IPAA, and PGAA, respectively). The collection includes moldavites from the major parts of the Central European tektite strewn field: Southern Bohemia (59 samples including 4 samples from Radomilice area), Cheb Basin (30 samples), Moravia (13 samples), and Lusatia (1 sample). The study provides information on detailed chemical composition of well documented (by site location, size, colour, etc.) samples, unbiased with interlaboratory systematic errors. Information on contents of some elements, as fluorine and boron determined at the ten ppm level by IPAA and PGAA, respectively, has so far been unavailable. Correlation/cluster analysis was applied to the obtained geochemical data and the results have been discussed in view of parent materials and processes involved in formation and subsequent geographical distribution of moldavites.

In agreement with previously published data, the analysis enabled quite clear distinction of the sample sets associated with individual moldavite substrewn fields, and assigning their parent materials based on the generally accepted concept of three main components of the moldavite parent materials - quartz sands, clay and clayey soil, and carbonates of Ca and Mg. From this standpoint, the Moravian moldavites (and the only available sample from Lusatia) represent samples with the most pronounced imprint of the clay component, expressed mainly by higher aluminium content and its perfect correlation with contents of the elements associated with the phyllosilicate minerals. The widespread elemental pattern of the largest group of the South Bohemian moldavites points to mixing of the three components in various ratios. Moldavites from the latest discovered substrewn field, the Cheb Basin, or at least their substantial fraction, have elemental patterns quite different from the other groups, which can be hardly satisfactorily interpreted by the present three-component system. Significant positive correlations between K, Ca, Mg and Mn, and the enrichment in these elements observed in the Cheb Basin moldavites, as well as other facts, as high K/Na and K/Rb ratios, extremely high Zn and Ba levels, etc., may be attributed to source materials originated from the uppermost soil layers, with possible contribution of the ash produced by burning of vegetation present in the pre-impact Ries area under the extreme thermal and pressure condition of the meteoritic impact.

Formation of pseudotachylitic breccias from the Vredefort Dome, South Africa

Mohr-Westheide, T.[1*], Reimold, W.U.[1], Gibson, R.L.[2], Mader, D.[3] & Koeberl, C.[3]
[1]Museum für Naturkunde, Leibniz Institute at Humboldt University Berlin, Germany ([*]Tanja.Mohr@mfn-Berlin.de)
[2]School of Geosciences, University of the Witwatersrand, Johannesburg, RSA
[3]Dept. of Lithospheric Research, University of Vienna, Austria

"Pseudotachylite" is friction melt formed along faults or shear zones. It is produced by frictional heating, which generally requires sliding velocities consistent with seismic slip. The distinction between "impact" and "tectonic" "pseudotachylite" plays an important role in impact settings, as melt breccias in impact structures often closely resemble tectonic friction melt but may have been formed by different processes: (1) shearing (friction melting); (2) shock compression melting (with or without a shear component); (3) decompression melting immediately after shock propagation through the target / related to rapid uplift; (4) combinations of these processes; (5) intrusion of allochthonous impact melt. Resolving this problem requires detailed multidisciplinary analysis in order to comprehensively characterize the nature of these breccias and to identify the exact melt-forming process(es). In order to distinguish between bona fide "pseudotachylite" and breccias of similar appearance in impact structures of still debated origin we refer in the latter case to "pseudotachylitic breccia" (PTB).

PTB are the most prominent impact-induced deformation in the central uplift of the Vredefort Impact Structure [1,2]; similar breccias occur in abundance also at Sudbury, Canada (e.g., [3,4]). We present chemical data for small-scale (1 mm – 3 cm) PTB from mafic (dioritic) and granitic host rocks and compare with the chemical compositions of their respective host rocks.

Electron microprobe analysis of PTB groundmass in comparison to XRF bulk chemical analysis of pseudotachylitic breccias and their host rocks revealed that PTB generally displays a close chemical relationship to the adjacent host rock. This confirms that melt was formed from material of the same composition and for mm to cm wide breccia veinlets is of local origin. In granitic environments, the refractory behavior of quartz seems to be the main reason for the slight chemical differences between PTB and host rock. Our first chemical investigations of PTBs in mafic host rocks revealed that the elements associated with plagioclase and/or hydrous ferromagnesian minerals are enriched in PTB veins. PTB seemingly occur preferentially in amphibole-rich host rock portions – an observation that confirms the macroscopic observations of [5,6]. Thus, PTB genesis in mafic host rock seems to be controlled by the mineralogical composition of the target rock. A further factor is likely the melting temperature of minerals involved that determines the ratio at which feldspar and mafic minerals are melted.

None of the analyzed veinlets has yielded any textural evidence supporting a significant influence from shearing /faulting. Our PTB's of up to 1 m width all contain clast populations that represent local lithologies only, with distinct differences between clast population and host rock mineral abundances likely the result of different mechanical behavior and different melting temperatures of the various minerals.

[4]Okayama University of Science, Okayama, Japan

A set of Antarctic Meteorites (30 polished thin sections) supplied by the National Institute of Polar Research (NIPR), Tokyo, Japan, was lent to Eötvös University 15 years ago. This availability has promoted our synthesis of an evolutionary path of regions (belts) in the chondritic parent body arranging the chondritic set members according to the degree of thermal metamorphism. We deduced crust and core region set members after the differentiation of the parent body. Metamorphism stages can be demonstrated for the H, L and LL chondritic types in the NIPR set [2]. Later stage differentiation after the primitive achondritic stage (represented by the primitive achondrite itself and by the ureilite sample) can be shown by various layers in the gradually differentiating body. A pallasite sample corresponds to the boundary region between the iron core and the outer olivine rich mantle. Mesosiderite is a representative of the region where partial melting of iron and iron-sulfide components began. Second stage partial melts are characteristic of the HED meteorites which moved to the surface. HED meteorites are both in igneous and brecciated forms in the set.

The NIPR set also contains two lunar and one Martian meteorite sample. Parallel use of the NASA Lunar Meteorite Set allows comparisons between in situ collected and impact delivered lunar samples. The main difference is in the shock stage between the two sources. Impact ejected samples always contain maskelynite. Shock effects also affect several chondrites. For example, L6 specimens frequently contain shock-transformed high pressure minerals.

The NIPR set has basic importance in space science and cosmomineralogical education. This collection involves thermal metamorphism, partial melting of components, and the shock events that occurred on the surface of the asteroids.. Mineralogical studies on the processes responsible for the chondritic assemblages were also closely related to other terrestrial and even industrial technological processes (in steel industry, ceramics) - broadening the perspective of the students in the course of cosmic material studies [3].

Acknowledgments: We thank the National Institute of Polar Research for the loan of the Antarctic Meteorite Educational Thin Section Set to Eötvös University.

Kaba carbonaceous chondrite is the most primitive unshocked CVoxB fall collected nearby the Kaba village, East Hungary. It contains many types of chondrules associated with porphyritic, granular, radial and barred olivine, which have a variety of composition including almost end members of forsterite and fayalite occasionally with normal or reversed zoning. Cathodoluminescence (CL) has been used to characterize meteoritic minerals such as olivine and feldspar for the investigation of thermal history and shock pressure effect due to high detection sensitivities of structural defects and activator elements with high spatial resolution. In this study CL imaging and spectroscopy have been conducted to clarify formation mechanism of luminescent forsterite characteristic of Kaba meteorite stored at Debrecen University.

CL color imaging was carried out using Luminoscope (ELM-3R). CL scanning images at high magnification were recorded by a Mini-CL detector (Gatan) installed in a SEM. CL spectroscopy was made by a SEM-CL system, which is comprised of SEM (JEOL: JSM-5410) combined with a grating monochromator (OXFORD: Mono CL2).

Highly forsteric olivine (Fo: 99.2-99.7) emits bright CL, whereas the olivine containing fayalitic composition, even if only slightly, shows no luminescence due to quenching effect of divalent Fe ions. Red luminescent forsterite is predominant, and occasionally zoned forsterite shows blue in the core and red in the rim. CL spectra of red luminescent forsterite have two broad bands at approximately 630 nm in red region and over 700 nm in the IR region. The former band can be assigned to impurity centers of divalent Mn ions as an activator. The latter one shows a magnificent red emission in a wide range of wavelength responsible for trivalent Cr ions, which possess two components caused by Cr activator and structural defect related to interstitial Cr ions. CL spectra from blue luminescent area in the core of forsterite give a characteristic broad band emission at approximately 400 nm, also associated with minor red emissions related to Mn and Cr ions. This blue emission is attributed to intrinsic structural defect because it can be detected in pure synthetic forsterite. EPMA analysis of the forsterite reveals that minor elements of Mn (0.01-0.08 wt%), Cr (0.11-0.34 wt%) and Fe (0.22-0.86 wt%) are concentrated in red luminescent rim, but Ca (0.60-0.88 wt%) and Al (0.19-0.46 wt%) in blue luminescent core. In this case, the quenching effect of divalent Fe ions on CL might be slight and homogeneous over a forsterite grain due to low and unvaried concentration of Fe. Therefore, CL color variation observed in Kaba forsterite should be attributed to intrinsic structural defect, of which distribution cannot be detected by any other methods. It implies that aqueous alteration on the forsterite might eliminate intrinsic structural defects progressively from the rim of the grain to the core, accompanied by the migration of diffusible ions of Mn, Cr and Fe to the rim where Ca and Al ions might still lie in the core. This process could proceed at low temperatures (<300°C) over a short reaction time.

Review study of shock metamorphism on specimens of the Antarctic Meteorite Educational Thin Section Set of the National Institute of Polar Research, Tokyo, Japan

In studies on shock metamorphism of impact craters of Earth, quartz is an important index mineral. Several measuring techniques are based on shock features in quartz. Additionally, in meteorites shock features are present also in olivines, pyroxenes, and feldspars. On the basis of shock features presented by these 3 minerals, Stöffler et al (1991) [1] has elaborated a sequence of shock metamorphic stages, going from **S1** (unshocked) to **S2 (**very weakly shocked), **S3 (**weakly shocked), **S4 (**moderately shocked), **S5 (**strongly shocked) and finally to **S6 (**very strongly shocked).

For defining their degree of shock metamorphism, olivines, pyroxenes and feldspars have been studied petrographically in thin sections, as well as by means of infrared spectroscopy (for feldspar), and micro-Raman spectrometry in Antarctic meteorite specimens from the National Institute of Polar Research (NIPR) collection. A brief description follows.

Y-691 - EH3 chondrite: The sample is built up of microchondrules in an iron oxide-rich matrix. Most chondrules show poikilitic and granular texture realized by pyroxene and olivine. Pyroxenes show mechanical twins.

ALH-77257 – Ureilite is built up of olivine and pyroxene. As a rule, olivines show carbon- ontaining veins and aggregates at crystal boundaries. Pyroxenes show exsolution (augite-pigeonite) features and differently spaced mechanical twins.

Asuka-881757 - Lunar gabbro meteorite has coarse-grained texture and consists of olivine and pyroxene phenocrysts. One of the pyroxenes shows abundant mechanical twin lamallae and strong mosaicism. In the proximity of the pyroxene, the olivine with strong mosaicism shows short PDFs perpendicular to the exsolution (miscibility) lamellae.

ALH- 77005 – Shergottite has a coarse grained texture; it contains olivine and pyroxenes rich in fractures and veins. Features of shock metamorphism (*e.g.* PFs, PDFs) can be observed in olivine. There is a melt pocket in the sample, which contains glass and olivine needles and larger subgrained olivines. Some olivines consist of subgrains aggregates, pointing to solid state recrystallization.

Y-86032 - Lunar breccia contains a number of shocked minerals. Fractured feldspar, olivine and feldspar with strong mosaicism were noticed. PFs and PDFs are present in the olivine showing strong mosaicsm. The shock metamorphism can be both progressive and retrograde. A melt pocket is also incuded, where the glassy material started to recrystallize into feldspar needles.

Shock metamorphic features occur locally in some minerals but not in the whole rock samples. For the studied metorites, the following shock stages (according to Stöffler's scale, [1]) were defined: Y-691 (EH3) S3, ALH-77257 (ureilite) S2-S3, Asuka-881757 (lunar gabbro) S3-S5, ALH- 77005 (shergottite) S2-S6, and Y-86032 (lunar breccia) S4-S6.

Cathodoluminescence spectroscopy on shock metamorphosed alkali feldspar

Kayama, M.[1*], Nishido, H.[1], Sekine, T.[2], Nakazato, T.[1] & Ninagawa, K.[3]
[1]Research Institute of Natural Sciences, Okayama University of Science, Okayama, Japan ([*]kayama@rins.ous.ac.jp)

[3]Dept. of Applied Physics, Okayama University of Science, Okayama, Japan

Shock pressure induced on meteorites and impactites has been estimated based on refractive indices of plagioclase-maskelynite, which has been not available for weakly shocked materials below 15 GPa and micro-size samples. Cathodoluminescence (CL) spectroscopy provides useful information on the existence and distribution of defects and trace elements with high spatial resolution. This technique could be applied to clarify shock pressure effect on the feldspar in meteorites and impactites. In this study, CL spectral analyses of experimentally shocked sanidines and alkali feldspars in Martian meteorites have been conducted to characterize their emission mechanisms related to shock metamorphism.

Single crystal of sanidine from Eifel, Germany was selected as a starting material for shock recovery experiments at pressure of 10 to 40 GPa by a propellant gun. Alkali feldspars inducing diaplectic glasses in shergotty of Dhofar 019 ($Or_{49}Ab_{42}An_9$), Shergotty ($Or_{71}Ab_{22}An_7$), Zagami ($Or_{67}Ab_{26}An_7$) and NWA 2975 ($Or_{69}Ab_{28}An_3$), and in nakhlite of Yamato 000749 ($Or_{70}Ab_{27}An_3$) were employed for CL spectral measurements. CL spectra were obtained by SEM-CL system, which is comprised of SEM (JEOL: JSM-5410) combined with a grating monochromator (OXFORD: Mono CL2).

CL spectrum of unshocked sanidines has an emission band at 430 nm in UV-blue region. Shocked sanidine above 20 GPa have UV-blue CL emissions at 380 and 330 nm of which intensities increase with an increase in shock pressure. The shocked samples above 30 GPa and alkali feldspars in shergottite have emission bands at 380 and 330 nm. It indicates that these emission bands might be characteristic of CL signals derived from diaplectic glass. Spectral deconvolution of the CL in energy unit can successfully separate the emission bands into four Gaussian components at 2.82, 2.95, 3.26 and 3.88 eV. The integral intensities of these components closely relate to shock pressure on the sanidine, suggesting CL emissions derived from shock-induced defect centers. The deconvoluted CL spectra of all alkali feldspars in shergottite and nakhlite have a component at 2.95 eV. This correlationship could be employed for the calibration to estimate shock pressure on Martian meteorites. Furthermore, CL component at 2.95 eV is detected in other shocked alkali feldspar such as microcline with different structural order. Therefore, CL spectral deconvolution method allows us a new indicator for an evaluation of shock pressure in a wide range below 40 GPa for the micron-size alkali feldspar in meteorites and impactites. Quantitative estimation of shock pressure on the Martian meteorites using CL spectroscopy will be discussed here in detail.

CL characterization of shock-induced effects on the rock-forming minerals from Ries meteorite crater

Kayama, M.[1*], Nishido, H.[1], Endo, Y.[1], Gucsik, A.[2] & Ninagawa, K.[3]
[1]Research Institute of Natural Sciences, Okayama University of Science, Okayama, Japan ([*]kayama@rins.ous.ac.jp)
[2]Max Planck Institute for Chemistry, Mainz, Germany
[3]Dept. of Applied Physics, Okayama University of Science, Okayama, Japan

Cathodoluminescence (CL) spectroscopy and microscopy provide important information on the existence and distribution of defects and trace elements in materials, which are related to shock metamorphism. CL of silica minerals and feldspars in impactites and meteorites has been applied to examine the textures formed due to the shock metamorphism such as Planar Deformation Features (PDFs) containing amorphous lamellae system and to clarify high-pressure minerals (e.g., maskelynite). Only a few CL studies on rock-forming minerals in impactites, however, have been reported so far. In this study, the CL of quartz and alkali feldspar from the Ries Crater has been measured to characterize their CL features related to shock metamorphism.

Quartz and alkali feldspar ($Or_{84-91}Ab_{9-15}An_{0-1}$) in the drilling core samples between 601 and 602 m depth from the surface in the Ries Crater wasselected for the CL measurements. CL spectroscopy were carried out in the range from 300 to 800 nm using a SEM-CL system, which is comprised of a secondary electron microscope (JEOL: JSM-5410) combined with a grating monochromator (OXFORD: Mono CL2). CL images were collected with a MiniCL (Gatan) equipped with a SEM-CL. Operating conditions of SEM-CL and MiniCL imaging system were set at 15 kV (accelerating voltage) and 1.0 nA (beam current).

CL spectra of quartz exhibit emission bands at around 390 and 650 nm in blue and red region. Blue CL emission is related to Ti^{4+} or $[AlO_4/M^+]^0$ (M^+: H^+, Li^+, Na^+ and K^+) defect center. An emission band at 650 nm is attributed to oxygen vacancy center. CL images of quartz at room temperature show a homogeneous distribution of intensity, whereas those at liquid nitrogen temperature indicate thin dark lines superimposed on more brightly luminescent background. Decreasing temperature leads to a drastic enhancement of CL intensity in quartz due to the temperature quenching effect, which might allow an observation of easily visible line texture at low temperatures. These textures correspond to PDFs by impact-shocked metamorphism observed under an optical microscope. Interference shock wave with high pressure might cause structural destruction with parallel array along wave front, resulting in non-luminescence in PDFs. This fact indicates that CL imaging at low temperature can be used to detect PDFs in shocked quartz.

Most of the alkali feldspar has CL emissions at around 430 and 720 nm. These blue and red-IR CL emissions are attributed to $Al–O^-–Al$ defect and Fe^{3+} impurity center, respectively. CL spectra of only isotropic alkali feldspar under optical microscope (crossed nicol) consist of an emission band at around 380 nm. Similar UV-blue emission has been reported in CL spectra of maskelynite. Therefore, this emission band of the isotropic alkali feldspar might be responsible for shock-induced defect center.

Paleomagnetism and new magnetic mineralogical investigations from Maâdna (Talemzane) impact structure (Algeria)

Lamali, A.[1*], Merabet, N.[1], Rochette, P.[2], Gattacecca, J.[2], Maouche, S.[1], Abtout, A.[1] & Ayache, M.[1]
[1]CRAAG, Algiers, Algeria ([*]lamani_atmane@yahoo.fr)
[2]CEREGE, CNRS/University of Aix-Marseille, France

The Maâdna (Talemzane, Algeria) simple impact structure is located on the Sahara Platform and occurs within sedimentary (limestones) rocks initially lying horizontally and ranging from Senonian to Eocene in age. It is located approximately 400 km south of Algiers, at 33°19' N, 4°19' E. The structure is circular, about 1.75 km in diameter, and 70 m deep. The age of this structure is not yet precisely known and several aspects of the cratering formation process and shock metamorphism phenomena remain poorly constrained. Previous studies have shown some petrographic evidence of shock metamorphism, which were reported in the form of poorly developed PDFs (planar deformation features) in a few quartz clasts [1]. A recent multidisciplinary research program, led by CRAAG with French collaboration (CEREGE), has initiated geological and geophysical surveys with mineralogical and paleomagnetic sampling to investigate the age of this structure. Other objectives are the investigation of the petrological and geochemical characteristics of the rocks at the various sites with a special emphasis toward determining the possible presence of a meteoritic component.

The processing of the geophysical data collected during the first measurement campaign suggest a magnetized body in the central zone of the crater that possibly relates to the presence of some magnetic rocks, maybe a melt component [2]. This geophysical signature (magnetic anomaly) will be further investigated by studying the magnetic properties of the collected samples, paleomagnetic data, and the effect of shock on the natural remanent magnetization [3-6]. We will present and discuss the rock magnetic and magnetic mineralogy data of the sampled target lithologies at the Maâdna impact structure. We also discuss the methods used to identify the impact effect on the intrinsic magnetic properties of sampled breccias and basement rocks inside and outside of the crater. Such data contribute to the understanding the mechanisms creating and modifying magnetic properties during impact cratering processes.

We will attempt to deduce the paleomagnetic age of the Maâdna impact structure by using the magnetostratigraphic data and Apparent Polar Wander Paths (APWP) for Africa (scale 10-100 My; [8,9]). Consequently, dating Algerian impacts is particularly interesting because of the rapid drift of Africa since the past 300 My.

Diagnostic shock features of the Serra da Cangalha impact structure, northeastern Brazil: preliminary analysis

Vasconcelos, M.A.R.[1*], Crósta, A.P.[1], Reimold, W.U.[2] & Kenkmann, T.[3]
[1]Institute of Geosciences, University of Campinas, Campinas, SP, Brazil ([*]vasconcelos@ige.unicamp.br)
[2]Museum für Naturkunde, Leibniz Institute at Humboldt University of Berlin, Germany
[3]Institut für Geowissenschaften, Albert-Ludwigs-Universität Freiburg, Germany.

The Serra da Cangalha (SdC) structure, located in Tocantins state, northeastern Brazil, is presumably a complex impact structure of 13.7 km in diameter with a central uplift of 5.8 km in diameter [1]. It was formed in ressentially undisturbed Phanerozoic sedimentary rocks of the Parnaíba Basin. Strata at the center were uplifted by ~ 0.6 km [2] which, in combination with erosional processes, resulted in a strong contrast in the local relief. Impact features, such as shatter cones and PDFs, were described in the 1980s in SdC rocks [3, unpublished]. Only the presence of diagnostic shock-metamorphic effects, such as shatter cones and PDF, besides chemical traces of the projectile, is generally accepted as unambiguous evidence for an impact origin [4]. Recent fieldwork conducted by the authors at SdC resulted in the discovery of some diagnostic macroscopic and microscopic impact features. In the collar of the central uplift the strongly folded strata are variably upturned or overturned [1]. Monomict and polymict breccias were found in the central uplift, as well as shatter cones. Both, breccias and shatter cones were found within the inner depression of the central uplift, wich corresponds to the area of occurrence of the lowermost stratigraphic unit, the Longá Formation. A small outcrop of sandstone with several cm sized shatter cones was found. Preliminarly analysis of some thin sections from the central uplift samples shows that sandstones and shales exhibit intense cataclasis of quartz and feldspar grains. Usually, the breccias show intense fracturing with distinctive planar features (PF), with up to three sets of different orientations in quartz grains. PF are also frequent in sandstone samples from the collar around the uplift, and also in quartz of shales from drill cores through the Longá Fm. (the core came from shallow boreholes drilled into the center in the early 1970s). Thin section analysis of these lithologies show the presence of feather features with planar fractures mostly parallel to (0001) in quartz. Furthermore, we found intersecting sets of PDF in quartz. The occurrence of these features allows to conclude beyond doubt that Serra da Cangalha was formed by a meteorite impact event.

Lithophile elements in iron meteorites

Palme, H.[1*], Vogel, I.[2], Spettel, B.[3] & Pack, A.[4]
[1]Sektion Meteoritenforschung Forschungsinstitut und Naturmuseum Senckenberg, Frankfurt, Germany ([*]herbert.palme@uni-koeln.de)
[2]Universität zu Köln, Germany
[3]Max-Planck-Institut für Chemie Mainz, Germany
[4]Geowissenschaftliches Zentrum, Universität Göttingen, Germany

Some of the major groups of iron meteorites are widely believed to have formed by fractional crystallisation of a molten mass of FeNi with some S, P and C. It is further assumed that metal segregated by melting of a chondritic mineral assemblage. This leads to equilibration of liquid metal and, partly or completely, molten silicate liquid. During this process a small fraction of typical lithophile elements will partition into the metal. The concentrations of lithophile elements in the metallic FeNi phase are sensitive indicators for the conditions of metal formation. Lithophile element concentrations in metal depend on the nature of the lithophile element, its compatibility of the metal species with FeNi (e.g. the activity coefficient), the oxygen fugacity during metal-silicate equilibration and the temperature. We have calculated the distribution of Si and Cr during metal-silicate equilibration by using experimentally determined activity coefficients of Si and Cr in FeNi-metal and we have measured the concentrations of Si (by SIMS) and Cr (by INAA) in iron meteorites [1,2].

The activity coefficients of Si in FeNi metal are, between 10^{-3} and 10^{-4} and they further decrease with increasing Ni contents. There is also a weak temperature dependence. The Cr activity coefficients are between 1 and 2, depending on temperature [1].

The concentrations of Si in iron meteorites as determined by SIMS are very low, between 0.1 and 0.3 ppm, independent of the type of iron meteorite and there is no difference between kamacite and taenite in a given meteorite. The Cr contents of iron meteorites are mostly below 100 ppm many are below 5 ppm [1,3]. Metal grains in chondrules of CR-chondrites representing metal-silicate equilibrium at magmatic temperatures have several hundred ppm Si and several thousand ppm Cr [4]. Although calculations show that concentrations of both elements decrease with decreasing temperature of metal-silicate equilibration, lower temperatures are not sufficient to explain the low observed concentrations of Si and Cr in iron meteorites. The only possibility is metal-silicate equilibration at low temperatures, below the solidus and/or metal-silicate equilibration at oxidizing conditions. The second effect is limited by the Ni contents of iron meteorites. Core formation at oxidizing conditions leads to high FeO in silicate and Ni-rich metals, not frequently observed in iron meteorites. Sub-solidus, low temperature equilibrations seems inescapable.

Do calcite veins in Antarctic CM2 carbonaceous chondrites indicate asteroidal fluid flow?

Sofe, M., Lindgren, P. & Lee, M.R.[*]
Dept. of Geographical and Earth Sciences, University of Glasgow, Scotland, UK ([*]Martin.Lee@ges.gla.ac.uk)

The CM2 carbonaceous chondrites contain minerals including phyllosilicates and carbonates that provide good evidence for the former presence of aqueous fluids within their parent body. A consistent problem in understanding the mechanism of aqueous alteration has been the paucity of petrographic indicators for fluid movement through parent body interiors. This is especially problematic as thermal modelling indicates that vigorous fluid convection should have taken place [1,2].

Using transmitted light and backscattered electron imaging, together with electron backscatter diffraction (EBSD) mapping, we have found Ca(Mg)-carbonate veins in two Antarctic CM2 finds, LON94101 and QUE93005. The millimetre sized vein in LON94101 is composed of twinned calcite crystals, some of which have detached from their host vein (Fig. 1). Small equant calcite grains that are typical of the CM2s are concentrated in one part of the thin section, with the vein lying at the edge of this carbonate-rich area. The veins in QUE93005 are smaller, they cross-cut the fine-grained rims around chondrules, and contain calcite, dolomite and pentlandite.

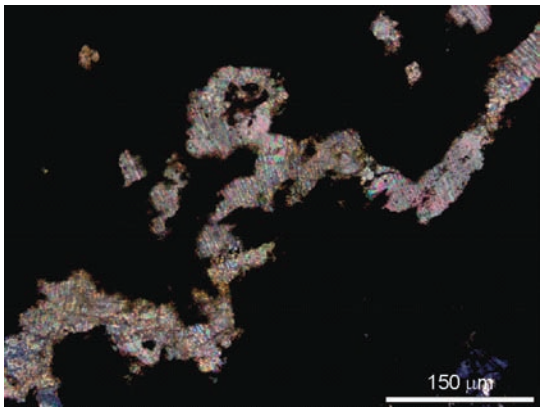

Fig. 1: Part of a twinned and fragmented calcite vein within LON94101. Transmitted light image between crossed polarisers.

The paucity of previous evidence for carbonate veins in the CM2, CM1 or CI1 meteorites could suggest that the veins described here are products of terrestrial weathering. However, we suggest that they formed within the parent body because: (i) it is very hard to imagine how the pressures required to twin and fragment the LON9410 calcite vein could have been attained whilst the meteorite was lying in the Antarctic ice, (ii) dolomite and pentlandite are very unlikely to form by weathering, and (iii) the fusion crust on QUE93005 is cut by abundant fine fractures, none of which contain carbonates. If water for calcite precipitation had been derived from outside of the meteorite, there should be some evidence for its movement through the fusion crust to the meteorite interior.

We conclude that veins in LON94101 and QUE93005 provide good evidence for fluid movement along open fractures within the CM parent body during aqueous alteration. The twinning and fragmentation of LON9410 calcite also suggests that it experienced >10 MPa pressures, probably during impact-related regolith gardening. These results beg the question of why carbonate veins are absent from other carbonaceous chondrites.

Heterogeneous condensation of Mg-silicate and metallic iron: implication for cosmochemical fractionation in the early solar nebula

Nagahara, H.* & Ozawa, K.
Dept. of Earth and Planetary Science, The University of Tokyo, Japan (*hiroko@eps.s.u-tokyo.ac.jp)

The solar system, at least its inner portion, was once vaporized to gas in its early stage of evolution and then cooled to condense Al- and Ca-rich oxides and silicates, Mg-silicates, and metallic iron as the major components in the decreasing order of temperature. Cosmochemical fractionation of elements basically controlled by volatility (e.g., [1]) is one of the most convincing evidence for the evaporation. The fractionation is, however, not fully explained solely by volatility of elements but it requires phase control. Though chemical equilibrium gives reference information about mineral formation, actual process should have proceeded in a kinetic condition and the phases appeared and the appearance temperature should have been different from estimation from chemical equilibrium.

We have developed a new kinetic condensation model, which describes heterogeneous condensation of minerals as a function of cooling time of the gas (τ) and critical dust separation size (R) in an open system. Heterogeneous condensation is evident in recent meteorite studies (e.g., [2]). A basic equation is the nucleation and growth of minerals derived from kinetic theory of gas molecules that includes condensation coefficients (α) and critical super saturation ratio (σ) for heterogeneous condensation as kinetic parameters. Another basic equation is the mass conservation. The system is assumed to consist of H-He-C-N-O-Mg-Al-Si-Fe and phases applied are corundum, forsterite, enstatite, SiO_2 and metallic iron. The total pressure of the system is fixed to be 10^{-5} bar. For α and σ, we used the values obtained by condensation experiments by our group. We have calculated size distribution, structure, and number density of grains and bulk composition of condensed dust and remaining gas.

The results show that chemical fractionation in the solar nebula was possible in a limited range in the space of τ and R. Cosmochemical fractionation among ordinary chondrites are explained by large supersaturation for forsterite condensation onto corundum and small supersaturation for Fe on forsterite, which suggests surface atomistic kinetics plays a key role than the scale of surface tension. Applying the grain size of corundum observed in primitive chondrites [3], plausible cooling time of the gas at the time of corundum condensation ranged from 10^2 to 10^3 year in order, which suggests advective transport of dust from gas.

The obtained condensation conditions were achieved in two disc models. One is condensation and large dust separation during inward movement of gas and dust, where the condensation of corundum should have started at the high temperature region of the surface layer of the disc followed by forsterite and Fe condensation at the lower temperature region in the lower portion of the disc. In this model, H, L, and LL chondrites were located in the inward order in the disc. Another model is more dynamic, where dust moves outward along the midplane of the disc. Condensation of corundum took place in the inner edge of the disc, which was followed by forsterite and metal at the farther region from the sun. H, L, and LL chondrite was located in this order from inner to outer regions.

Evaporation experiments for studying the interaction between air and cosmic Fe,Ni metals

Pack, A.[1*], Albrecht, N.[1] & Hezel, D.C.[2]
[1]Geowissenschaftliches Zentrum, Georg-August-Universität Göttingen, Germany (*apack@uni-goettingen.de)
[2]Mineralogy Dept., Natural History Museum, London, UK

Iron meteorites and I-type micrometeorites are frictionally heated to high temperatures when passing through the atmosphere. I-type micrometeorites consist of Fe,Ni-oxides and most probably formed by aerial oxidation of cosmic Fe,Ni metal [1]. They are enriched in heavy isotopes [2,3]. The metal isotope enrichment is related to evaporation during atmospheric entry [3]. For oxygen isotopes, exchange with ^{18}O-rich stratospheric oxygen [2] or evaporation [3] was suggested. Iron meteorite fusion crusts are moderately enriched in $\delta^{18}O$ with values around +13.5 ‰ [2] and no fractionation in metal isotopes [4].

We attempted to simulate the atmospheric entry using an aerodynamic levitation device in combination with infrared laser heating [5] in order to test if fusion crust and I-type micrometeorites can be used as probe for the isotope composition of oxygen at different heights [2].

We used Fe,Ni-oxides with approximately chondritic element ratios (4.8 mol% Ni) as starting material. Samples were fused and evaporated while floating on a vertical air gas stream for up to several hours. The mass loss was determined by measuring the mass of the sample before and after the experiment in combination. The Fe and O isotope composition of starting materials and run products was determined by solution MC-ICPMS (Imperial College, London) and by laser fluorination (Göttingen), respectively.

The mass loss varied between 39 and 80 %. The $\delta^{18}O$ ($\Delta^{17}O$) of the starting oxide mixture was –4.7 ‰ (–0.07 ‰) and changed to +12.3±0.2 ‰ (–0.17±0.02 ‰) after evaporation. No relation between mass loss and $\delta^{18}O$ is observed. The $\delta^{56}Fe$ of the starting material was +0.4 ‰. After evaporation $\delta^{56}Fe$ varied between +1.4 and +6.0 ‰. The $\delta^{56}Fe$ systematically increased with mass loss. Modeling all data with a Rayleigh process gives $\alpha_{liquid\text{-}gas} \approx 1.00458$.

The oxygen isotope composition is likely to be caused by *equilibration* of the molten oxides with air O_2 ($\delta^{18}O$ = +23.9 ‰, $\Delta^{17}O$ = –0.384 ‰, [6]). Kinetic fractionation should vary with time and with degree of evaporation; none of both/neither of them are observed. The fractionation in $\delta^{18}O$ is –11.4 ‰ and the 3-isotope exponent for the fractionation is $\beta = 0.5063$. Our results explain the $\delta^{18}O$ = +13.4 ‰ and $\Delta^{17}O$ = –0.17 ‰ in iron meteorite fusion crusts [2] by equilibration with air O_2. The variability of $\delta^{18}O$ in I-type micrometeorites, however, may indicate that some fractionation during evaporation occurs [3].

The Fe isotope fractionation is smaller as expected from Rayleigh-type evaporation of Fe or FeO. The α-value suggests evaporation of a species with a molar mass exceeding that of magnetite. One explanation would be evaporation in form of molecule clusters that have molar masses of ~270. Alternatively, evaporated material back-reacts with the liquid. We suggest that the difference between our results and the α-value (57/54) of 1.0274 from vacuum evaporation of wüstite [7] is related to the 1 bar atmosphere in which our experiments have been conducted.

Calcium-aluminum-rich inclusions in CK3/4 carbonaceous chondrites

Chaumard, N.[1*], Devouard, B.[1], Devidal, J.-L.[1] & Zanda, B.[2]
[1]LMV, Univ. Blaise Pascal - CNRS, Clermont-Ferrand, France
([*]n.chaumard@opgc.univ-bpclermont.fr)
[2]Muséum National d'Histoire Naturelle - CNRS, Paris, France

Dated at 4568.5 ± 0.5 Ma [1] calcium-aluminum-rich inclusions (CAIs) are the first solids in the solar nebula. They mainly occur in CV and CO carbonaceous chondrites [2]. CK chondrites, which comprise the only metamorphic series (petrological types 3 to 6) among carbonaceous groups [3], were initially described as CAI-poor objects. However, at least some CKs have CAI abundances similar to those of CVs [4]. We studied CAIs in CK chondrites at the 3 to 4 transition to characterize their modification by parent-body processes.

This study was carried out on DAG 431 (CK3-An.), NWA 1559 (CK3), NWA 4724 (CK3.8), NWA 4425 (CK3.8), NWA 4423 (CK3.9), NWA 4422 (CK4), NWA 2519 (CK4), TNZ 057 (CK4), Karoonda (CK4), and Maralinga (CK4). CAIs were recognized by visual identification on polished slabs or/and SEM-BSE imaging, depending on the sample size.

No CAIs were recognized in Karoonda, Maralinga, and NWA 2519. All other CKs display CAIs with abundances from 1.4 to 16.4%. Abundances obtained from small sections should be considered as poorly representative. Samples for which pluri-centimetric surfaces were available (NWA 4425, 20 cm^2, and TNZ 057, 865 cm^2) give CAI abundances of 10.3 and 8.9%, respectively.

Fine-grained CAIs, irregularly shaped, mm to cm-sized, are ubiquitous in most CKs. They are composed of Ca-rich pyroxene and plagioclase (An_{15-97}), with minor low-Ca pyroxene and olivine. Coarse-grained CAIs up to ca. 2 cm, often surrounded by a fine-grained Ca-pyroxene-plagioclase rim, were observed in NWA 1559, DAG 431, NWA 4425, and TNZ 057. Two coarse-grained CAI were analysed in TNZ 057 and DAG 431. They display a primary spinel-fassaite-anorthite assemblage and secondary grossular, forsterite and Ca-pyroxene. The replacement of primary phases by grossular is interpreted as evidence for parent-body alteration. All CAIs in CK chondrites were enriched in Fe during parent body metamorphism. Fe diffuses from matrix to CAI phases and causes chemical zonations, mainly in spinel and fassaite. Fassaite is locally destabilized to Ca-pyroxene and Ti-rich oxydes. In CK4s, the fine-grained CAIs are chemically equilibrated with the matrix and recrystallized as irregular assemblages of plagioclase + Ca-rich pyroxene +/- olivine +/- Ca-poor pyroxene.

We analysed several CAIs in TNZ 057 by LA-ICP-MS. In some fine-gained CAIs, rare earth element (REE) patterns in Ca-rich pyroxene are similar to those of group II CAIs [5] and of CV bulks [6]: light REE (LREE) enriched compared to heavy REE (HREE), with a positive anomaly of Tm. In other CAIs, REE in Ca-rich pyroxene are enriched (ca. 20×CI) with patterns similar to those reported in fassaite. These reequilibrated CAIs thus retained a pristine signature in spite of thermal metamorphism.

Silicate mineral inclusions in the Muonionalusta iron meteorite

Fujimaki, H.[1*] & Fuyuya, K.[1,2]
[1]Dept. of Earth and Planetary Material Science, Graduate School of Science, Tohoku University, Sendai, Japan
([*]h-fujimaki@m.tains.tohoku.ac.jp)
[2]Dept. of Earth Planetary Sciences, Graduate School of Science, Kobe University, Kobe, Japan

Mineralogical and geochemical investigation has been carried out on a magmatic iron meteorite. Although many magmatic iron meteorites have been investigated so far, only four IVA irons contain silicate inclusions. Two IVA irons contain a few number of tridymite crystals, and two others contain up to 50 percent silicates in volume; they are mostly pyroxene and tridymite mixed with metal; some of them reach to centimeter size. Muonionalusta iron meteorite (IVA) has been investigated and the results are reported in this presentation. Previous investigation has found stishovite that was presumably trydimite before impact. In contrast, I found many other different kinds of silicate and oxide minerals in the iron meteorite. Alkali feldspars, plagioclase, olivine, zircon, garnet, micas and hornblendes were recognized for the first time not only in the Muonionalusta iron meteorite but in the entire iron meteorites. I identified those minerals using Raman micro spectroscopy, and their compositions were analyzed by energy-dispersive micro probe spectroscopy. Especially the occurrence of hornblende in iron meteorites is unusual. It occurs as a rectangular grain up to 0.8 mm long surrounded by hematite matrix. Its composition is close to magnesio-hornblende, and the texture indicates that it formed as a primary (pre-terrestrial) mineral. Such mineral assemblages imply that these silicates might have crystallized from felsic magma generated by partial melting of the parent body. We now may see the fragments of the planet that once had crust like Earth. On the other hand, it is impossible to deny the possibility as follows: the iron meteorite was partially molten and included terrestrial minerals at the impact. However, no similar occurrence has been reported. In the latter case we may have to consider new physical model of impact. Possibility and the origin of such magma on the parent body should be discussed in feature. We may have unconsciously disregarded such minerals and mineral assemblages in meteorites.

Structural parameters of chromites from H6 Kernouvè chondrite and detrital extraterrestrial L-chondrites

Lenaz, D.[1*], Schmitz, B.[2] & Princivalle, F.[1]
[1]Dept. of Geosciences, University of Trieste, Italy
([*]lenaz@units.it)
[2]Dept. of Geology, University of Lund, Sweden

Chromite is a minor but regular constituent of ordinary chondrites and its chemistry in meteorites have been studied since the 60es. Besides the main components FeO and Cr_2O_3, it contains minor amounts of MgO and Al_2O_3. It has been noticed that Fe and Mg content of chromites is related to that of the olivines in the H, L and LL groups of equilibrated chondrites.

The here studied chromites are from the Kernouvè H6 chondrite and from ~ 470 Ma old fossil micrometeorites, found in Ordovician limestone at Kinnekulle in Sweden and derived from the disruption of the L-chondrite parent body [1].

Despite the fact that their chemistry has been studied since about 40 years, to our knowledge no single crystal diffraction studies have been performed on extraterrestrial chromites. The cell edge in H6 chondrite ranges from 8.3480 (2) to 8.3501 (1) Å, while in L-chondrite it varies from 8.3347 (3) to 8.3463 (3). The oxygen positional parameter is comprised between 0.2627 (2) and 0.26291 (7) in H6 and between 0.2625 (1) and 0.26267 (9) in L. These values show that there are some little differences between the two chondritic typologies. By comparison with the structural parameters of chromites from terrestrial occcurrences, in an oxygen positional parameter vs. cell edge diagram (Fig. 1) the extraterrestrial chromites fall in a proper field close to those of chromites from komatiites [2], kimberlites and included in diamonds [3].

Because meteoritic material on the Earth surface is rapidly altered or weathered away with the exception of chromite, different methologies have been recently developed to recognise the extraterrestrial detrital chromitic material [1, 4]. This work demonstrates that a structural study can, as well, identify extraterrestrial from terrestrial material and also that different chondritic origin can be recognised.

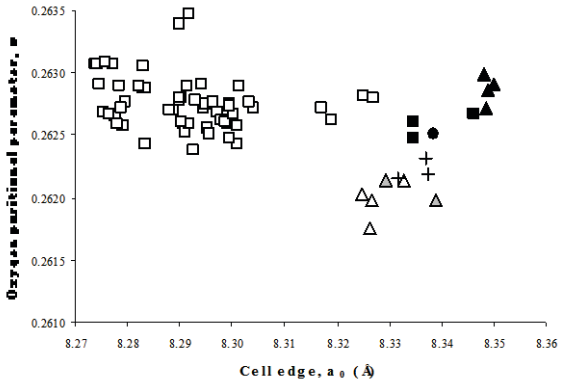

Fig. 1: Oxygen positional parameter vs. cell edge. Full triangle: H6 chondrite; Full square: L-chondrite. Full circle: Acapulco meteorite; Open square: layered intrusions; Open triangle: diamond inclusions; Grey triangle: kimberlites; Crosses: komatiites.

Dust in protoplanetary disks

Henning, T.K.
Max Planck Institute for Astronomy, Heidelberg, Germany
(henning@mpia.de)

Circumstellar disks around young stellar objects are the birthplaces where planetary systems form. Small solid particles and molecular gas in these protoplanetary disks are the building blocks for planets. Space-based infrared spectroscopy with the "Spitzer" and "Herschel" observatories and infrared data from the gound constrain the nature of protoplanetary dust. This talk will summarize the main properties of the small particles, including their mineralogy. In addition, the various formation and evolution processes of the dust grains will be discussed.

The mineralogy of circumstellar silicates preserved in cometary dust

Keller, L.P.* & Messenger, S.
Code KR, NASA Johnson Space Center, Houston, TX, USA
(*Lindsay.P.Keller@nasa.gov)

Interplanetary dust particles (IDPs) contain a record of the building blocks of the solar system including presolar grains, molecular cloud material, and materials formed in the early solar nebula [1]. Cometary IDPs have remained relatively unaltered since their accretion because of the lack of parent body thermal and aqueous alteration. We are using coordinated transmission electron microscope (TEM) and ion microprobe studies to establish the origins of the various components within cometary IDPs. Of particular interest is the nature and abundance of presolar silicates in these particles because astronomical observations suggest that crystalline and amorphous silicates are the dominant grain types produced in young main sequence stars and evolved O-rich stars (e.g. [2]).

Five circumstellar grains have been identified including three amorphous silicate grains and two polycrystalline aggregates. All of these grains are between 0.2 and 0.5 μm in size. The isotopic compositions of all five presolar silicate grains fall within the range of presolar oxides and silicates [3], having large ^{17}O-enrichments and normal ^{18}O/^{16}O ratios (Group 1 grains from AGB and RG stars). The amorphous silicates are chemically heterogeneous and contain nanophase FeNi metal and FeS grains in a Mg-silicate matrix. Two of the amorphous silicate grains are aggregates with subgrains showing variable Mg/Si ratios in chemical maps. The polycrystalline grains show annealed textures (equilibrium grains boundaries, uniform Mg/Fe ratios, [4,5]) and consist of 50-100 nm enstatite and pyrrhotite grains with lesser forsterite. One of the polycrystalline aggregates contains a subgrain of diopside. The polycrystalline aggregates form by subsolidus annealing of amorphous precursors [4].

The bulk compositions of the five grains span a wide range in Mg/Si ratios from 0.4 to 1.2 (avg. 0.86). The average Fe/Si (0.40) and S/Si (0.21) ratios show a much narrower range of values and are ~50% of their solar abundances. The latter observation may indicate a decoupling of the silicate and sulfide components in grains that condense in stellar outflows.

The amorphous silicate grains described here were not extensively affected by irradiation, sputtering, or thermal processing and may represent relatively pristine circumstellar grains. They are strong candidates for the "dirty silicates" in astronomical observations of circumstellar dust shells. The polycrystalline grains were originally amorphous silicate grains that were likely annealed in the early solar nebula [5] but the processing was not sufficient to erase their anomalous oxygen isotopic compositions.

Mixing and thermal processing of pre-planetary materials in protoplanetary disks

Apai, D.
Space Telescope Science Institute, Baltimore, USA
(apai@stsci.edu)

Protoplanetary disks are the both the site and the raw material for the formation of planets. With the rapidly increasing number of exoplanets and the wealth of high-quality observations of protoplanetary disks it is compelling to place the formation of the Solar System in the broader context of planet formation in the Galaxy.

A key question in this endeavour is how the bulk composition of planets is influenced by their formation process; and, in particular, what is the extent and role of the thermal and chemical processing of preplanetary components.

Primitive meteoritic materials reveal abundant evidence for thorough processing and mixing of solids in the proto-Solar nebula. Chondrules, Ca-Al-rich inclusions, interplanetary dust particles, or chondritic matrix all suggest that at least 80% of the solids in the inner Solar System underwent powerful heating and melting, often under high pressures. Recently, the Spitzer Space Telescope revealed widespread evidence for crystalline silicates in a broad variety of protoplanetary disks. The presence of crystalline silicates evidence thermal processing in the disks; but, surprisingly, the strongest crystalline features were observed around the coolest stars and brown dwarfs (e.g. [1,2]).

In this talk I will review the presence and properties of crystalline silicates in disks. I will connect these observations to evidence for thermal processing in the proto-solar nebula and discuss the constraints they provide on the mixing of solids in protoplanetary disks. I will also briefly describe a large, coordinated effort by astronomers and cosmochemiststs to develop a consistent framework for the formation and evolution of the proto-solar nebula and protoplanetary disks around other stars [3].

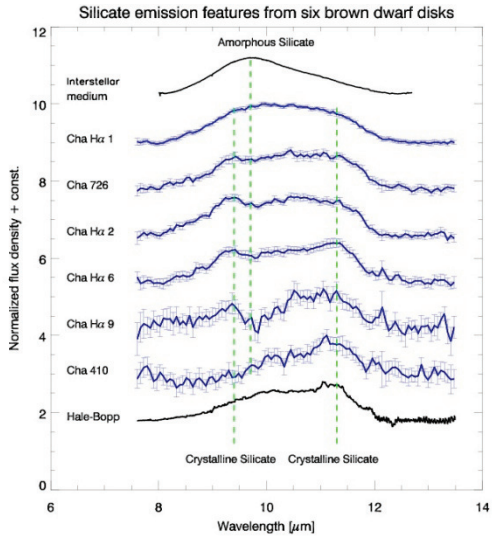

Fig. 1: The prominent crystalline silicate peaks reveal powerful thermal processing of the solids in protoplanetary disks, a surprising finding around very cool stars. From [1].

Crystalline silicates are known to be missing from the interstellar medium, but they are frequently observed in protoplanetary disks as well as Solar System comets. Although there were indirect evidences for the formation of crystalline silicates in protoplanetary disks the process itself was not yet observed.

Here, we report on the first direct observation of on-going crystal formation in the disk of EX Lup, the prototype of the EXor class of young eruptive stars. These stars are known to show repetitive outbursts at optical wavelengths, which are thought to be related to runaway accretion onto the central star.

EX Lup went into its most recent outburst at the beginning of 2008 and returned to the quiescent phase in Sep. 2008. We observed the source with the Infrared Spectrograph (IRS) onboard the Spitzer Space telescope in Apr. 2008 and compared it to that from the pre-outburst phase from the Spitzer archive. The pre-outburst spectrum shows the typical triangular-shaped 10 micron feature of amorphous silicates, signatures of crystals are not present in the spectrum. The outburst spectrum, however, shows new peaks at 10, 16 micrometer and a shoulder at 11.3 micrometer, which are the characteristic band positions of crystalline forsterite. Our analysis shows that the only possible explanation for the 'new' features is the in-situ formation of forsterite crystals in hot inner disk of EX Lup.

Spitzer IRS spectra were taken also in the post-outburst phase (Oct. 2008 and Apr. 2009). These spectra show forsterite bands also at 24 and 28 micrometer. Our modeling shows that the most likely explanation for the strength of these forsterite bands is the fast radial transport of crystals in the disk. The freshly produced crystals must have been transported by about 30-40km/s. Such high velocities require some kind of stellar/disk wind driven radial transport mechanism [2].

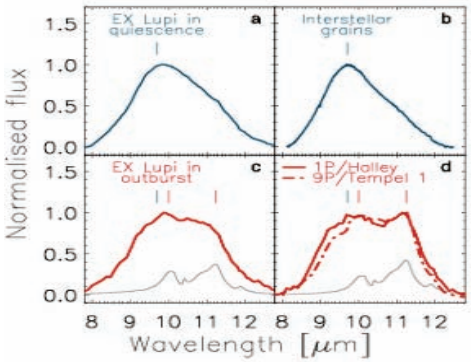

Fig. 1: 10 μm silicate feature of EX Lup in the pre-outburst phase (a) and in the outburst (c). For comparison the silicate feature of the interstellar dust grains (b) and comet Halley and 9P/Tempel 1 (c) are also shown. The grey line in the bottom panel shows the emissivity of sub-micron sized forsterite grains at 1250K (c) and 300K (d).

Experimental demonstration of a forsterite cycle from evolved stars to the solar system

Kimura, Y.[1*] & Nuth, J.A. III[2]
[1]Dept. of Earth and Planetary Materials Science, Tohoku University, Sendai, Japan ([*]ykimura@m.tains.tohoku.ac.jp)
[2]Astrochemistry Laboratory, Code 691, NASA's Goddard Space Flight Center, Greenbelt MD, USA

Magnesium rich silicate minerals are widely and abundantly distributed in the solar system and also in many other astrophysical objects. During the formation of silicate dust particles in the outflows of AGB stars, whether a silicate grain becomes crystalline or amorphous depends sensitively on its' temperature history. The presence of both amorphous and crystalline silicates around AGB stars suggests that the formation conditions, such as cooling rate or the temperature at which grain nucleation begins in such objects may vary or that the crystalline silicates are a result of annealing previously formed amorphous silicates.

In our solar system, several comets show 10 μm emission features characteristic of a mixture of amorphous and crystalline silicates. In addition, mixtures of amorphous and crystalline silicates are observed in stratospherically collected IDPs (e.g. [1]) and their IR spectra are coincident with that of comets [2]. Crystalline silicates have also been identified in comet Wild-2 (Stardust) samples [3]. Since most interstellar silicates are in an amorphous state, it has been proposed that the amorphous silicates gradually crystallized via thermal annealing in the hot inner solar nebula over time.

In the scenario to get crystalline silicates by annealing, there are difficulties. For examples, thermal annealing will not produce forsterite unless the chemical composition of the precursor particles is of olivine composition. In addition, the oxygen isotopic compositions of crystalline silicates (200 – 1,000 nm) in IDPs and Wild-2/Stardust samples is indistinguishable from solar [4,5]. The abundant presolar crystalline silicates, determined from oxygen isotopic anomalies, are much less abundant than presolar amorphous silicates, which are thought to be GEMS [6]. Therefore, it is possible that solar silicates are the result of condensation, and not of annealing of interstellar amorphous particles. One experiment achieved the direct formation of crystalline silicate (forsterite) via homogeneous nucleation so far [7]. The smoke particles showed various degrees of crystallinity of forsterite. This result suggested that the crystallinity depends on the interval time of reactions. Recently, Kimura and Nuth (2009) [8] suggested another possible origin of solar forsterite by oxidation of magnesium silicide. There are several possible formation processes, annealing of presolar grains, direct condensation of crystalline grains, condensation of amorphous grains followed by annealing and oxidation of metallic precursors such as Mg_2Si. Solar system silicates may be a result of all of these processes, i.e., degree of contribution should be elucidated. Recent laboratory studies have given us more complex results. In this study, we will show the selective formation of amorphous and crystalline silicates in hydrogen absent or dominant gas atmosphere and alteration by thermal annealing using differential scanning calorimetry (DSC).

Comparison of the mineralogy of comet Wild 2 coma grains to other astromaterials

Frank, D.[1*] & Zolensky, M.[2]
[1]ESCG/Hamilton Sundstrand, NASA Johnson Space Center, Houston, TX, USA ([*]david.r.frank@nasa.gov)
[2]ARES, NASA Johnson Space Center, Houston, TX, USA

We propose that Kuiper Belt samples (in this case comet coma grains from the Jupiter family comet Wild 2) are recognizably different from the bulk of materials in outer belt asteroids, because of their different formation positions and times in the early solar system. We believe this despite similarities found between some Wild 2 grains and components of carbonaceous chondrites (i.e. some CAI and chondrules). Kuiper Belt samples must preserve measurable mineralogical and compositional evidence of formation at unique positions and times in the early solar nebula, and these formational differences must have imparted recognizable special characteristics. We hypothesize that these characteristics include: (1) Unique major element compositional ranges of common astromaterial minerals, especially olivine and pyroxene; (2) Unique minor element compositions of major silicate phases, especially olivine and low-Ca pyroxene; (3) Degree and effects of radiation processing – including amorphous rims, metal coatings, and Glass with Embedded Metal and Sulfides (GEMS) [1-3]; (4) Presence of abundant presolar silicate grains as recognized by anomalous oxygen in silicates [1,3,4]; (5) Oxidation state of the mineral assemblage [5].

We will work our way through all available Wild 2 samples as they are allocated to us, selecting 1-2 non-consecutive viable TEM grids from each possible extracted Wild 2 grain. We especially prefer TEM grids from grains for which complete mineralogical details have not been published (which is to say the majority of the extracted grains). We are performing a basic mineralogic survey by E-beam techniques, to establish the essential features of the extracted Wild 2 grains. We are making a particular effort to carefully and accurately measure minor elements of olivine and pyroxene, as these minerals are widespread in astromaterials, and comparisons of their compositions will serve to place the Wild 2 silicates in contact with asteroids, meteorites and chondritic interplanetary dust particles processing [1-6]. We are also making a special effort to search for mineralogical products of aqueous alteration, since their presence would reveal that Wild 2 was once internally heated, a result with dramatic implications for models of early solar system primitive bodies. Thus far carbonates are the only potential evidence for aqueous alteration for Wild 2.

The discovery of new warm debris disks around F-type stars: implications for recent collisions

Moór, A.[1*], Apai, D.[2], Pascucci, I.[2], Ábrahám, P.[1], Grady, C.[3], Henning, Th.[4], Juhász, A.[4], Kiss, Cs.[1] & Kóspál, Á.[5]

[5]Leiden Observatory, Leiden University, The Netherlands

We report on the results of a Spitzer program devoted to studying debris disks around F-type stars. The motivation of the program was to outline disk evolution effects in a constrained stellar mass range, and also to make the bridge between the major Spitzer surveys of debris disks around A-type and G,K-type stars. We observed 86 F-type stars with IRS and MIPS instruments, many of them with previous indications for infrared excess from IRAS or ISO. The observed debris disk population shows a large variety in dust temperatures. In this contribution we report the discovery of four warm debris disks, which significantly increases the number of such systems known. Based on the fractional luminosity and age, three out of the four warm debris systems are consistent with a steady state disk evolution picture. The oldest source, HD 169666, displays a dust fractional luminosity too high to be in a steady state and we suggest that this system recently underwent a transient event of dust production. In addition, two spectra of this star separated by approximately three years show silicate emission features, indicative of submicron- to micron-sized grains. We argue that such small grains would be rapidly depleted and their presence in both spectra suggests that the production of small dust is continuous over a timescale of at least a few years. We predict that systems showing variable mid-infrared spectra, if they exist, will provide valuable help in distinguishing the possible scenarios proposed for dust replenishment.

Erosion rate determination of Allchar region (Macedonia) with cosmogenic radioactive (^{10}Be, ^{26}Al, ^{53}Mn) and stable (^{3}He, ^{21}Ne) nuclides

Pavićević, M.K.[1], Vermeesch, P.[2], Niedermann, S.[3], Amthauer, G.[1*], Boev, B.[4], Jelenković, R.[5] & Pejović, V.[6]
[1]Dept. of Materials Engineering and Physics, University of Salzburg, Austria ([*]georg.amthauer@sbg.ac.at)
[2]School of Earth Sciences, Birkbeck University of London, Great Britain
[3]Deutsches GeoForschungsZentrum GFZ, Potsdam, Germany
[4]Faculty of Mining and Geology, University of Štip, FYR Macedonia
[5]Faculty of Mining and Geology, University of Belgrade, Serbia
[6]Faculty of Physics, University of Belgrade, Serbia

Allchar is a Sb-As-Tl-Au deposit located at the north - western margin of the Kozuf Mountains in Macedonia, close to the Greek border. The mine contains the world's largest known concentration of thallium-bearing minerals, especially lorandite ($TlAsS_{2)}$. LOREX, the acronym for LORandite EXperiment, is the only geochemical solar neutrino experiment still actively pursued. It addresses the determination of the long-term average of the solar neutrino flux, based on the neutrino-capture reaction $^{205}Tl + \nu_e \rightarrow {}^{205}Pb + e^-$ occurring in the lorandite of the Allchar mine. The final step of LOREX will be the extraction of the lorandite and the quantitative determination of the ^{205}Pb / ^{205}Tl ratio, thus providing the product of solar neutrino flux and neutrino-capture cross section, integrated over the lorandite age of $4.31 \cdot 10^6$ yr. Based on the present-day solar luminosity, it is expected that about 23 atoms of ^{205}Pb of solar neutrino origin will be found per gram of lorandite. In contrast with the production of ^{205}Pb by solar neutrinos, which is independent of depth, cosmogenic ^{205}Pb produced from fast muons of cosmic ray origin is strongly depth-dependent and very sensitive to the long-term erosion history of the field area. For erosion rate determination, we have so far applied three independent series of measurements of cosmogenic ^{26}Al, ^{10}Be and ^{53}Mn. First, the ^{26}Al concentration in quartz was determined using the AMS system at VERA (**V**ienna **E**nvironmental **R**esearch **A**ccelerator). Second, a series of measurements of the ^{10}Be and ^{26}Al contents was performed at the AMS of PRIME Lab, Purdue University, and finally AMS measurements at the Tandem facility of the TU Munich provided concentration of ^{53}Mn in pyrite (FeS_2). For the two ore bodies containing lorandite, we derived lower limits of the erosion rate of ~33 m/Myr at Crven Dol (NW part of Allchar deposit) and 67 m/Myr in the central part (SE part of Allchar deposit), in fair agreement with quantitative geomorphologic studies. In addition, mass spectrometric determinations of comogenic ^{3}He and ^{21}Ne concentrations in diopside, quartz and sanidine from three different Allchar locations (near to Central part) are currently underway at GFZ Potsdam. The combination of various cosmogenic nuclides will enable us to accurately decipher the erosion history of the Allchar deposit, including any period of intermediate cover, e.g. by ice or sediments. Such knowledge is critical in order to assess the production of cosmogenic ^{205}Pb, which interferes with that produced by solar neutrino and cosmic ray interaction.

Colours of stardust: absorption properties of selected oxides and silicates in their transparency regimes

Zeidler, S.[1], Mutschke, H.[1*], Posch, T.[2], Richter, H.[2] & Wehrhan, O.[3]
[1]Astrophysikalisches Institut, Jena, Germany
([*]mutschke@astro.uni-jena.de)
[2]Institut für Astronomie, Vienna, Austria
[3]Institut für Optik und Quantenelektronik, Jena, Germany

Several astrophysically relevant solid oxides and silicates have extremely small values of the imaginary part k of their complex indices of refraction in the visual and near-infrared spectral ranges. Datasets for the absorption index k are hardly available in these cases, but very important for thermal and dynamical properties of stardust grains. With increasing absorbance the equilibrium temperature of grains in circumstellar shells increases.

We aimed at closing the 'gaps' in the sets of optical constants particularly characterizing spinels and olivines with different contents of Cr and Fe. For that, two principal methods have been used: preparing small sections of natural minerals and synthesizing melt droplets under the electric arc furnace. In both cases, the absorption properties of the samples were measured by transmission and scattering spectroscopy. From these data the optical constants have been derived.

For the synthesized Cr doped spinels ($MgAl_{2-x}Cr_xO_4$), we investigated the strength of the absorption features, which arose by successive exchange of Aluminum with Chromium(III)Ions. On the other hand we used a natural spinel from Burma to compare the influence of both Chromium and Iron with the pure stoichiometric and only Chromium doped spinels.

For the investigations on the olivines, two natural crystals with different Fe content have been used: one from San Carlos and another one from Sri Lanka. We studied the influence of Iron on the absorption spectra of olivine for both polarized and unpolarized light in the near infrared to the UV.

Presolar nanodiamonds in meteorites: properties and origins

Ott, U.
Dept. of Biogeochemistry, Max-Planck-Institute for Chemistry, Mainz, Germany (uli.ott@mpic.de)

Primitive meteorites contain grains of stardust, i.e. "pre-solar" grains that formed in the outflows or ejecta of stars [1]. Among these are nanodiamonds with a mean size of ~2.6 nm and a nominal abundance reaching up to ~0.15 % by weight [2]. The identification of a presolar origin rests on the observation of trace elements within them, notably the noble gas xenon, with an unusual isotopic composition. However, since the isotopic analysis of single diamonds (some 1000 carbon atoms on average) is not feasible, and "bulk" analysis of large numbers (millions or so) of diamonds results in a C isotopic composition in the range of normal solar-system carbon, it is presently unclear what fraction of the nanodiamonds really is pre-solar.

The isotopic composition of "HL"-xenon is characterized by excesses of both the heaviest and the lightest isotopes, which is reminiscent of the p- and r-processes of nucleosynthesis that are thought to occur during supernova explosions [3]. There are differences in detail, however, which may indicate some unconventional types of element synthesis in stars [4] or modification by secondary processes [3]. Recoil loss from nanometer-sized grains during decay of unstable precursor nuclides has been suggested as an explanation, but experiments we have performed do not support this idea [5].

Astronomical observations indicate the presence of diamonds around young stars, but have not unambiguously identified them in the interstellar medium or around evolved stars. Raman spectroscopy of nanodiamonds from the Allende meteorite has revealed a shift of the 1332 cm^{-1} diamond peak downward to ~1326 cm^{-1}, but it is not clear whether this is due to origin by shock or a feature caused by small grain size [6]. The small size leads also to quantum confinement effects observable in their x-ray absorption fine structure [7]. TEM observations are more in line with a CVD origin [8].

Gases within the diamonds were probably trapped by ion implantation [9] and occupy two different types of sites characterized by different release temperatures [10]. Excesses of ^{21}Ne and ^{3}He are probably due to cosmic ray effects, partly from recoil implantation and possibly also from cosmic ray ^{3}He trapped as such [11]. The latter may offer a possibility to extract information about the diamonds' residence time in the molecular cloud from which the solar system formed.

[3]School of Earth and Space Exploration, Arizona State University, Tempe, Arizona, USA

Nanodiamonds (Fig. 1) with sizes down to 1 nanometer are abundant in meteorites, impact craters, and as globally dispersed products caused by extraterrrestrial impacts. Their morphology, polymorphic modifications, and lattice defects can provide information regarding formation conditions (e.g., [1]).

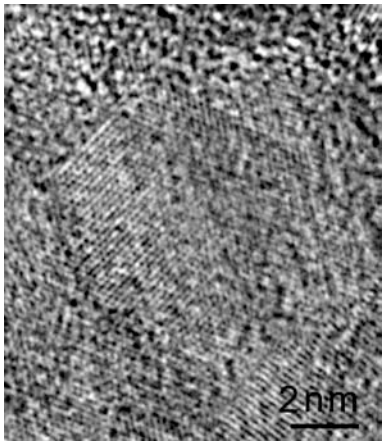

Fig. 1: Nanodiamond from the Gujba meteorite.

The last decade has revealed numerous new carbon allotropes with cell parameters and space groups that differ from those of Fd-3m diamond. In particular, large numbers of new carbon modifications have been described from synthetic materials, but the structures and properties of many of these have only been incompletely characterized.

The transmission electron microscope (TEM) is the most powerful tool to identify different diamond allotropes, but challenges exist because of both the small sizes and the subtle differences of the carbon phases. Moreover, dynamic effects such as multiple scattering arising from thickness variations make the identification of given modifications difficult. To link such allotropes as direct indicators of a specific geological phenomenon is problematic.

In our presentation we examine carbonaceous materials from the Gujba and Canyon Diablo meteorites and illustrate the atomic-scale structural complexity of nanodiamonds. Furthermore, we draw attention to the difficulties and challenges occurring during the identifications of diamond polytypes.

Study of impurities in nanodiamonds from meteorites by spectroscopic methods: implications for their formation

Shiryaev, A.A.[1*], Fisenko, A.V.[2], Vlasov, I.[3] & Semjonova, L.[2]
[1]Institute of Physical Chemistry, Moscow, Russia
([*]a_shiryaev@mail.ru)

[3]General Physics Institute, Moscow, Russia

Meteoritic nanodiamonds (MND) are the most abundant protoplanetary Solar System relic phases in comparison with other compounds (graphite, SiC etc.). Nanodiamonds contain isotopically anomalous Xe, presumably originated in r- and p-processes of type II supernovae explosion. Mass-spectrometry shows that H and N are the main chemical impurities in MND. The N content of some of the grains (up to 4 %) exceeds significantly not only the average (0.04 %), but also the maximal (0.3 %) N content reported for terrestrial natural and synthetic (nano)diamond. Therefore, models of MND formation must explain high impurity content.

Speciation of N in MND is unknown and up to now no reliable spectroscopic evidence of N-related defects in MND has been reported. We will present results of our extensive spectroscopic comparative investigation of meteoritic nanodiamonds from Efremovka CV3 and Orgueil CI chondrites with synthetic nanodiamonds produced by very different methods: CVD, detonation (DND), Physical Vapour Deposition (PVD). The samples were analysed using luminescence and Raman spectroscopies, EELS, and NEXAFS at C and N absorption edges. The structure and size distribution of the grains was analysed using X-ray diffraction and scattering.

XRD and PEEM show that the phase composition of the MND and UDD are similar. This observation may indicate similarities of their structures in the sense that they presumably consist of diamond core surrounded by (semi)amorphous and graphite-like carbon. EELS and XANES analysis of the nanodiamond grains with high spatial resolution showed that both MND and UDD contain high amount of nitrogen located almost exclusively in twin lamellae and other similar imperfections. This N does not have obvious spectroscopic manifestations. Such localisation of nitrogen is also encountered in some nanocrystalline diamond films. No unambiguous manifestations of radiation defects are observed.

This work has direct implications for the origin of meteoritic nanodiamonds: high concentration of nitrogen in nanodiamonds could be achieved only if their growth (or, at least, nucleation) is extremely fast and proceeds on the time scale of 1-5 microseconds. In case of quasi-equilibrium growth when impurity trapping is determined by kinetics of absorption-desorption, the impurity content is invariably much smaller, than that encountered in meteoritic nanodiamonds. The grains enriched in nitrogen, most likely, were formed in a fast process, probably from a C-N-rich plasma.

For the first time the silicon-vacancy complex (the “silicon” defect) is observed in meteoritic nanodiamond by photoluminescence spectroscopy. Moreover, this is the first observation of this defect in dispersed nanodiamond of any origin. The current study suggests a new isotopic system in studies of the meteoritic nanodiamond – silicon, which is potentially capable to improve understanding of the astrophysical environment of its formation.

Fluid-induced dislocation pipe diffusion along olivine low-angle subgrain boundaries

Plümper, O.* & Austrheim, H.
Physics of Geological Processes, University of Oslo, Norway
(*oliver.pluemper@fys.uio.no)

Low-angle subgrain boundaries are a common microstructure in olivine that is a result of dislocation alignment into planar arrays due to crystal-plastic deformation. These dislocation arrays can act as fast pathways for diffusing atoms and dissociated water molecules. This phenomenon, known as pipe diffusion [1], is thought to originate from the disordered core region that lowers the activation energy for diffusion [2]. Recent in-situ transmission electron microscopy (TEM) experiments on a single dislocation line observed enhanced diffusivity along the dislocation cores of up to three orders of magnitude difference when compared to bulk diffusion [3]. However, most investigations have observed these phenomena in metals and ceramics only. Here we present new observations supporting dislocation pipe diffusion in olivine from the hydrated upper mantle section of the Leka Ophiolite Complex, Nord-Trøndelag, Norway.

Intragranular striped chemical zoning in olivine grains was observed using optical microscopy and back-scattered electron imaging. The zoning is parallel to the typical olivine kink bands and the optical undulose extinction that is caused by intragranular misorientation. Two types of chemical zoning were found; (1) Fe-enriched and (2) Fe-depleted zoning. Both types of zoning had distinct, parallel spacing across the olivine grains. The most pronounced zoning was found to spread out from serpentine needles that transect into the olivine. Focused ion beam sample preparation technique combined with transmission electron microscopy revealed that the observed striped zoning is in direct spatial relationship with low-angle (100)ol subgrain boundaries composed of (010)[100] edge dislocations. The edge dislocation cores in the (010)[100] system are parallel to the c (i.e. [001]) direction. Scanning TEM, utilizing high-angle annular dark field imaging coupled with energy-dispersive X-ray spectrum profiling, revealed that the striped chemical zoning (Fe-enriched & Fe-depleted) is located at the subgrain boundary on the nanometer scale.

Nanometer-sized serpentine clusters and fluid inclusions (100-200 nm in size) were found at subgrain boundaries associated with the Fe-depleted zoning. High-resolution TEM revealed serpentine nuclei, several unit cells large, in direct relationship with the subgrain boundaries. However, subgrain boundaries associated with Fe-enriched zoning showed no evidence for olivine replacement by serpentine.

From the striped chemical zoning and serpentine replacement we infer that (100)ol subgrain boundaries, the locus of edge dislocation piling, potentially channels fluid entry. We suggest that this channeled entry causes highly anisotropic diffusion and physico-chemical alteration due to pipe diffusion along edge dislocation cores within the subgrain boundaries. Pipe diffusion could lead to a dislocation core instability at Fe-depleted subgrain boundaries which potentially could trap water, resulting in the transformation of olivine to serpentine via dissolution and reprecipitation.

This could dramatically weaken the olivine grains and have overall implications for the rheology of the hydrated upper mantle. Furthermore, this could have an important influence on the homogeneity of fluid infiltration and hence the hydration of olivine to form serpentine.

Atomic structures and energies of grain boundaries in Mg_2SiO_4 forsterite from atomistic modelling

Adjaoud, O.* & Jahn, S.
Deutsches GeoForschungsZentrum GFZ, Section 3.3, Potsdam, Germany (*adjaoud@gfz-potsdam.de)

Most real materials are not single crystals but consist of crystalline grains of various sizes, misorientated with respect to each other. The grain boundaries influence many of the material properties. For example, when considering mantle rocks these boundaries become important since they provide a means for creep and ion migration, likely causes of mantle rheology. Olivine is a major component of the Earth's upper mantle and therefore it is of considerable importance to study its physical and thermodynamic properties.

The structure of grain boundaries can be investigated using high-resolution transmission electron microscopy (HRTEM) [1]. Atomistic simulations are not only useful to provide the structural model needed for the interpretation of the HRTEM images, but they are also a unique tool to link structure and physical or thermodynamic properties of grain boundaries. In the present study, we report the results on the atomic structure, the respective energies and excess volumes of symmetric tilt grain boundaries in Mg_2SiO_4 forsterite with different tilt angles. We construct [100] symmetrical grain boundaries with tilt angle α by aligning a chosen crystallography plane (0kl) parallel to the tilt axis [100] and misoriented with $\alpha/2$ to the (010) plane. One-half crystal (grain) is rotated by a 180° rotation relative to the other about the normal [0kl]. Since we use periodic boundary conditions, our simulations have large cells containing a few thousand atoms. The interactions between the atoms are described by an advanced ionic potential model [2] that accounts for polarization and deformation of the ions. In order to find stable grain boundary structures, we first perform molecular dynamics simulations to relax atomic positions. Then, we apply a combination of molecular dynamics and metadynamics method [3] to map the free energy surface and to search for other low energy grain boundary structures. We have found that the energies and excess volumes of the grain boundaries in Mg_2SiO_4 forsterite depend significantly on the misorientation angle of the grain boundary. We compare our results with HRTEM observations and relate them to previous studies of grain boundaries in ionic materials and in metals.

Mineral replacement: modeling, phenomena, and mechanisms in terms of crystallogenesis

Glikin, A.E.
Dept. of Crystallography, St.Petersburg State University, St.Petersburg, Russia (glikin@ag2460.spb.edu)

Crystallogenesis is the principal basis for interpretations of mineral origin. It introduces fundamental concepts of layer and normal growth mechanisms, faceting, capturing impurities and inclusions, etc. Classical concepts concern crystal formation in unary and binary systems (quantitative and qualitative approaches, respectively). On the contrary, minerals form in a strongly complicated way while natural systems are of a multi-component/multiphase character. The main complication is a chemical reaction between different crystal compounds, which accompanies any crystal formation. The interaction consists of coordinated dissolution and growth processes and causes various forms of mineral replacement.

Modeling of replacement processes was carried out as interaction of a crystal with a foreign aqueous solution using more than 200 systems at room temperature. The systems included couples of soluble salts of either fixed or isomorphic compositions. Special devices enabled the microscopic in-situ observation of morphological and kinetic phenomena. The results were interpreted in terms of crystallogenesis based on traditional and modified concentration phase diagrams.

Metasomatic substitution of crystals occurs itself under isothermal conditions as interrelated synchronous dissolution and growth. The product shape is either inherited from the protocrystal (pseudomorphs) or different from that (automorphs) depending on the kinetic properties of the system. The product pattern (remaining monocrystalline or becoming polycrystalline) and volume effect are determined by the phase equilibria and can be resulted from the concentration phase diagram. A temperature change results in additional growth or dissolution and can cause negative (hollow) products. Joint growth of several phases under a finite supercooling includes an urgent metasomatic stage which effects on the kinetics and causes a profound case of a temporary metastable dissolution of a phase. A mutual influence of the phase compounds on their solubility causes a nonmonotonic effect of supercooling on the growth kinetics including conversion to dissolution. Recrystallization of two-phase aggregates consists in a complex combination of the metasomatic substitution, growth and dissolving of individuals. Temperature oscillations or gradients cause it. Temperature oscillation in salting-in-systems results in a redistribution of matter in a two-phase aggregate of stationary mineral-granulometric composition, and a monomineral aggregate. Recrystallization does not undergo in salting-out-systems. Temperature gradients result in a cavity near the maximum temperature and layered rearrangement of matter around the cavity. Mixed crystal formation is characterized by unordinary phenomena. Monocrystal substitution is accompanied either by inclusion implantation (volume deficit) or inhomogeneous crystal extension (volume excess) with a specific face relief. The substitution is reduced at a supercooling down to halting corresponded to the metastable heterogeneous crystal-solution equilibrium. Spontaneous precipitation results in a multi-modal distribution of crystals in composition. The mechanisms are controlled by the isomorphic miscibility of the substances and interpreted with help of modified concentration diagrams.

The considerations give novel crystallogenetic approaches and adequate mineralogical models.

Acknowledgements: The investigation is supported by RFBR (10-02-01303).

Potassium diffusion in alkali feldspar – an experimental study

Neusser, G.[1*], Norberg, N.[2], Abart, R.[3] & Harlov, D.[2]
[1]Inst. für Geologische Wissenschaften, Freie Universität Berlin, Germany ([*]neusser@zedat.fu-berlin.de)
[2]Helmoltz Zentrum Potsdam, Germany
[3]Dept. For Lithospheric Research, Universität Wien, Vienna, Austria

Cation exchange experiments were conducted using alkali feldspars and KCl rich salt melts. A gem quality sanidine (Or85Ab14Cs1) from the Eifel (Germany) was used as starting material. To obtain defined sample geometries 3 mm long cylinders with a diameter of 2 mm were milled out of a homogeneous feldspar crystal of about 6 cm size. The long axis of the cylinders coincides with the a axis of the feldspar, the cross section contains the b and the c* axis. All experiments were carried out at 850°C and room pressure in sealed quartz glass tubes. To establish a quasi infinite salt reservoir 30 moles salt per one mole of feldspar were used. Three different salt compositions with the molar KCl/NaCl ratios of 0.8, 0.9 and 1 were used for a time series with run durations of 1, 2, 4, 8 and 16 days. Because of the hygroscopic nature of the salt the ion exchange reaction is assumed to take place under anhydrous conditions.

At 850°C the salt mixture is completely molten and reacts with the feldspar cylinders inducing an exchange reaction during which the initial feldspar is progressively transformed and a rim of almost pure sanidine forms. The newly-formed rim is chemically homogeneous and separated from the pristine core by a relatively well defined exchange front. The width of this front and the composition gradients within it seem to be primarily controlled by the salt composition. After reaction with pure KCl the exchange front is less than 10 µm wide, whereas, if salt mixtures with $K_{0.9}Na_{0.1}Cl$ and $K_{0.8}Na_{0.2}Cl$ are used, the front width increases up to more than 20 µm. In contrast, the run duration does not seem to have a significant effect on the sharpness and the shape of the exchange front. Both seem to remain largely unchanged until the feldspar grain is completely exchanged. The propagation of the exchange front into the pristine crystal seems to be linear with $\sqrt{t}$, which indicates a diffusion-controlled mechanism. The reaction is driven by chemical potential gradients between the initial feldspar and the K-rich salt melts. Potassium is favored to enter the monoclinic sanidine structure, which results in an ion exchange of K^+ ions from the salt melt for Na^+ ions from the feldspar lattice. WDX mappings show that tetrahedrally incorporated trace elements such as Fe are not involved in this reaction. They remain homogeneously distributed within the feldspar crystal. Therefore alkali diffusion occurs within an inert tetrahedral framework. The assumed water-free environment in combination with the immobility of trace elements and the lack of secondary porosity indicates a strictly diffusion-controlled mechanism. However, a chemically homogeneous rim combined with a rather sharp reaction front as observed in this study is not characteristic for a simple diffusion setting, where a smooth diffusion profile from the crystal surface towards the interior is expected. Therefore, secondary effects such as elastic strain within the exchange front may also play an important role during the exchange process. During the exchange of larger K ions for Na the molar volume of the feldspar increases up to 0.74%. Since HR-TEM measurements show that the feldspar lattice remains coherent across the reaction front, the change in volume induces elastic strain. This strain-build up seems to have a large effect on the shape of the chemical profile across the reaction front.

Reaction kinetics and akali diffusion during replacement of K-rich alkali feldspars in (Na,K)Cl solutions

Norberg, N.[1*], Neusser, G.[2], Harlov, D.[1] & Abart, R.[3]
[1]Helmoltz Zentrum Potsdam, Germany
([*]nicholas@gfz-potsdam.de)
[2]Inst. Für Geologische Wissenschaften, Freie Universität Berlin, Germany
[3]Dept. For Lithospheric Research, Universität Wien, Vienna, Austria

The kinetics of the feldspar replacement reaction $K_{1-x}Na_xAlSi_3O_8+Na^+/K^+ \rightarrow Na_{1-y}K_yAlSi_3O_8+K^+/Na^+$ were studied experimentally between 500°C and 750°C at 200 MPa. Fragments and cylinders of gem-quality sanidine (Eifel, Germany, Or85Ab14Cs1) and orthoclase (Madagascar, Or95Ab5) were reacted in aqueous (Na,K)Cl solutions with molar Na/K ratios of 1, 0.8 and 0.75 in order to initiate different molar volume changes between initial and product phase. A 20 molar excess of salt was used to provide a quasi-infinite cation reservoir. The dominant replacement process was identified as dissolution-reprecipitation showing all characteristic textural features (e.g. [1]). In the early stages of replacement when the initial reaction interface coincides with the grain surface, the replacement proceeds linearly with time indicating interface-reaction control. After the reaction rim reaches a critical thickness the mechanism changes and the reaction seems to become increasingly transport-controlled. In this regime the rate of replacement depends on the mass flux from the fluid reservoir to the reaction front through already replaced areas. The overall reaction rate as well as the transition from an interface- to transport-controlled mechanism significantly depends on temperature, the difference in molar volume ΔV (causing porosity) and the chemical potential gradients between the initial feldspar and the fluid.

In general fluid-aided replacement reactions produce extremely sharp interfaces, characterized by abrupt chemical and microstructural changes within less than 10 nm. However, at hypersolvus temperatues (750°C) these initially sharp boundaries are blurred by volume diffusion of Na and K across the moving reaction front with time. At lower temperatures as well as during the interface-reaction controlled stage of the replacement at high temperatures, the progress of the fluid-driven reaction front into the parent crystal exceeds the velocity of the Na/K interdiffusion across the interface. Consequently the resulting front is chemically sharp. However, due to the significantly increased diffusivities of Na and K at 750°C, volume diffusion of alkalis becomes dominant after the fluid-assisted replacement becomes transport-controlled and the front propagation decreases relatively to the mobilities of Na and K. For example, in the case of pure NaCl solutions this results in diffusive Na and K distributions with profile widths of >10 µm after 4 days, superimposed on a sharp interface caused by dissolution-reprecipitation.

The position of this interface is represented by an abrupt change in the concentrations of tetrahedrally incorporated Fe and Al indicating a complete breakdown of the initial feldspar framework during dissolution-reprecipitation. This transition remains chemically sharp independent of run duration due to the much lower diffusivities of Fe and Al at these conditions. With regard to structural characteristics of the reaction interface, HR-TEM revealed that despite the complete reorganization of the Si/Al framework it seems that the reaction front is not characterized by a total break in lattice coherency. Hence, molar volume differences of up to 7.6%, although partly compensated by nano-porosity, defects or twinning, induce elastic strain along the interface, which results in reaction-induced fracturing.

Replacement of plagioclase by cordierite in hydrothermal experiments

Hövelmann, J.[1*], Austrheim, H.[1] & Putnis, A.[2]
[1]Physics of Geological Processes, University of Oslo, Norway
([*]j.e.hovelmann@fys.uio.no)
[2]Institut für Mineralogie, University of Münster, Germany

Commonly, Al-rich minerals such as corundum, sillimanite, cordierite and sapphirine are considered indicators for a sedimentary origin of a metamorphic rock. However, the presence of sapphirine and corundum has recently been reported in gabbroic rocks from the Bamble sector, South Norway [1]. The formation of the Al-rich minerals in these rocks is interpreted to be a result of pervasive Mg-metasomatism. Based on this interpretation a metasomatic origin has also been suggested for the orthoamphibole-cordierite schists that occur in the same area.

We have performed hydrothermal experiments (T: 600-700°C, P: 2 kbar) on the interactions between calcic plagioclase ($Na_{0.4}Ca_{0.6}Al_{1.6}Si_{2.4}O_8$) and Mg-rich aqueous solutions in order to investigate the possibility of a metasomatic origin of Al-rich minerals. Back scattered scanning electron microscope images of cross sections of the reacted crystals reveal that the original plagioclase has been partly replaced by cordierite ($Mg_2Al_4Si_5O_{18}$), indicating that Mg from the fluid has been consumed, while Ca and Na from the plagioclase have been released during the reaction. The Al that was released from plagioclase dissolution has been consumed by subsequent cordierite precipitation. The cordierite product forms rims, up to 200 µm thick, around relicts of the original plagioclase commonly occurring as several isolated islands within the "cordierite matrix". Optical microscopy demonstrates that these islands have the same crystallographic orientation indicating that they were originally part of one single crystal. The cordierite is orthorhombic with a high degree of Al,Si ordering ($Q_{od} \approx 0.97$), as indicated by Raman spectroscopy, and shows sector-like twinning with opposite sectors having the same crystallographic orientation. Previously, sector twinning in cordierite has been attributed to the transformation from the hexagonal to the orthorhombic form during annealing [2,3]. However, the sector-like twinning in the cordierite from our experiments possibly formed directly during growth.

Our study may have implications for both the origin of sector twinning in cordierite and the origin of Al-rich minerals in metamorphic rocks. The experimental results confirm that Al-rich minerals may be formed by metasomatic processes and, in particular, also support the hypothesis of a metasomatic origin of the orthoamphibole-cordierite rocks in the Bamble sector.

Growth mechanisms for decompression plagioclase rims around metastable kyanite from high-pressure felsic granulites (Bohemian Massif)

Tajčmanová, L.[1*], Abart, R.[2], Rhede, D.[3] & Wirth, R.[3]
[1]Institute of Geological Sciences, Free University, Berlin, Germany ([*]lucataj@gmail.com)
[2]Dept. of Lithosphere Research, University of Vienna, Austria
[3]Helmholtzzentrum Potsdam, Deutsches GFZ, Potsdam, Germany

We investigate two different textural settings for decompression plagioclase rim growth in high-grade metamorphic rocks. The studied samples are felsic granulites from the Bohemian Massif (Variscan belt of Central Europe) characterized by a Grt-Ky/Sil-Bt-Pl-Kfs-Qtz mineral assemblage. These rocks show well developed plagioclase reaction rims around metastable kyanite grains which are either randomly distributed in the polycrystalline matrix or enclosed within large perthitic K-feldspars. Kyanite is regarded as a relic of an earlier high-pressure metamorphic assemblage, which became metastable during low pressure overprint.

Growth of the plagioclase rims around the metastable kyanite crystals requires transfer of CaO and Na_2O components from the surrounding matrix or host K-feldspar. Through the plagioclase rim, the kyanite grains are successively isolated from the quartz- and K-feldspar-bearing matrix. Mass balance considerations show that only a small amount of kyanite was consumed to provide the Al_2O_3–component for the growing plagioclase. In majority, Al_2O_3 and SiO_2 were supplied together with CaO and Na_2O from the surrounding matrix material. Plagioclase rims from both microstructural settings show continuous changes in composition from An_{25} at the contact to kyanite to An_{19} at the contact to the K-feldspar or to the matrix. Plagioclase rims developed around kyanite inclusions within large K-feldspar blasts have a radial thickness of up to 50 µm. In contrast, the radial thickness of plagioclase rims around kyanites in the polycrystalline matrix is significantly larger, up to 200 µm. Another peculiarity for both microstructures is the crystallographic character. The plagioclase rims around kyanite in the matrix are polycrystalline, whereas the plagioclase rims around kyanite inclusions in perthitic hosts are single crystals of plagioclase. This difference has a profound effect on mass transfer across the growing plagioclase rim and explains the systematic difference in rim thickness for the two microstructural settings. Assuming that the cation availability in the source (either host alkali feldspar or rock matrix) was the same in both settings, it is hypothesized that the comparatively large thickness of the plagioclase rims grown around kyanite in the matrix is due to the contemporaneous operation of grain-boundary and volume diffusion. On the other hand, in the large K-feldspar grain only volume diffusion was efficient, which only allowed for comparatively slow volume diffusion across the plagioclase rims.

Electron beam microanalytical techniques combined with high spatial resolution (FEG-EMS, FEG-SEM, TEM) and FIB sample preparation technique were used to directly observe the traces of intergranular diffusion both, within the alkali feldspar or matrix and across the plagioclase rims. Using these techniques and comparing single crystal and polycrystal reaction rim growth from the two different microstructural settings, the relative contributions of volume and grain boundary diffusion are assessed in a semi-quantitative manner. This offers new insights into the kinetic processes, which controlled the microstructural and chemical evolution during the decompression of felsic high grade rocks.

How reliable are microstructural criteria defining a “metamorphic event”?

Putnis, A.[1*] & Austrheim, H.[2]
[1]Institut für Mineralogie, University of Münster, Germany ([*]putnis@uni-muenster.de)
[2]Physics of Geological Processes, University of Oslo, Norway

A metamorphic event is defined in terms of a sequence of metamorphic reactions in P,T space. However, the distinction between reactions driven by changes in P,T and those driven by compositional changes due to infiltration of fluid (i.e. metasomatic reactions) is not always clear [1]. Metamorphism and metasomatism both involve material transport but on different length scales, so every metamorphic reaction is metasomatic on a local scale. Fluids provide a transport mechanism which is orders of magnitude faster than solid state diffusion and induce reequilibration through dissolution of parent phases and reprecipitation of products. Albitisation is used as an example to describe the coupling between dissolution and precipitation. Albitisation of feldspars in nature and in experiments is a pseudomorphic replacement which generates porosity in the albite [2,3]. Porosity generation associated with interface-coupled dissolution-precipitation allows rapid material transport and together with fluid induced fracturing, is the mechanism of pervasive fluid flow through reacting crystals.

Examples of metamorphic reactions in granulite-eclogite rocks illustrate the role of fluids in inducing chemical changes along fluid pathways. Microstructural criteria for a metamorphic event are critically reviewed by describing the corona formed by reaction between kyanite and garnet, as well as partial replacement textures. We conclude that both corona structures and partial replacement textures are as indicative of a metasomatic reaction as they may be of a metamorphic reaction. This raises the question of the extent to which fluids play not only a catalytic role, but also a thermodynamic role in determining the course of a metamorphic reaction [4].

Kelyphite and symplectite after garnet: the microstructure, formation processes and reaction kinetics

Obata, M.[1*], Ozawa, K.[2] & Spengler, D.[3]
[1]Dept. of Geology and Mineralogy, Graduate School of Science, Kyoto University, Kyoto, Japan ([*]obata@kueps.kyoto-u.ac.jp)
[2]Dept. of Earth and Planetary Sciences, Graduate School of Science, University of Tokyo, Japan
[3]Geodynamics Research Center, Ehime University, Ehime, Japan

Kelyphite is a fine grained, fibrous and radially-oriented mineral assembly typically surrounding garnet. Texturally it appears to represent a replacement of garnet, although not isochemical to garnet, suggesting that the replacement reaction is a chemically open-system phenomenon involving material transfer across the reaction zone. We made a comparative study of kelyphites developed in mantle-derived garnet peridotites from various localities (including Czech Moldanubian, western Norway), using optical microscopy, electron probe microanalyzer and EBSD analysis for consideration of the reaction mechanism.

In garnet peridotites, fine-grained kelyphite (Opx+Cpx+Sp with or without accessory Amp) is typically surrounded by a thin (ca. a few hundreds of micron) rim of coarse Opx, which separates the kelyphite from the matrix olivine. Optical microscopy shows that kelyphite consists of several domains of Opx. EBSD studies show that each domain represents a single crystal of Opx, which includes small patches of Cpx, and both pyroxenes contain thin (sub-micron size) lamellae of spinel, forming a spinel-pyroxene symplectite. Each kelyphite domain has an internal coherent structure of lineation defined by the spinel lamellae. The kelyphite Opx is optically and crystallographically continuous to the adjacent coarse rim-Opx, forming a larger domain of a single crystal. We refer to this domain covering the fine-grained kelyphite and the adjacent Opx rim as a 'cell' and consider it as a growth unit. EBSD analyses revealed that each domain (cell) has a topotaxic relationship between Opx and Cpx by sharing (100) and (010) and [001]. Two kinds of cells are recognized according to the topotaxic relationships between spinel and pyroxene: (1) topotaxic cell, in which one of spinel {111} coincides with pyroxene (100) and one of spinel {110} coincides with pyroxene (010); (2) non-topotaxic cell, in which topotaxic relationships between spinel and pyroxene are incomplete or absent. The topotaxic relationship may be understood in terms of the oxygen close-packed structure of crystals. It appears that kelyphite that formed at relatively high-temperatures (e.g. Czech Mohelno garnet peridotite [1]) contains topotaxic cells whereas kelphite of lower-temperature origin, such as western Norway, dominantly consists of non-topotaxic cells. The spinel-pyroxene symplectite from the Horoman spinel peridotite is regarded to represent a topotaxic cell that was formed after garnet at highest temperatures (>1000 degree C) [2]. From these observations we hypothesize that a topotaxic relationship may form when spinel nucleates at the initial stage of kelyphitization and the initial crystallographic relationship may be inherited during subsequent growth of the cell in the kelyphite. At relatively low temperatures, such topotaxic relationships may fail to form probably because of the large degree of supersaturation of the reaction.

Textural development and fluid flow during mineral vein formation

Okamoto, A.[*], Saishu, H. & Tsuchiya, N.
Graduate School of Environmental Studies, Tohoku University, Sendai, Japan ([*]okamoto@mail.kankyo.tohoku.ac.jp)

Ubiquitous occurrences of quartz veins indicate that precipitation of silica minerals is of special importance for spatial and temporal variations of rock permeability and rock strength at shallower crustal levels. However, the physico-chemical conditions during quartz vein formation (fluid compositions, flow rate, fracture geometry etc.) have been poorly constrained. In this study, we conducted hydrothermal flow-through experiments at 430°C and 31 MPa on silica precipitation to understand the controlling factor for textural development of quartz veins. Then, implications to the formation of natural veins are discussed.

In the reaction vessel (internal diameter = 10.8 mm, length = 550 mm), eighteen granite blocks (6.5x6.5x30 mm) are placed along the flow path. Two types of Si- saturated solutions were used: a pure Si solution created by dissolution of quartz sand and a multi-component solution created by dissolution of garniate sand. We found that the mineralogy and textures of silica precipitates systematically changes depending on the degree of supersaturation ($\Omega = C_{Si}/C_{Si,eq,Qtz}$), presence of additive ions (Al, Na, K with several ppm) in the solution and substrate type. In the case of the low degree of supersaturation ($\Omega < 1.5$), silica precipitation occurred only as overgrowth on the substrate quartz. On the other hand, the precipitation mechanism from solutions with higher Si content ($\Omega > 1.5$) was more complex due to nucleation. From the pure Si solutions, amorphous silica and/or opal-C predominantly formed and partly translated into quartz. From the impure solutions with additive ions, quartz nucleated directly from the solutions. Our experimental results suggest that vein textures are good indicators of Si concentration during vein formation.

The textures observed in the hydrothermal experiments are comparable to those of the natural quartz veins that (1) epitaxial growth from quartz grains within the wall rocks (elongate-blocky, fibrous textures), and (2) filling of equant grains (blocky textures) [1,2]. The mineral veins hosted in the pelitic schists in the Sanbagawa metamorphic belt, Japan, are divided into two types [1]: Qtz-Ab-Kfs-Chl veins are characterized by quartz and albite crystals grown from the wall and bridge to the opposite side (stretched crystal textures), and show the mineral distribution depending on the compositional banding of the host rocks. Qtz-Ab-Cal veins are filled by double-terminated euhedral quartz and albite crystals (blocky texture), and mineral distribution is homogeneous along the vein length. Both veins formed at the same stage of the exhumation of the Sanbagawa belt (200-400˚C, 0.2-0.4 GPa), but show contrasting vein width; the former is much thinner than the latter. These observations suggest that the materials were transported by molecular diffusion from the adjacent host rock for the stretched crystal veins, whereas by advective fluid flow from distant sites for the blocky veins. Okamoto & Tscuhiya [2] suggest that high flow ascent rate (0.01-0.1 m/s) is required for the formation of the blocky veins, based on the analyses of crystal size distributions and crystal settling theory. Such a high fluid flow rate realized the high degree of supersaturation that enabled the nucleation of quartz in fluids as observed in the experiments. In contrast, in the case of stretched crystal veins, fluid was static, the rate limiting process was diffusion, and thus epitaxial growth preferentially occurred in solutions with a low degree of supersaturation.

Retention of colloids at rough limestone surfaces

Fischer, C.[1,3*], Darbha, G.K.[1], Michler, A.[1], Schäfer, T.[2] & Lüttge, A.[3]
[1]Georg-August University, Göttingen, Germany
([*]cornelius@rice.edu)
[2]INE, KIT, Karlsruhe, Germany
[3]Rice University, Houston, TX, USA

Colloid-aided mobilization and immobilization of contaminants is an important environmental process. Deposition of colloids on mineral and rock surfaces is predominantly caused by attractive electrostatic forces. However, close to the point of zero charge (PZC) of minerals or mineral aggregates as well as during conditions of electrostatic repulsion, the importance of surface roughness for deposition of colloids is increased. According to a previous study [1], at PZC of calcite, a positive correlation between the number of adsorbed particles and the surface roughness of the crystal surface with etch pits was found. The range of root mean square roughness *Rq* was about 10 to 40 nm, particle size was 499 nm and 903 nm.

Here we expand the investigation of particle adsorption at rough calcite surfaces to fine-grained, micritic limestone. Grain-size of the dense limestone investigated here is 5-10 µm according to thin-section analysis. Polished limestone samples were etched at pH = 4.7 for 60', 120', 180', and 240' in a fluid cell to obtain a rough surface similar to those in nature. For reaction periods > 60' the limestone surface areas show a constant maximum root mean square roughness (*Rq* ~ 400 nm). Surface topography was characterized and quantified using vertical scanning interferometry (VSI). The resulting three-dimensional data sets were used for roughness parameter calculation [2].

Particle adsorption experiments were carried out using negatively charged polystyrene latex colloids (d = 1 µm). Deposition experiments were conducted at PZC of calcite. First results based on VSI data show a pattern of high-density particle adsorption sections at the micrite surface. Such sections have a diameter of about 20 µm. The density of adsorbed particles of such sections is approx. 20 times higher compared to adjacent surface sections. First results also indicate that enhanced particle adsorption occurred preferentially at surface sections where *Rq* is relatively low (*Rq* ~ 200 nm).

In the environment, e.g., in karstic regions, adsorption of clay minerals as well as iron and manganese oxides at limestone surfaces modifies fundamentally the original fluid-rock interface. As a consequence, dissolution as well as adsorption kinetics are altered. With the results of our experimental approach we try to provide quantitative constraints to predict the evolution of fluid-rock interfaces due to particle adsorption.

The influence of mineral replacement reactions on rock deformation and shear zone development

Brouwer, J.* & Putnis, A.
Institut für Mineralogie, University of Münster, Germany
(*J.Brouwer@uni-muenster.de)

Natural shear zones show that reaction and deformation are often spatially interrelated. Study of these reactions shows that often fluids are involved (e.g. [1]). Fluid–assisted mineral replacement is generally not isovolumetric [2] and may therefore lead to an increase in permeability through the formation of pores or cracks. Subsequent fluid infiltration can lead to further progress of the replacement process and reaction weakening of the rock.

When the rock is stressed, the combination of physical and chemical driving forces may trigger simultaneous reaction and deformation, where the rates of both processes may be significantly higher than if they would be operating separately. The combination of localized, reaction-induced permeability leading to further fluid-infiltration may thus lead to a localization of deformation. This is possibly a key issue in shear-zone development.

We have performed compaction experiments using a set-up as described by [3] that show the effects of volume change during deformation and how mineral reaction influences pressure solution rates and vice versa. Using chemical systems with a limited number of reactants and products, they form a starting point in our understanding of the complex interplay between reaction and deformation in natural rocks.

Symplectite formation during decompression induced garnet breakdown in lower crustal mafic granulite xenoliths: mechanisms and rates

Dégi, J.[1,2*], Abart, R.[3], Török, K.[4], Bali, E.[5], Wirth, R.[6] & Rhede, D.[6]
[1]Research Institute for Solid State Physics and Optics, Budapest, Hungary (*julia.degi@gmail.com)
[2]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary
[3]Dept. of Lithospheric Research, University of Vienna, Austria
[4]Eötvös Loránd Geophysical Institute of Hungary, Budapest, Hungary
[5]Bayerisches Geoinstitut, University of Bayreuth, Germany
[6]GFZ German Research Centre for Geosciences, Helmholtz Centre Potsdam, Germany

The complex microstructure of kelyphitic rims around garnet in lower crustal garnet granulite xenoliths from the Bakony–Balaton Highland Volcanic Field, Central Pannonian Basin has been studied in order to identify controls on garnet breakdown. Symplectites comprised of a vermicular intergrowth of submicron sized anorthite, orthopyroxene and spinel replace garnet at a sharp reaction front. Based on element distribution maps the transformation of garnet to symplectite is isochemical. Phase diagram calculations indicate this reaction was induced by a pressure decrease and/or a temperature increase.

In site-specific TEM foils prepared by FIB technique and oriented parallel and perpendicular to the reaction front 200 nm wide rods of anorthite and 20 nm wide rods of spinel are identified. The rods are oriented approximately perpendicular to the replacement front and are embedded in an orthopyroxene matrix. The regular spacing of the symplectite phases along the reaction front suggests that their growth is controlled by diffusion. The kinetics of symplectite formation has been modelled based on irreversible thermodynamics.

During interaction of the xenolith with the host basalt the microstructure and chemistry of the An–Opx–Spl symplectite was significantly modified and it was partially replaced by an olivine bearing symplectite. In contrast to primary symplectite formation, these processes were metasomatic in nature including addition of sodium, titanium and some trace elements from the basaltic melt and can clearly be discerned from the garnet breakdown. Based on these observations it is inferred that symplectite formation took place within the deep crust during the extension of the Pannonian Basin between 15–30 km depth at high temperature (850–1050°C) prior to the volcanic transport to the surface.

Unidirectional solidification texture (UST) and garnet layering textures from the Y-enriched garnet-bearing aplite-pegmatites, western part of the Cadomian Brno Batholith, Czech Republic

Hönig, S., Leichmann, J.* & Novák, M.
Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic (*leichman@sci.muni.cz)

Felsic layered garnet-bearing aplite-pegmatite dykes of the Hlína granitic suite, ~2 to 50 m thick and up to ~200 m long with general NW–SE orientation and dip 40-80° into ESE or WSW, cut granodiorites to granites at the SW part of the Brno Batholith, Brunovistulicum. Aplite-pegmatite bodies are characterized by alternation of two main textural units: (i) a fine-grained aplite unit and (ii) a coarse-grained pegmatite with comb-like UST unit both developed in zones with the thickness varying from several cm to ~ 1-2 m for the aplite unit, and ~ 10 cm for the UST unit. In this paper, we use the term "UST" (unidirectional solidification texture) which describes rock layer composed of crystals oriented perpendicularly to the plain of layering.

All rock types are characterized by high contents of SiO_2 (74.6 – 75.7 wt. %), K_2O (4.61 – 4.94 wt.%), Na_2O (3.82 – 4.21 wt.%), moderate concentrations of CaO (0.94 – 1.11 wt. %), and low to very low concentrations of Fe_2O_3 (0.62 – 0.93 wt.%), MgO (0.02 – 0.03 wt. %), and TiO_2 (≤ 0.03 wt. %). Low K/Rb (212–241), high K/Ba ratios (1034 – 2303) and deep Eu anomalies indicate a high degree of fractionation. Both textural units consist of perthitic microcline, plagioclase An_{15-8} and quartz. The total amount of accessory minerals is typically very low, commonly < ~ 1 vol.% in the aplite unit, in the UST unit they are almost absent. Accessory minerals include relatively common Y-rich garnet Sps_{42-38} Alm_{32-28} And_{15-7} Grs_{21-15} Prp_{2-1} (1.10 wt.% Y_2O_3 - 0.06 apfu, 0.53 wt.% Yb_2O_3 and 0.20 wt.% Er_2O_3) with oscillatory and sector zoning. Other minerals commonly closely associated with garnet are extremely rare: magnetite, chloritized biotite, muscovite, Ta-rich titanite I, Al,F-rich titanite II, and ilmenite. Primary zircon, xenotime-(Y), monazite-(Nd), fersmite, ferrocolumbite, REE,Y-rich pyrochlore are strongly altered. Geochemical and mineralogical features of the Hlína aplite-pegmatites characterized by (i) metaluminous to slightly peraluminous A-type (NYF) affinity indicated by elevated concentration of Y, REE (especially HREE), Zr, U, Th, (ii) specific accessory minerals including Y-rich garnet, Nb>>Ta, HREE>>LREE, (iii) almost entire absence of micas and other minerals with volatiles (B, F, P and also H_2O) are remarkable. They differ from all other granitic rocks with UST textures described to date typically characterized by high activity of volatiles and peraluminous signature. Magmatic layering of garnet is explained by the formation of a boundary chemical front bordered margin of the coarse-grained UST unit.

Modelling of nonlinear inter-granular diffusion under local equilibrium with a mineral: an example in the system muscovite – quartz – H_2O

Nishiyama, T.
Dept. of Earth & Environmental Sciences, Kumamoto University, Kunamoto, Japan (tadao@sci.kumamoto-u.ac.jp)

Diffusion through an inter-granular fluid plays an important role in texture formation of the metamorphic rocks such as reaction zones and metamorphic layering. The nature of the diffusion is, however, not well understood. This paper will discuss the situation such that a fluid species diffuses down its chemical potential gradient under the constraint of local equilibrium with a co-existing mineral. The constraint will cause a coupling of diffusive fluxes, which is described by nonlinear diffusion equations. The aim of this paper is to evaluate the effect of the coupling which possibly contributes to the texture formation in metamorphic rocks.

Suppose a metamorphic rock in the system muscovite – quartz – H_2O, which consists of a muscovite – rich layer and a quartz – rich layer. At an initial pressure - temperature condition, the system is in an equilibrium, namely, muscovite, quartz and H_2O (an inter-granular fluid) are in equilibrium with each other in both layers. The system will destabilize according to a pressure – temperature change. If temperature is raised, the solubility of minerals increases. The muscovite – rich layer will reach the muscovite saturation condition before arriving at the new quartz – muscovite equilibrium condition, because the amount of dissolved species is proportional to the total surface area of the mineral and hence the concentration of dissolved Al species is higher than that at the new quartz – muscovite equilibrium condition. Similarly, the quartz – rich layer reaches the quartz saturation condition before arriving at the new quartz – muscovite equilibrium condition. Then spontaneous diffusion will take place between the two layers. The diffusion is assumed to occur under local equilibrium with muscovite. The local equilibrium condition with quartz is not introduced, because it does not drive diffusion of Si species. We will discuss only diffusion of Al and Si species, assuming that diffusion of K is much faster than that. The model nonlinear diffusion equations become coupled PDEs. By Boltzmann transformation, the coupled PDEs are transformed into coupled ODEs. Perturbation expansion decomposes the coupled ODEs into uncoupled ODEs. Finally the uncoupled ODEs are solved numerically with MATLAB. Essential features of the nonlinear diffusion can be summarized as the following. (1) The coupling of diffusive fluxes causes advection in Al concentration profiles. (2) The case of smaller D_{SiSi}/D_{AlAl} shows larger advection effects in Al. (3) The coupling causes suppression in Si concentration profiles. (4) The case of smaller D_{SiSi}/D_{AlAl} shows uphill diffusion of Si in a muscovite – rich layer. This study is a first step to clarify the effect of nonlinear diffusion on the development of texture in metamorphic rocks.

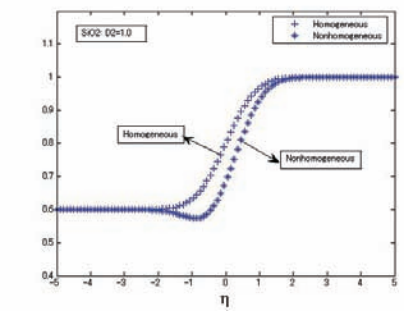

Fig. 1: Comparison of Si profiles between normal and nonlinear diffusion. Nonlinear diffusion shows uphill diffusion near the boundary.

New calorimetric data on feldspars: implications for modelling the ternary mixing behaviour

Benisek, A.[1*], Dachs, E.[1] & Kroll, H.[2]
[1]Materialforschung und Physik, Universität Salzburg, Austria
([*]artur.benisek@sbg.ac.at)
[2]Institut für Mineralogie, Universität Münster, Germany

New calorimetric work [1-3] on feldspars in the $NaAlSi_3O_8$-$KAlSi_3O_8$-$CaAl_2Si_2O_8$ system enabled the formulation of a mixing model, which is based exclusively on calorimetric and volumetric data [4]. When compared to models based on phase equilibrium experiments distinct differences are revealed. The calorimetry based model shows less solubility for both K in Ca-rich plagioclase and Ca in K-rich alkali feldspar. On the other hand, the stability field of Na-rich feldspars is broadened.

The two approaches are tested on natural feldspar assemblages from different rocks. One of these rocks is the Klokken syenogabbro, South Greenland, which was thoroughly investigated by Parsons and Brown [5]. The rock contains two perthites whose bulk compositions should lie on the ~970°C/1kbar isotherm derived from melting experiments and petrologic reasoning [5]. The figure below compares this isotherm calculated from different mixing models. The calorimetry based model far better agrees with the petrologic expectation than do the phase equilibrium based models.

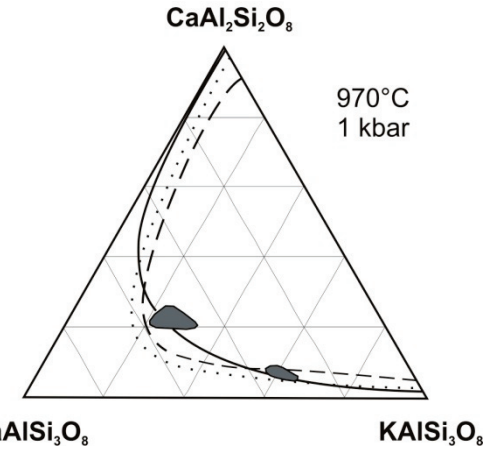

Fig. 1: Compositions of the feldspars from the Klokken syenogabbro, South Greenland [5]. The 970°C/1kbar isotherm of this study (*solid line*) is compared to those resulting from phase equilibrium experiments [6] - *dashed line*; [7] - *dotted line*.

Garnet is an important rock-forming mineral and a detrmination of its thermodynamic properties is imperative in order to undertake various Earth science investigations [1]. Many thermodynamic studies on aluminosilicate garnet have been made. However, there are still gaps of knowledge concerning the various thermodynamic functions for even the garnet end-members. This is the case for spessartine.

The heat capacity of two different synthetic spessartine samples was measured on 20-30 mg-size samples in the temperature range 2 to 864 K by heat-pulse calorimetry (HPC) and differential scanning calorimetry (DSC). Samples were synthesized in two different laboratories and characterized by X-ray powder diffraction and electron-microprobe analysis. The heat capacity data show a prominent lambda transition with a peak at 6.2 K, which is interpreted to be the result of a paramagnetic-antiferromagnetic phase transition. The calorimetric standard entropy for the two samples is S^o = 334.6 ± 2.7 J/mol/K and 336.0 ± 2.7 J/mol·K. The preferred standard third-law entropy for spessartine is S^o = 335.3 ± 3.8 J/mol/K. The DSC data around ambient T agree well with the HPC data and can be represented by the C_p polynomial at T > 250 K as:
C_p(J/mole/K) = 610 - 3060 $\cdot T^{-0.5}$ -1.45 $\cdot 10^7 \cdot T^{-2}$ + 1.82 $\cdot 10^9 \cdot T^{-3}$.

The vibrational heat capacity was analyzed giving $S_{vib}^{298.15}$ = 297.7 J/mol/K at 298.15 K. The magnetic heat capacity and entropy of spessartine, S_{mag}, were also calculated. S_{mag} is 38.0 J/mol/K, which is 85% of the maximum possible magnetic entropy given by the Boltzmann relation (i.e. 3Rln6 = 44.7 J/mol/K).

Published model-dependent lattice-dynamic calculations of $S_{vib}^{298.15\ K}$ are analyzed and compared to the experimental data. An analysis shows that there is no need to include a S^{conf} term to give the third-law entropy of spessartine. The large entropy value for aluminosilicate garnets is related to the large amplitude, low-frequency vibrational behavior of the E-site cation.

Using these new calorimetric data, together with high P-T experimental phase equlibrium data on Mn-Mg partitioning between garnet and olivine, allows calculation of the standard enthalpy of formation of spessartine. This gives $\Delta H^o_{f,Sps}$ = -5693.6 ± 1.4 kJ/mol, a value that is nearly 50 kJ more negative than published estimates. The Gibbs free energy of spessartine was also calculated as $\Delta G^o_{f,Sps}$ = -5364.3 kJ/mol at 298.15 K.

Internally consistent thermodynamic data for divalent sulfate hydrates

Grevel, K.-D.[1,2*] & Majzlan, J.[1]
[1]Institute of Geosciences, Friedrich-Schiller University, Jena, Germany
[2]Institute for Geology, Mineralogy and Geophysics, Ruhr-University, Bochum, Germany ([*]Klaus-Dieter.Grevel@rub.de)

Divalent metal sulfate hydrates (general formula $M^{2+}SO_4 \cdot nH_2O$) are a diverse group of minerals and are characteristic for the surface environments of the Earth. They play an important role in the storage and transport of metals released upon weathering of metallic ore deposits or mine wastes. [1] In numerous reversal experiments, it was shown that they will change their hydration state in response to the local temperature and humidity conditions. Commonly, *n* decreases as the relative humidity is decreased or temperature is increased [2-7].

Quite often, the results of these experiments are in poor agreement with calculations based on thermodynamic properties of the respective substances taken from the literature. Here, using mathematical programming (MAP) techniques [cf. 8], standard thermodynamic values consistent both with calorimetric data taken from the literature and reversal experiments could be derived (Table 1).

Table 1: Thermodynamic properties of selected sulfate hydrates

Phase	Formula	$\Delta_f H^0_{298}$ [kJmol^{-1}]	S^0_{298} [JK^{-1}mol^{-1}]
Rozenite	$FeSO_4 \cdot 4H_2O$	–2128.89	281.52
Melanterite	$FeSO_4 \cdot 7H_2O$	–3014.39	409.29
Bianchite	$ZnSO_4 \cdot 6H_2O$	–2777.42	363.41
Goslarite	$ZnSO_4 \cdot 7H_2O$	–3077.54	388.87
Retgersite	$NiSO_4 \cdot 6H_2O$	–2683.10	334.40
Morenosite	$NiSO_4 \cdot 7H_2O$	–2976.77	378.99
Moorhouseite	$CoSO_4 \cdot 6H_2O$	–2683.43	367.31
Bieberite	$CoSO_4 \cdot 7H_2O$	–2979.32	406.36
Bonattite	$CuSO_4 \cdot 3H_2O$	–1684.53	221.40
Chalcanthite	$CuSO_4 \cdot 5H_2O$	–2279.54	301.20

Enthalpies and entropies of mixing in alkali-bearing aluminosilicate mineral and glass solutions

Hovis, G.L.
Dept. of Geology and Environmental Geosciences, Lafayette College, Easton, PA, USA (hovisguy@lafayette.edu)

Over the years this laboratory has investigated the thermodynamic mixing properties of numerous solid-solution series. Enthalpies of solution have been measured at 50°C in 20.1 wt% HF under isoperibolic conditions for four alkali feldspar series having different Al-Si ordering states [1], three nepheline-kalsilite series having various Al:Si ratios [2-4], Rb- and Cs-leucite-analcime analogue series [5], multiple hydrated alkali aluminosilicate glasses [6,7], anhydrous Qz-Or-Ab glasses [8], and sodium silicate glasses [9]. In systems that show substantial thermodynamic nonideality, e.g., feldspars and feldspathoids, enthalpies of mixing can be correlated well with immiscibility [4,10,11] that is reflected by experimentally determined solvi (e.g., the nepheline-kalsilite system shown above [4]) as well as exsolution in natural samples. It becomes clear, however, that the overall Gibbs free energies of mixing cannot be explained solely by the non-ideal behaviour of enthalpy [4,12]. Nor does consideration of configurational entropy completely account for the differences. This leaves excess vibrational entropies to account for the connection between the enthalpy data and the Gibbs free energies of mixing. Such entropies, based on low-temperature heat-capacity measurements for multiple samples across solid-solution series, are available for relatively few systems (e.g., [12-15]). It is important that such data be collected, not only to fully characterize and understand thermodynamic mixing behaviour in mineral and glass systems, but also so that phase equilibria can be calculated for intermediate members of solid-solution series.

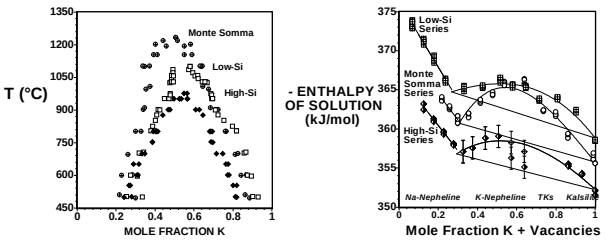

Fig. 1: (left): Directly-determined nepheline-kalsilite solvi, based on reversed phase equilibria, for solutions with various Al:Si ratios [4]. (right): Negative enthalpies of solution for the same three nepheline-kalsilite series shown on the left [4].

[3]MSD, Lawrence Berkeley National Laboratory, Berkeley, CA, USA
[4]Dept. of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada
[5]Dept. of Chemistry and Biochemistry, Brigham Young University, Provo, USA

Jarosite phases are common minerals in acidic, sulfate-rich environments. In addition to being the flagship minerals in acid mine drainage, they are notable for their unusual magnetic properties, namely frustrated magnetism and spin-glass character of some of them. We studied samples close to the nominal composition $A Fe_3(SO_4)_2(OH)_6$, where A = K, Na, Rb, and NH_4. One of the samples has a significant number of defects on the Fe sites and is called the defect jarosite; others are referred to as A-jarosite. The measured heat capacities (C_p) of the jarosite phases were fitted with a set of appropriate polynomials and the integration of C_p/T from 0 to 298.15 K gave the entropies (all values in $J \cdot mol^{-1} \cdot K^{-1}$) of K-jarosite of 427.4, Na-jarosite 436.4, Rb-jarosite 411.9, NH_4-jarosite 447.2, and defect jarosite 412.7. There are additional configurational entropies of 13.14 and 8.23 $J \cdot mol^{-1} \cdot K^{-1}$ in defect and NH_4-jarosite, respectively. A detailed analysis of the synchrotron X-ray diffraction patterns showed a large anisotropic peak broadening for defect and NH_4-jarosite. The fits to the low-temperature (< ~12 K) C_p data showed that our samples can be divided into two groups. The first group is populated by the K-, Na-, Rb-, and NH_4-jarosite samples, antiferromagnetic at low temperatures. The second group contains the H_3O-jarosite (studied previously) and the defect jarosite. H_3O- and defect jarosite are spin glasses and their low-T C_p was fit with the expression $C_p = \gamma T + \Sigma B_j T^j$, where j = (3,5,7,9). The linear term is typical for spin glasses and the sum represents the lattice contribution to C_p. Surprisingly, the C_p of the K-, Na-, Rb-, and NH_4-jarosite samples, which are usually considered to be antiferromagnetic at low temperatures, also contains a large linear term. This finding suggests that even these phases do not order completely but have a partial spin-glass character below their Néel transition temperature.

Lattice dynamics and theoretical spectroscopy at high pressure

Caracas, R.
CNRS, ENS de Lyon, Laboratoire de Sciences de la Terre, Lyon, France (razvan.caracas@ens-lyon.fr)

We present some of the latest applications of the density-functional perturbation theory in the characterization of solids under extreme thermodynamic conditions. We determine stability fields and compute thermodynamic properties of different structures, we build phase diagrams and we compute elastic constants tensors and accurate Raman spectra (with both peak position and intensity) of various solids under pressure.

We find that the analysis of the phonons can reveal even fine effects associated to weak structural distortions, like in the case of the pressure-induced spin transitions in Fe-bearing $MgSiO_3$ perovskite. These compounds are major constituents of the Earth lower mantle and thus benefit of a special attention from the geoscientific community. Lattice dynamical analysis shows that unstable phonon modes develop for structures with low-spin configurations. The atomic displacements associated to these phonons break the local symmetry and induce high-spin to low-spin transitions. The phase transition sequence can then be deciphered from the accurate analysis of the phonon instabilities.

At least as spectacular, we show that the stability field of ice X, the high-pressure ionic form of water ice is delimited by a disordered structure below 114GPa and by an orthorhombic pseudo-hexagonal structure beyond 430GPa. Both transitions are obtained and explained based on the analysis of the unstable phonon modes. An alternative phase to ice VIII can be deduced and analyzed from lattice dynamics. The transition regimes and our new structures give excellent explanations to previously unexplained experimental and computational results.

We determine Raman spectra of materials under pressure as a diagnosis tool. The Raman spectra depend on the frequency of the incident laser, on the temperature, on the active-mode frequency (which comes straightforward from calculations) and on the Raman tensor. This latter factor is obtained today from the derivative of the dielectric tensor with respect to the atomic displacements that correspond to the vibrational pattern of the mode. Formerly, these derivatives were computed from finite differences. The calculations of the Raman spectra are very encouraging, given the extreme requirements for convergence and accuracy of dielectric properties, usually hard to obtain. The agreement to experiment is excellent for both peak position and intensity.

A new dense phase of silica initiating silicates breakdown in giant terrestrial planets

Tsuchiya, T.[1*], Tsuchiya, J.[2], Metsue, A.[1] & Ishikawa, T.[1]
[1]Geodynamics Research Center, Ehime University, Matsuyama Ehime, Japan ([*]takut@sci.ehime-u.ac.jp)
[2]Senior Research Fellow Center, Ehime University, Matsuyama Ehime, Japan

Silica (SiO_2) is one of the most common, most fundamental and also most important materials from several research fields of solid-state physics and chemistry, materials science and geoscience. It has been known that silica shows a sequential phase evolution from quartz, coesite, stishovite, $CaCl_2$, α-PbO_2 and pyrite (modified fluorite) with elevating pressure [1-3]. However, further denser phases are still underdetermined, although studies on some low-pressure analogs such as ZrO_2 and HfO_2 [4], TiO_2 [5], MgF_2 [6] and most recently SnO_2 [7] have suggested an orthorhombic cotunnite phase as the final high-pressure phase.

In order to elucidate the post-pyrite phase of silica, we performed structure search based on the *ab initio* density functional computation method. After examining several dense structure types with AX_2 compound, we successfully discovered a new phase transformation of pyrite type SiO_2 at multi-megabar condition to an unexpected phase (New-HP), which possesses quite high nine-fold coordinated Si and eclipses the cotunnite stability field in the entire pressure range up to 1500 GPa (Fig. 1). We subsequently investigated high-pressure stabilities of some important silicate compounds ($MgSiO_3$ and $CaSiO_3$) and found that the new phase change in silica could initiate breakdown of these silicates to oxide mixtures in the conditions relevant to the interior of super-Earths and exoplanets, which would lead to various complexities in their internal structures. High-*P*,*T* phase boundaries, changes in density, elasticity and also electronic property associated with the new phase transitions, which are the most fundamental information to understand the structure and dynamics of giant terrestrial planets, will be presented.

Fe^{3+} incorporation in Mg-rich garnet

Woodland, A.B.
Institut für Geowissenschaften, Universität Frankfurt, Germany
(woodland@em.uni-frankfurt.de)

Equilibria involving Fe^{3+}-bearing components in garnet can be used to estimate the prevailing oxygen fugacity within the garnet peridotite facies of the Earth's mantle (e.g. [1,2]). Since mantle garnets are generally pyrope-rich, it is important to understand how Fe^{3+} substitution occurs in Mg-bearing garnets. To this end, the joins $Mg_3Al_2Si_3O_{12}$–$Ca_3Fe_2Si_3O_{12}$ (pyrope-andradite) and $Mg_3Al_2Si_3O_{12}$–$Fe_3Fe_2Si_3O_{12}$ (pyrope -"skiagite") have been investigated experimentally and by EMPA, XRD and Mössbauer spectroscopy.

Synthesis of pyrope-andradite garnets was unsuccessful, even at 6 GPa. Partial reduction of Fe^{3+} to Fe^{2+} occurred even in the presence of PtO_2 as an O_2 source. A significant $Ca_3Al_2Si_3O_{12}$ component was also found by EMPA. The additional presence of Fe^{3+}-rich spinel or Fe_2O_3–Al_2O_3 solid solutions indicates Fe^{3+}-saturation in the garnets, with maximum Fe^{3+} contents increasing with increasing Ca. A significant miscibility gap must exist between pyrope and andradite at least up to 6 GPa.

Pyrope-"skiagite" synthesis at 9 GPa was more successful, although minor reduction produced an additional $Fe_3Al_2Si_3O_{12}$ component. Unit-cell parameters calculated assuming ideal mixing in ternary garnets are smaller than those measured.

Hyperfine parameters from Mössbauer spectra reveal: 1) the electronic environment of 8-fold Fe^{2+} is similar in all solid solutions involving "skiagite" or almandine components, 2) Fe^{3+} in pyrope-"skiagite" garnets has the same parameters as the "skiagite" endmember. Thus, octahedral cation substitutions have little effect on the electronic environment of Fe^{3+} occupying this site. Mg-Fe^{2+} substitution on the adjacent 8-fold site has likewise only a minor effect on the hyperfine parameters of Fe^{3+}. This behaviour contrasts with the stronger effects observed for Ca-Fe^{2+} substitution in andradite-"skiagite" garnets [3].

Determining $Fe^{3+}/\sum Fe$ in garnets requires consideration of differing recoil-free fractions for Fe^{2+} and Fe^{3+}. Simple correction factors for spectra measured at room T and 80 K were reported by [3], based upon spectra from a series of almandine-"skiagite" and andradite-"skiagite" solid solutions. Comparison of ratios determined at room T and 80 K for the pyrope-"skiagite" garnets reveal a slight systematic difference in this correction factor, although this difference lies well within the uncertainties. Thus, it is concluded that the correction factors to account for the differing recoil-free fractions for Fe^{2+} and Fe^{3+} reported by [3] are generally applicable to silicate garnets, including those that are Mg-rich.

Single-crystal H*T* X-ray diffraction study of anthophyllite

Cámara, F.[1*], Welch, M.D.[2] & Oberti, R.[1]
[1]CNR-IGG, UOS Pavia, Italy ([*]camara@crystal.unipv.it)
[2]The Natural History Museum, London, UK

The crystal chemistry of amphiboles is now well understood. However, very little is known about their physical properties, such as compressibility and thermal expansivity [1], both of which are fundamental to mineral stability. Of the few published expansivity data, all are for monoclinic amphiboles, including cummingtonite, tremolite and richterite and recently also pargasite [2]. There are no data for orthorhombic amphiboles. Furthermore, rapid disordering of divalent cations between *M*(1,2,3,4) sites in monoclinic amphiboles on heating has been observed *in situ* to occur within 2–4 hours at $T \sim 300 – 700$°C [3,4]. Beyond 600°C, dehydrogenation has been also observed [2]. The absence of thermal expansivity data for orthorhombic amphiboles and the possibility of *in situ* disordering of cations led us to undertake a high-temperature diffraction experiment on anthophyllite. A gem-quality Mg-rich crystal of anthophyllite coming from American Museum of Natural History (AMNH 34856) with composition $^{A}Na_{0.05}{}^{B}(Mg_{1.34}Mn_{0.56}Ca_{0.09})\ ^{C}(Mg_{4.98}Fe_{0.02})\ ^{T}(Si_{7.97}\ Al_{0.03})\ O_{22}(OH_{1.99}F_{0.01})$ was studied by single-crystal XRD. Data were collected *in situ* using a micro furnace. Lattice parameters were refined at intervals of 25 K in the *T* range 298-1073 K; intensity data were collected at 298, 473, 673, 873, 973 and 1073 K. Above 973 K a homogeneous contraction in volume is observed which is related to dehydrogenation accompanied by a increase in mosaicity indicating the decomposition of the crystal. Thermal expansivities for *V*, *a*, *b*, *c* were obtained by fitting the equation $V(T) = V_T e^{[\alpha\ (T-Tr)]}$: $\alpha_V = 3.668(3) \times 10^{-5}$ K^{-1}, $\alpha_a = 1.49(1) \times 10^{-5}$ K^{-1}, $\alpha_b = 0.969(2) \times 10^{-5}$ K^{-1}, $\alpha_c = 1.206(9) \times 10^{-5}$ K^{-1}. These values are the highest observed so far for amphibole. Thermal expansion is thus anisotropic with $\alpha_a{:}\alpha_b{:}\alpha_c$ = 1.53:1:1.24, with a larger expansion in the (010) plane, essentially along [100]. This behaviour contrasts with the chemically similar but monoclinic manganoan cummingtonite [2] which shows a lower α_c, although α_b values are almost the same in both monoclinic and orthorhombic structures. Structure refinements show that, after correcting for thermal motion, while tetrahedra behave as rigid units up to 1073 K, C-group octahedra expand at the same rate within experimental error ($\alpha_{M1,2,3} = 5(2) \times 10^{-5}$ K^{-1}), whereas *M*(4) expands more ($\alpha_{M4} = 7.8(3.1) \times 10^{-5}$ K^{-1}).

A change in rate is observed in the *c* parameter which starts around 700 K and coincides with disordering of Mn from the B to the C sites in agreement to previous observations in manganocummingtonite [3]. However, on disordering at high-*T* in anthophyllite, the Mn^{2+} site preference is *M*(1,2) > *M*(3), in contrast with *M*(2) > *M*(1,3) reported by [3] in manganoan cumingtonite and also with $M(1,3) \geq M(2)$ found in richterite [4]. This result indicates that the composition of *M*(4) is more constraining than topology in determining the thermal behaviour of amphibole.

Experiments to determine thermodynamic controls for the transition from garnet-biotite to garnet-talc in metapelites and metagreywackes

Chmielowski, R.M.*, Fumagalli, P. & Poli, S.
Dipto. Scienze della Terra, Università degli Studi, Milan, Italy
(*reia.chmielowski@unimi.it)

The thermodynamic controls which govern the transition from garnet-biotite to garnet-talc assemblages during the metamorphism of mica-dominated sediments are not yet well understood. Investigations on synthetic compositions in the model system CaO-K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O are carried out in a piston cylinder apparatus at pressures and temperatures from 2 to 3 GPa and to 600-700°C. Experiments are buffered with graphite, and are generally run under fluid saturated conditions.

The experiments are run using bulk compositions representative of both metapelites (NM and H) and metagreywackes (NP and L). Variations in the bulk compositions studied were chosen to bracket the almandine-chlorite tie line in the Al_2O_3-Annite-Phlogopite plane and the annite-aluminosilciate and annite-almendine tie lines in the Al_2O_3-K_2O-(Mg,Fe)O plane (Fig. 1) to provide greater control of the compositional effects on the reactions.

The preliminary results of this study are presented (Fig. 2).

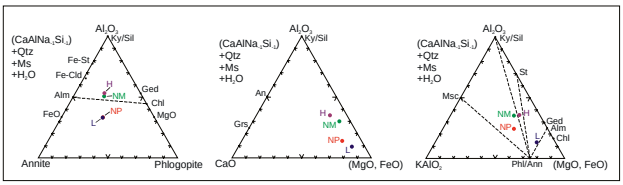

Fig. 1: (a) Projection from Ms, Qtz, H_2O and exchange vector CaAlNa-1Si-1 in the Al_2O_3-Annite-Phlogopite plane (note that H and NM plot above the almandine-chlorite join, L and NP below); **(b)** projection from Ms, Qtz, H_2O and the exchange vector CaAlNa^1Si^1 in the Al_2O3-K_2O-(Mg,Fe)O plane; H and L plot on the right-hand side of the join connecting Ky/Sil to Phl/Ann (i.e. lower $KAlO_2$ than NM and NP); **(c)** projection from Ms, Qtz, H_2O and the exchange vector CaAlNa-1Si-1 in the Al_2O_3-CaO-(Mg,FeO) plane.

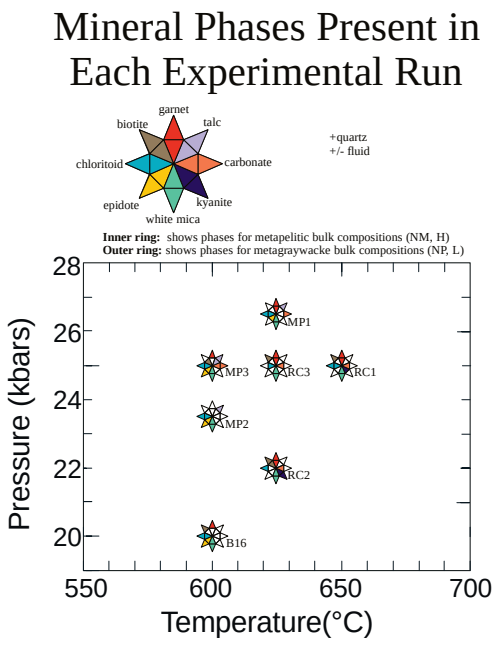

Fig. 2: The phases present in each experimental run are indicated.

Crystal chemistry of fluor-chlorapatite solid solutions

Gottschalk, M.[1*], Schettler, G.[2] & Harlov, D.E.[1]
[1]Dept. of Chemistry and Physics of Earth Materials, GFZ, Potsdam, Germany (*gottschalk@gfz-potsdam.de)
[2]Dept. of Climate Dynamics and Landscape Evolution, GFZ, Potsdam, Germany

A series of synthetic apatite crystals along the fluorapatite-chlorapatite $Ca_5(PO_4)_3(F, Cl)$ join have been synthesized at 1220 to 1375 °C from $Ca_3(PO_4)_2$ dissolved in a CaF_2-$CaCl_2$ melt. The solid solutions have then been characterized both chemically and structurally. The apatite solid solutions were characterized by IR spectroscopy, X-ray powder diffraction using Rietveld refinements (XRD), and single crystal diffraction (SCXRD) structure determinations. IR-spectra indicate no or only a very minor OH-apatite component in the solid solutions. Lattice parameters of the apatite solid solutions vary systematically with composition. IR-spectra indicate no or only a very minor OH-apatite component in the solid solutions. Lattice parameters of the apatite solid solutions vary systematically with composition. The *a*-lattice parameter varies linearly.

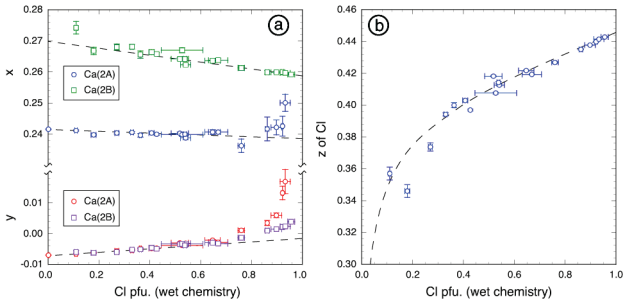

Fig. 1: a) The x- and y-position of the Ca(2A) and Ca(2B)-site and b) the *z*-position of Cl as a function of chlorine-content.

In contrast to F^-, which occupies a special position at (0,0,1/4) in the unit cell, because of the larger ionic radius of Cl^-, this position is split for Cl^- with *z*-coordinates ranging from 0.346(4) to 0.4428(2). Single crystal structure determinations reveal that the Ca(2)-site is also split into Ca(2A)- and Ca(2B)-sites for F^- and Cl^- as nearest neighbors, respectively. In comparison to the Ca(2A)-F^- arrangements, the larger Cl^- ion presses the triangular arrangement of Ca-ions outward to facilitate an energetic more favorable constellation to form Ca(2B)-Cl^- arrangements.

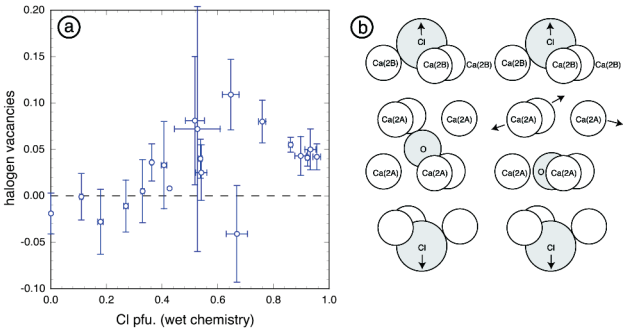

Fig. 2: a) Halogen deficiency as a function of chlorine-content. b) Avoiding symmetry reduction by the insertion of O^{2-} for charge balance.

Apatites rich in Cl (x_{Cl} > 0.5) show a deficiency in halogens, which is charge balanced by oxygen forming an oxyapatite component. The oxyapatite component prevents F-absent apatites from crystallizing in the monoclinic modification and stabilizes the hexagonal modification.

The melting curve of ice re-examined - anomalous high pressure behaviour of H_2O

Mirwald, P.W.
Inst. of Mineralogy & Petrography, University of Innsbruck, Austria (peter.mirwald@uibk.ac.at)

A compression study of water combined with determinations of the dehydration boundary of gypsum ($CaSO_4$*$2H_2O$) to bassanite and anhydrite respectively led to the conclusion that H_2O is characterised by a complex system of high pressure anomalies [1,2]. These experiments were conducted in a piston cylinder apparatus using pressure change and related piston displacement as monitoring parameters (Differential Pressure Analysis). Based on this DPA-technique, a detailed re-examination of the melting curve of the ice polymorphs I, III, V and VI was a further step to elucidate this phenomenon. The data obtained reveal several anomalies in the dP/dT course of the melting line: ice I at 27 MPa, Ice III: 290 MPa, Ice VI: 780 and 1180 MPa. In addition, compression anomalies were found in ice clearly to be related to the other data. Fig. 1 gives a synoptic P-T overview of the the data obtained so far.

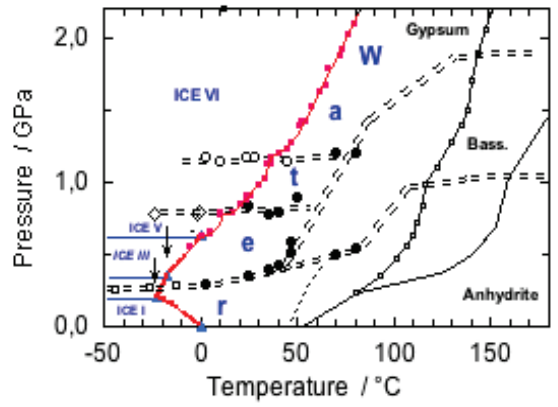

Fig. 1: Synoptic diagram of anomalous PVT behaviour of H_2O documented by the dehydration boundary system of gypsum-bassanite-anhydrite, the ice melting curve and H_2O compression anomalies (dashed double lines).

The new data augment the picture lined out previously [1,2] and strongly support the concept of anomalous PVT behaviour of H_2O. Apart from the anomalous compression behaviour of H_2O, the anomalies are indicated by a specific dP/dT behaviour of dehydration boundaries, e.g. of gypsum and bassanite as well as by the ice melting curve: in each case the dP/dT boundary slope shows a distinct increase below the anomaly followed by a break at the anomaly which then leads to a shallower dP/dT-course towards higher pressure. In accordance with the Clausius Clapeyron and Ehrenfest relation this aprupt slope change may be related to a drastically increased change of entropy or of the thermal expansion. First results of a QM/MM molecular dynamic simulation of water compression (Randolf, Mirwald, Rode; unpublished data) suggest that these anomalies may be related to changes of the coordination assemblages of the H_2O-molecules.

Stability field of the high-temperature orthorhombic phase in $Mg_2Si_2O_6$-$CaMgSi_2O_6$ system

Ohi, S.[1,2*], Miyake, A.[2] & Yashima, M.[3]
[1]Dept. of Interdisciplinary Enviroment, Graduate School of Human and Environmental Syudies, Kyoto University, Kyoto, Japan ([*]shugo-ohi@kueps.kyoto-u.ac.jp)
[2]Dept. of Geology and Mineralogy, Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, Kyoto, Japan
[3]Dept. of Materials Science and Engineering, Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology, Yokohama, Japan

In the system $Mg_2Si_2O_6$-$CaMgSi_2O_6$, there had been the controversy about the appearance and stability of the orthopyroxene (Opx) phase near 1400°C other than protoenstatite (Pen) since the discovery by Foster [1]. In recent years, Ohi et al. [2] observed the phase transition between low-temperature Opx (LT-Opx) and high-temoperature Opx (HT-Opx) for the composition of $(Ca_{0.06}Mg_{1.94})Si_2O_6$ at 1170°C. They concluded that Opx the phase near 1400°C was HT-Opx. In previous studies, phase diagrams for $Mg_2Si_2O_6$ and the En–Di system at high pressure were drawn without taking account of HT-Opx. The purpose of our study was to reconsider the phase diagrams for $Mg_2Si_2O_6$ and the En–Di system and to calculate the stability field of HT-Opx at high pressure.

First, we performed differential scanning calorimetry (DSC) experiments to obtain the transition enthalpy (ΔH) between LT-Opx and HT-Opx and then calculated the dP/dT line along the LT-Opx = HT-Opx boundary. Furthermore, to estimate the transition temperature (Tc) toward Ca-composition, we examined Ca-free orthoenstatite (Oen) with HT-XRD.

The transition enthalpy, transition temperature, volume change, and transition slope for the composition of $(Ca_{0.06}Mg_{1.94})Si_2O_6$ were estimated to be 6.2 kJ/mol, 1170°C, 10.25 Å^3/unit cell, and 0.0056 GPa/°C, respectively, and the phase boundary between LT- and HT-Opx was defined as P (GPa) = 0.0056T (°C) – 6.55. The transition temperature of Ca-free LT-Oen to HT-Oen was estimated to be 1120°C, which was lower than that of Ca-poor LT-Opx to HT-Opx (about 1170°C); hence, dTc/dX_{Di} (X_{Di} = 2Ca/(Ca+Mg) × 100) has a positive slope. This slope shows that, at the same temperature, LT-Opx is a more Ca-rich phase than HT-Opx.

The phase boundary between LT- and HT-Opx defined as P (GPa) = 0.0056T (°C) – 6.55 shows that the invariant point of four-phase equilibria for Pen + HT-Opx + pigeonite + diopside is at around 1240–1280°C and 0.1–0.2 GPa, rather than the equivalent system involving LT-Opx as described in previous studies. We developed phase diagrams for $Mg_2Si_2O_6$ and the $Mg_2Si_2O_6$–$CaMgSi_2O_6$ system taking into account the results of previous synthetic experiments and the phase boundary that we determined between LT-Opx and HT-Opx.

Our phase diagrams for $Mg_2Si_2O_6$ showed that HT-Oen is more stable than Pen at pressure above ~0.8 GPa, and that the boundary between HT-Oen and Pen has a gently negative slope. As pressure rises from 1 atm to about 0.2 GPa, the lower temperature limit of stability of HT-Opx decreases from ~1370°C to ~1200°C. Above 0.9 GPa, the stability field of Pen disappears and Ca-free HT-Oen becomes stable. On the basis of our results, we suggest that further high-resolution analyses of the thermodynamics of the $Mg_2Si_2O_6$-$CaMgSi_2O_6$ system at high temperatures and high pressures are required.

A thermodynamic model for titanium and ferric iron solution in biotite

Tajčmanová, L.[1*], Connolly, J.A.D.[2] & Cesare, B.[3]
[1]Institute of Geological Sciences, Free University, Berlin, Germany ([*]lucataj@gmail.com)
[2]Dept. of Earth Sciences, Swiss Federal Institute of Technology, Zürich, Switzerland
[3]Dept. of Geosciences, University of Padova, Italy

Recent crystallographic data indicate that in biotite Ti and Fe^{3+} order preferentially onto the M2 octahedral site rather than onto the M1 site as assumed in previous solution models for K2O–FeO–MgO–Al_2O_3–SiO_2–H_2O–TiO_2–O_2 (KFMASHTO) biotite. In view of these data, we reformulate and reparameterize the former biotite solution model. Our reparameterization takes into account Fe-Mg order-disorder and ferric iron contents of natural biotites as well as both natural and experimental observations on biotite Ti-content over a wide range of physicochemical conditions. In comparison to previous biotite models, the new model reproduces the Ti-content and stability field of biotite as constrained by experiments with significantly better accuracy. The predictive power of the model is tested by comparison with petrologically well-characterized natural samples of SiO_2-saturated and SiO_2-undersaturated rocks that were not used in the parameterization. In all of these tests, the reformulated model performs well.

The crystal structure of δ-Al(OH)$_3$ at high pressures

Matsui, M.[1*], Ikeda, E.[1] & Komatsu, K.[2]
[1]School of Science, University of Hyogo, Japan
([*]m.matsui@sci.u-hyogo.ac.jp)
[2]Geochemical Research Center, The University of Tokyo, Japan

A high pressure phase of Al(OD)$_3$, called δ, was synthesized at 18 GPa and 973 K using a Kawai-type multi-anvil apparatus [1]. Based on powder X-ray diffraction at ambient conditions, Komatsu et al. [1] showed that δ-Al(OD)$_3$ is isostructural with δ-Al(OH)$_3$ with space group *Pnam*, previously synthesized at high temperatures and high pressures [2]. Using the Rietveld method and the difference-Fourier analysis, Komatsu et al. [1] reported a structural model for δ-Al(OD)$_3$, in which positional disorders of the D atoms were proposed in their hydrogen bonds. However, successive neutron diffraction measurements at ambient conditions [3] revealed that the real space group of δ-Al(OD)$_3$ is $P2_12_12_1$, but not *Pnam* as reported by X-ray diffraction experiments [1]. Komatsu et al.[3] suggested that the positions of D atoms may be in ordered in hydrogen bonds in the $P2_12_12_1$ structure. Here we use first-principle calculations to study structural and enegetic properties of δ-Al(OH)$_3$ in more detail.

All calculations were performed with the Vienna Ab Initio Simulation Package VASP [4]. The projector-augmented wave (PAW) method [5] was used in the generalized-gradient approximation (GGA) for the exchange-correlation functional [6]. Atomic positions were relaxed with observed crystal-symmetry constraints. In order to check the reliability and applicability of the computations, we first calculated the structures and energies of the three known Al(OH)$_3$ polymorphs, gibbsite, bayerite, and η-Al(OH)$_3$, with the results that the calculated values reproduce the observed ones accurately.

There exist 7 independent atoms, including one Al, three O and three H atoms, in the asymmetric unit in the $P2_12_12_1$ δ-Al(OH)$_3$ structure. The initial lattice parameters and atomic positions of both Al and O were taken from previous X-ray data for the *Pnam* structure [1], while the H atom positions were taken to be in ordered configurations and were selected from either one of the two disordered sites in the hydrogen bonds in the *Pnam* structure [1]. We tested several structural models, and finally found an energy-minimized model that 1) reproduces the measured lattice parameters of δ-Al(OH)$_3$ accurately, 2) gives reasonable Al-O, O-H, and hydrogen bond distances, and 3) shows reasonable energetic relations between the Al(OH)$_3$ polymorphs; namely gibbsite is stable at ambient pressure, the δ phase has the lowest enthalpy at pressures greater than about 1 GPa, while both bayerite and the η phase are metastable over the whole pressure range. We further confirmed that the calculated powder neutron diffraction intensities based on the present δ-Al(OH)$_3$ structural model reproduces well the observed data [3]. In addition we found the $P2_12_12_1$ δ phase transforms to another high pressure form with space group *Pnam* and with symmetrical hydrogen bonds at around 80 GPa.

[3]SISSA & INFM-DEMOCRITOS National Simulation Center, Trieste, Italy

Phase boundaries amond the various forms of ice are difficult to be determined experimentally because of large hysteresis involved at low temperatures. Theoretically, there are also great challenges, including the order-disorder transition. The ice VII-VIII boundary is a typical order-disorder phase boundary, which has been well constrained experimentally over a wide pressure range, and is a good target to be studied theoretically. We present a first-principles study consisting in the complete statistical sampling of molecular orientations within a 16-molecule supercell. Vibrational effects are included within quasi-harmonic theory. Our calculation accounts well for several important aspects: equation of state of ice VII, negative Clapeyron slope, and isotope effect. We will discuss also some factors to be improved, including XC functionals.

The spin transition in Fe-bearing perovskite and its consequences for the lower mantle

Caracas, R.[1*], Mainprice, D.[2] & Thomas, C.[3]
[1]Laboratoire de Sciences de la Terre, CNRS, ENS de Lyon, France ([*]razvan.caracas@ens-lyon.fr)
[2]CNRS, Géosciences Montpellier, Université Montpellier, France
[3]Institut für Geophysik, Westfälische Wilhelms Universität Münster, Germany

In the last years more and more evidence emerged, from both experimental and theoretical sides, that points to a magnetic phase transition in Fe2+-bearing perovskite and post-perovskite at high-pressure [1-3]. Experimentally it was observed that the ferrous iron in perovskite and post-perovskite undergoes a high-spin to intermediate-spin to low-spin transition. First-principles calculations based on density functional theory suggest that Fe-bearing $MgSiO_3$ perovskite undergoes a spin transition from high-spin state to low-spin state. This high-spin to low-spin transition has been found first by applying random displacements on the atomic positions in the Pbnm orthorhombic parent structure. These displacements create enough energy in the system that it was able to break the potential barriers corresponding to the spin transition. Non-randomized structures are uniquely obtained by the replacement of Mg by Fe in the Pbnm structure, leading to much higher transition pressures [4].

Using a novel approach we are able to disentangle a part of the complex phase diagram and spin behavior of the $FeSiO_3$ perovskite. To to this we investigated the dynamic stability of Pbnm $FeSiO_3$ perovskite and show the existence of unstable phonon modes. We tracked the eigen-displacements of the phonons modes to find the low-spin and the intermediate spin states. On solid state physical basis we explored, a set of hypothetical structures with various spin configurations and considerably lower enthalpy than the parent orthorhombic Pbnm structure. At mega-bar pressures we studied various stable monoclinic and triclinic configurations with intermediate spin state and a triclinic low-spin structure.

Our results demonstrate that distorted perovskite with intermediate spin state can exist in the Earth as an independent phase or can coexist with domains in a high-spin configuration. Changes due to chemistry or temperature or both can easily shift the equilibrium from one spin configuration to the other; this would in turn affect the thermal and electrical conductivities, the seismic properties, the rheology and the chemical behavior of the mantle and thus could be at the origin of small-scale mantle heterogeneities and enhance chaotic convection.

Then we determine the elasticity of Fe-bearing perovskite for various spin configurations using density-functional theory calculations. The elastic moduli and the bulk seismic wave velocities are weakly affected by the spin transition. However, we show that the intrinsic differences in seismic anisotropy between the high-spin and low-spin phases of Fe-bearing perovskite coupled with lattice preferred orientation that can develop during mantle flow leads to distinct seismic signatures between the top and the bottom of the lower mantle. These signatures should be detectable by seismic observations and they need to be taken into account in tomographic studies of the Earth's lower mantle.

Physico-chemical features of aluminium hydroxides as modelled with hybrid B3LYP functional and localized basis functions

Demichelis, R.[1*], Noel, Y.[2], Ugliengo, P.[1], Zicovich-Wilson, C.M.[3] & Dovesi, R.[1]
[1]Dipto. di Chimica IFM, Università di Torino and NIS – Nanostructured Interfaces and Surfaces – Centre of excellence Torino, Italy ([*]raffaella.demichelis@unito.it)
[2]Institut des Sciences de la Terre de Paris (UMR 7193 UPMC-CNRS), UPMC - Paris Universitas, France
[3]Facultad de Ciencias, Universidad Autónoma del Estado de Morelos, Cuernavaca, Morelos, Mexico

Aluminium hydroxides are a family of seven compounds (akdalaite, boehmite, diaspore, bayerite, doyleite, gibbsite, nordstrandite) covering an important role as row materials in the aluminium industry, which involves various technological fields. An extremely large variety of experiments and simuations were performed in the last 50 years on this class of materials. However, many of their properties still remain a matter of investigation and debate. Moreover, a unitary and comparative overview of the full family is still lacking.

Some of the open questions related to their structure (space group definition, H order-desorder), energetics (relative stability with respect to each other and to the dehydrated phase) and vibrational spectrum (broad bands in the OH stretching region: large differences in the interpretation of the experimental IR and Raman spectra by the various authors) are here tackled with a quantum mechanical *ab initio* approach, using the CRYSTAL09 periodic code, a rich all-electron Gaussian type basis set and the hybrid B3LYP functional (comparison to results obtained with other DFT functionals are also provided). [1-7]

Calculated properties are compared to experimental data when available. H positions were optimised, so that it is possible to attribute a space group to boehmite, akdalaite and doyleite, and propose a unit cell for nordstrandite. The thermodynamic and vibrational analyses of Al hydroxides here presented are shown to be extremely helpful for the interpretation of the experimental results.

This work represents the first complete, systematic and homogeneous (same method, computational parameters, basis set and Hamiltonian) analysis of the crystal structure, energetics and vibrational spectra of this family of compounds, showing how important can be the contribution of simulation to the field.

Calculated and experimental Raman spectra of the polymorphic forms of $Y_2Si_2O_7$

Kaindl, R.*, Többens, D.M. & Kahlenberg, V.
Institute of Mineralogy and Petrography, University Innsbruck, Austria (*reinhard.kaindl@uibk.ac.at)

Crystalline material with the chemical composition $Y_2Si_2O_7$ shows not only promising properties in the fields of laser materials, high-energy phosphors or advanced ceramics, but also a complex polymorphism, which at present reports about seven different modifications [1]. Principally, Raman spectroscopy can provide structural information, but the interpretation of the spectra is challenging and frequently prone to error. This contribution presents experimental spectra of the different polymorphic forms of $Y_2Si_2O_7$, and compares them with calculated data obtained from density functional theory (DFT) approximations implemented in the CRYSTAL 06 program [2,3].

Experimental Raman spectra were recorded for six modifications, whereas the computations were performed for five polymorphs of $Y_2Si_2O_7$. Various functionals were evaluated. The results of the Dirac-Slater (LDA) exchange in combination with the Vosko-Wilk-Nusair (VWN) correlation, for example, agreed within 1% for the lattice parameters and within 2% for interatomic distances with the respective experimental values. The average and maximum deviation between observed bands and computed modes was ± 8 cm^{-1} and 20 cm^{-1}, respectively. Structurally, the different polymorphs can be divided into three main groups: Two forms are composed of $[Si_2O_7]$ dimers in antiparallel, three with parallel orientation and two forms can be classified as mixed anion silicates, containing both trimers and monohedra. Specific spectral features can be used to gain information about the degree of condensation of the $[SiO_4]$ tetrahedra. For example, a characteristic band around 660 cm^{-1}, which is assigned to O-Si-O bending mode appears in all forms composed of $[Si_2O_7]$-units whereas it is absent in the structures containing $[Si_3O_{10}]$-trimers.

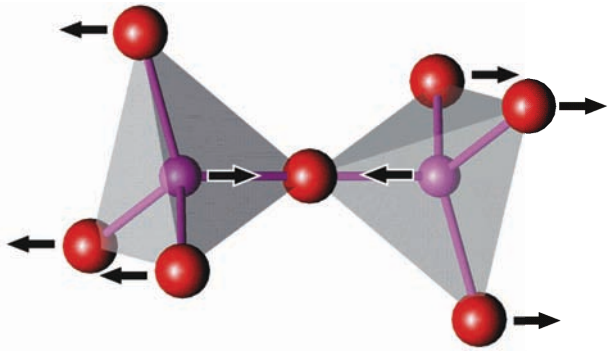

Fig. 1: O-Si-O bending mode at 660 cm^{-1}, appearing in all $Y_2Si_2O_7$ forms composed of double tetrahedra.

The relations between the highly variable structures and Raman spectra of the polymorphs of $Y_2Si_2O_7$ could be derived and most bands assigned to certain vibrational modes. Combining experimental and computational data allowed conclusions on structural details such as tetrahedral configurations.

Dissolution morphology of galena and sphalerite crystals from the Madan Pb-Zn deposits, Bulgaria

Atanassova, R.
Geological Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria (radi@geology.bas.bg)

Polyhedral sulphide crystals and aggregates with diverse morphology are well known from the Madan ore district. The economically important Pb-Zn hydrothermal deposits include both veins and metasomatic ore bodies and are enclosed in the metamorphic rocks of the Rhodope massif. The mineralization consists of: -early skarns mainly of Mn-pyroxene and pyroxenoide composition, replacing marbles; -main sulphide ores of galena, sphalerite, pyrite and chalcopyrite and others; and -late quartz and carbonates [1].

Sometimes, sulphide crystals are affected by selective natural hydrothermal dissolution [2-4]. The dissolution morphological features of large galena and sphalerite crystals and their various local differences are described. Several types of anisotropic dissolution morphology are revealed by SEM studies. Dissolution patterns inheriting the growth features are specific along the different crystallographic direction on a given crystal face. In the study of surface dissolution topography the orientation relation in respect to the outline of the crystallographic faces, presented in the different habits, are taken into account, thus distinguished are dissolution patterns on galena along <100>, <111> and <110> (Fig. 1).

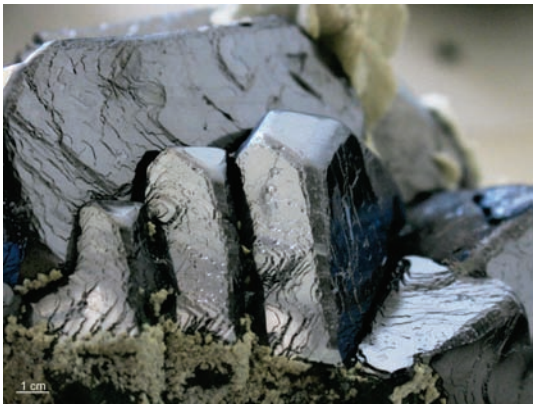

Fig. 1: Large galena cubo-octahedral crystals with dissolution macro patterns on (100) // <111>, Yuzhna Petrovitsa.

The dissolution features, formed under the control of defects result in characteristic morphological elements of the corroded galena and sphalerite surfaces. Such are: separated etch pits, dissolution grooves developed along sub grain or preferential etching at the galena twin (111) boundaries, triangular or square pyramidal hillocks, 3D channels and oval internal cavities after former fluid inclusions, etc.

The dissolution forms depend mainly from the undersaturation of the solutions, which is driving force of the process [5] and can be grouped as follows. At low undersaturation fine-layered, oval and rounded forms arise, starting from the original crystal edges and corners. Whereas at larger undersaturation single etch pits, grooves along grain and twin boundaries, pores, channels, bulges, etc. are predominant, formed under the control of the main surface defects [3].

X-ray study and molecular dynamics computer simulation on melanophlogite

Ida, A.[1*], Kihara, K.[1], Okudera, H.[1] & Fujinami, S.[2]
[1]Graduate School of Natural Sciences and Technology, Kanazawa University, Kanazawa, Japan
([*]akihiro-ida@earth.s.kanazawa-u.ac.jp)
[2]School of Chemistry, College of Science and Engineering, Kanazawa University, Kanazawa, Japan

Melanophlogite (MEP), $23SiO_2 \cdot M^{12} \cdot 3M^{14}$ (Z = 8 and 2 for low- high-temperature phases, respectively), is one of silica clathrate minerals. MEP can accommodate small gas molecules (CO_2, CH_4, N_2, etc.) in two kinds of cages M^{12} and M^{14}. These guest molecules are held in the cages via van der Waals contact with the framework atoms.

Single crystals of guest-free MEP (GF-MEP) were prepared by heating natural ones from Mt. Hamilton, USA, and the structures at -50, 23, 100, 200 and 400°C were refined with X-ray single-crystal diffraction method together with that of guest-bearing one at 23 and 84°C. Space group *Pm*-3*n* gave the most satisfactory results and there was no sign of phase transitions in our experiments over the range of the temperatures.

The unit cell volume was slightly expanded *c.a.* 0.9% with removing guest molecules. In spite of this change, the original framework structure was retained with nominal Si-O bond length. Since the cell expanded, Si-O-Si bond angles should be changed to enlarge the cages. This change could be seen, though not large.

Difference-Fourier calculations revealed some guest molecules remained in these cages. Less than a half of M^{12} and more than a half of M^{14} were still occupied by unidentified guest molecules. Molecular dynamics (MD) calculations with different occupancy states at constant pressure and temperatures indicated that a model, CO_2-filled M^{14} and empty M^{12}, could represent experimental structure. M^{12} was expanded ≈ 1% by removing CH_4 from the cage. The volume of SiO_4 tetrahedron was constant even in these MD calculations. Presence of guest molecule, and interaction between the guest molecule and the host framework, is strong enough to change the volume of cage and thus the unit cell.

Car Parrinello molecular dynamics study of Fe-bearing smectites

Liu Xiandong[1,2*], Meijer, E.J.[2], Lu Xiancai[1] & Wang Rucheng[1]
[1]State Key Laboratory for Mineral Deposit Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, P. R. China ([*]xiandongliu@nju.edu.cn)
[2]Van't Hoff Institute for Molecular Sciences and Amsterdam Center for Multiscale Modeling, University of Amsterdam, The Netherlands

In order to identify the influences imposed by iron substitution, density functional theory-based Car-Parrinello molecular dynamics simulations are performed to study both oxidized and reduced Fe-bearing smectites. The following fundamental properties are investigated: local structures in the structural layer, hydroxyl orientations, and the vibration dynamics of hydrogen and silicon. Structural analyses indicate that the average Fe-O bond lengths are about 2.08 Å and 2.02 Å in the reduced and oxidized models respectively, and both Fe substitutions do not affect the coordination structures of the Al-O and Si-O polyhedrons. For hydroxyl orientations, Fe(III) substitution has no obvious influences but Fe(II) makes the coordinated hydroxyls present another high-angle distribution (Fig. 1).

The present work proves that both substitutions can red-shift the hydroxyl in-plane bending mode. The analyses also reveal Fe(III) substitution has no effect on the Si-O stretching, while Fe reduction causes a blue-shift of the out-of-plane stretching mode. These results provide quantitative constraints and clues for future research.

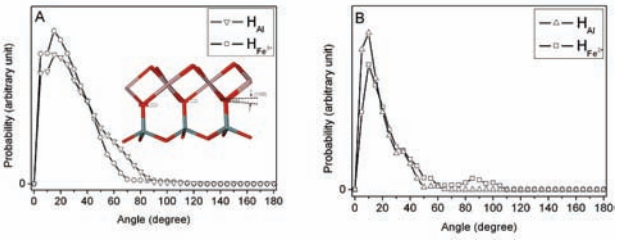

Fig. 1: Hydroxyl orientations in the (A) oxidized and (B) reduced models. Here H_{Fe} means the H from the hydroxyls coordinating with the Fe atom and H_{Al} denotes the other H atoms. The OH orientations are characterized by the distributions of the angle denoted on the stick model shown in panel A.

High-temperature molecular dynamics simulation of aragonite

Miyake, A.[1*] & Kawano, J.[2]
[1]Dept. of Earth and Planetary Science, Graduate school of Science, Kyoto University, Kyoto, Japan ([*]miya@kueps.kyoto-u.ac.jp)
[2]Research Institute for Applied Mechanics, Kyusyu University, Fukuoka, Japan

Calcium carbonate ($CaCO_3$) has various polymorphs, such as calcite and aragonite, and is important both in the earth science, as rock-forming minerals, and in chemical technology, as raw materials for industrial processes. Although calcite undergoes various structural phase transitions involving rotation of CO_3 groups or slight differences in the position of Ca^{2+} ions, structural transitions such as these have not been reported for aragonite. In a molecular dynamics (MD) simulation, Bearchell and Heyes [1] obtained a structure in which CO_3 groups were rotated through an angle of 30° around a three-fold axis from their positions in aragonite. However, they did not analyze the structure in detail. To extend this previous work, we used MD simulations using the aragonite structure as the initial state, to investigate the possible existence of a new polymorph related to aragonite.

MD calculations were carried out using the MXDTRICL [2] program with the two-body central force interatomic potential function, which includes terms for the Coulombic interaction between two point charges, short-range repulsion, van der Waals attraction, and Morse potential. The parameter set was empirically derived to reproduce aragonite structure at 300 K and 1 atm, which was based from our previous studies [3, 4] for calcite. We used the Verlet method for integration of equations of atomic motion and the Ewald method for summation of electrostatic interactions. Temperature and pressure were controlled by scaling atomic velocities and simulation of cell parameters, respectively. The time step was 0.5 fs throughout our simulations. Periodic boundary conditions for aragonite were imposed with a basic MD cell of 144 crystallographic units containing 2880 atoms.

The cell parameters changed with increasing temperature. From 300 to 500 K, each of these parameters gradually increased with temperature. Around 510 K, however, *a* and density decreased, whereas *b* and *c* increased. Above 510 K, b was about 1.73 times *a*. The coordination number changed from 9 to 6 at around 510 K. These abrupt changes of unit-cell parameters, density, and coordination number indicate that a first-order phase transition from aragonite to a high-temperature phase occurred at around 510 K, which occurs metastably within the stable region of calcite and the dT/dP slope of the phase boundary between them was about 1.25×10^3 K GPa-1. The point group and space group of the high-temperature phase were determined uniquely as 622 and $P6_322$, respectively (hexagonal aragonite). In the hexagonal aragonite structure, CO_3 groups were rotated by 30° around the c-axis and move up and down along the c-axis from their position in aragonite, and Ca ions were 6-coordinated as they are in calcite. The CaO_6 octahedron of hexagonal aragonite was strongly distorted, whereas in the calcite structure it is an almost ideal octahedron. The transition between hexagonal and orthorhombic aragonite involves only small movements of CO_3 groups. Therefore, it is possible that hexagonal aragonite plays an important part in the metastable formation of aragonite within the stability field of calcite and in the development of sector trilling in aragonite.

Bct C_4: a new viable sp^3-carbon allotrope

Umemoto, K.[1*], Wentzcovitch, R.[2], Saito, S.[3] & Miyake, T.[4]
[1]Dept. of Geology and Geophysics, University of Minnesota, Minneapolis, USA ([*]umemoto@cems.umn.edu)
[2]Dept. of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, USA
[3]Dept. of Physics, Tokyo Institute of Technology, Tokyo, Japan
[4]Research Institute for Computational Sciences, AIST, Tsukuba, Japan

We have investigated by first principles the viability of a new form of sp^3 crystalline carbon recently found in tight-binding molecular dynamics simulations of carbon nanotubes (CNT) under pressure [1]. It consists of unique 4-membered rings and has body-centered-tetragonal structure (henceforth bct-C_4). It is also a polymerized form of (2,2) CNT, the smallest CNT. This phase is dynamically stable at zero pressure and is more stable than graphite beyond 18.6 GPa. At zero pressure it is also more stable than fcc C_{60} and (7,0) and (8,0) CNTs. Inspection of this transparent polymorph shows a peculiar relationship with hexagonal diamond, which suggests that this phase might be an intermediate phase along the graphite to hexagonal diamond transformation path. This possibility appears to be supported by the good agreement between simulated x-ray diffraction pattern of bct-C_4 and that of an intermediate transparent and hard phase of carbon produced by cold compression of graphite [2].

Ab-initio study of dolomite cation disordering. Preliminary results

Zucchini, A.[1*], Prencipe, M.[2], Comodi, P.[1] & Frondini, F.[1]
[1]Earth Sciences Dept., University of Perugia, Italy ([*]azzizuc@libero.it)
[2]Mineralogical and Petrological Sciences Dept., University of Turin, Italy

Disordering of Ca/Mg cations can strongly affects thermodynamic and kinetic properties of dissolution of dolomite [$CaMg(CO_3)_2$] which may have important implications on several fields, i.e. the capability of dolomite horizons as geological reservoirs, strongly depends on dedolomitization processes. By *in-situ* heating experiments it is well known that disordering on Ca/Mg positions first appears at a temperature of about 1200K and it increases up to a temperature of about 1400K where it is complete [1]. By *ex-situ* studies of synthetic and natural dolomite samples it is not possible to reach high degree of disorder, probably due to a very rapid reordering rates occurring during the quench [2].

To improve our knowledge on cation disordering in dolomite structure, and to study thermodynamic stability of different disordered dolomite structures (Fig. 1), first-principle calculations, at the hybrid Hartree-Fock/Density Functional Theory (HF/DFT) level [3,4], have been carried out in this work, by using a development version of the CRYSTAL program [5]. *Ab-initio* calculations were computed by using the WC1LYP Hamiltonian which includes a non local exact Hartree-Fock exchange contribution.

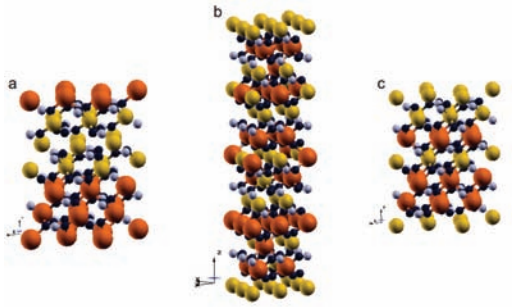

Fig. 1: Examples of *Ab-initio* simulated cation distribution of a stoichiometric dolomite in non-conventional supercell 2x2x2 (b) and conventional cell (a, c). (C-gray, O-black, Ca-red, Mg-yellow).

Total-energy calculations have shown that all of the disordered structures are, on average, about 15 KJ/mol energetically less stable than the ordered one. Moreover, we developed thermodynamic data processing in order to trace the characteristic disordering temperatures (T_{cd}). Analyzing the results we noticed that calculated the T_{cd} are quite in agreement with experimental values [1,6]. However, the calculated temperature disordering range (between about 800 K to 2000 K) resulted larger than the experimental one.

The results allowed us to conclude that highly disordered dolomites are energetically stable only at relatively high temperature conditions. The effect of pressure on cationic disordering will be investigated to better understand the natural environmental disordering conditions.

Further and thorough data will be presented in the extended work.

Characterisation of the structural bonding of selenium in pyrite by XAFS and XPS analysis

Diener, A.* & Neumann, T.
Institut für Mineralogie und Geochemie, Karlsruher Institut für Technologie, Karlsruhe, Germany (*alexander.diener@kit.edu)

The Se-79 radionuclide is highly mobile and has a long lifetime. Hence, it´s geochemical behaviour has to be considered for the assessment of a high-level nuclear waste repository. Pyrite itself is considered as one important host phase for radionuclides in high level nuclear waste disposal sites. Therefore, our investigations focus on selenium in pyrite as solid solution phase for acidic and anoxic conditions predicted for a nuclear waste repository. A main topic is the stability of Se fixture due to its type of bonding in the crystal structure.

The preparation of Se-doted Fe-sulfide grains were accomplished under argon atmosphere in a glove box from solutions with different constant acidic pH- and Eh-levels, containing Se-concentrations (–II, IV) between 10-3–10-6 M.

Results via XRD and SEM analysis reveal a synthesis of pure spheroidal pyrite grains with a mean diameter of 1-2 µm and Se contents up to 2 mol-%. XANES measurements determine the k-edges of Se at an energy of 12656.5 – 12657, typically for Se(-I,-II). Independant of the chosen Se-concentration and pH value, all XANES-spectra are very similar.

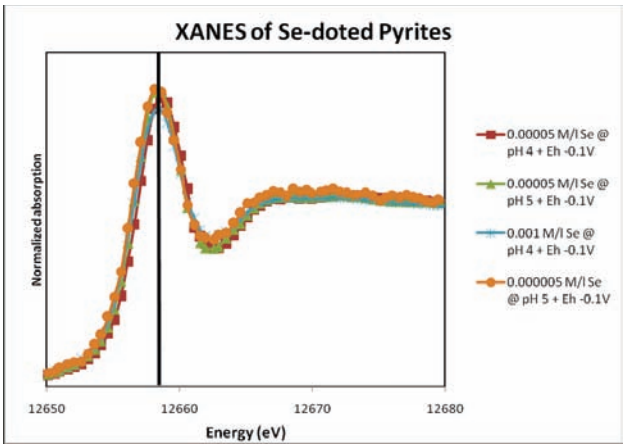

Fig. 1: XANES-spectra of Se-doted pyrite.

Based on the EXAFS results, the distance of Se to the atomic neighbours will be presented and experimental results will be compared with calculated stability diagrams. First XPS measurements complement the XANES results indicating a reduced valence state of the structural substitution of sulfide by selenide.

Crystal truncation rod studies of the pyrite (001) surface

Gilbert, B.[1*], Eng, P.J.[2], Banfield, J.F.[3] & Waychunas, G.A.[1]
[1]Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, USA (*bgilbert@lbl.gov)
[2]University of Chicago, USA
[3]Dept. of Earth & Planetary Science and Dept. of Environmental Science, Policy and Management, University of California – Berkeley, USA

Pyrite, FeS_2, is a common sulfide mineral that can exert a huge environmental impact when it is oxidized following exposure to air. Oxidation leads to the formation of acid mine drainage (AMD), low pH waters that typically contain elevated levels of heavy metal contaminants. The chemical pathway of pyrite oxidation has been studied by numerous researchers. The information obtained from these studies are limited since they use surface analysis techniques that require ultra-high vacuum conditions, provide only indirect structural information or require large amount of oxidation products.

Crystal truncation rod (CTR) analysis is a synchrotron-based scattering technique that is capable of determining the atomic-scale structure of hydrated interfaces. We are employing CTR to solve the structure of the water - pyrite (001) interface and to determine how oxidants such as ferric iron interact with the surface. This effort is a foundation for subsequent studies that will seek to capture changes in the surface structure that accompany the first steps in the oxidation process.

The preparation of high-quality pyrite surfaces for CTR is challenging because it lacks natural cleavage planes and because it is susceptible to oxidation under ambient conditions. We have developed an anaerobic chemical – mechanical polishing method that creates low-roughness pyrite (001) surface shown by atomic force microscopy (AFM) to be dominated by irregularly shaped (001) terraces (Fig. 1).

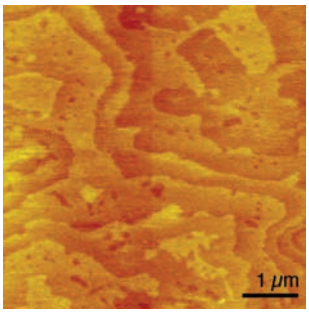

Fig. 1: Atomic force microscope image of a pyrite (001) surface prepared by anaerobic polishing method.

CTR studies of two pyrite (001) surfaces under a helium atmosphere confirm that a reproducible surface structure is obtained in this way. We are combining CTR data with surface electronic and vibrational spectroscopy in order to derive a detailed model for the pristine surface.

A first principles study of the structure and stability of iron-sulfides and their surfaces

Spagnoli, D.*, Wright, K. & Gale, J.D.
Nanochemistry Research Institute, Dept. of Chemistry, Curtin University of Technology, Perth, Australia (*dino@ivec.org)

Iron sulfide minerals are an intrinsic and essential part of the global biogeochemical sulfur cycle [1] and have also been proposed as possible candidates for the catalytic reactions involved in the origins of life [2]. As yet there are very few computational studies which examine the structure and stability of iron-sulfide surfaces that are thought to be important in the iron-sulfur-world.

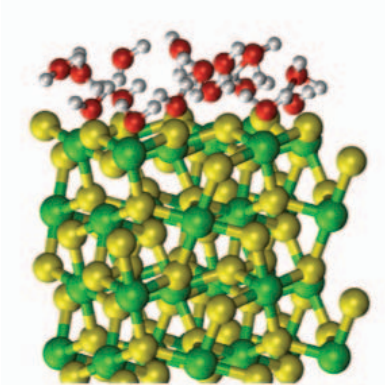

Fig. 1: Simulation of water at the pyrite (001) surface.

Using first principles quantum mechanical methods we preformed a study of the bulk phases of pyrite, marcasite, troilite, and pyrrhotite. Good agreement of the lattice parameters and spin states was found between experimental and simulation data. From these bulk minerals we are able to construct surfaces and begin to explore the structure and stability of solvated iron-sulfide surfaces. Based on this, it is possible to begin to explore both the thermodynamics and activation energies for plausible reaction pathways that control the kinetics for the formation of the precursors of life as catalysed by iron sulfides.

Incorporation of trivalent actinides and lanthanides into Ca-carbonates: process understanding on a molecular level

Stumpf, T.
Karlsruher Institut für Technologie KIT, Institut für Nukleare Entsorgung INE, Karlsruhe, Germany
(Thorsten.Stumpf@kit.edu)

Demonstrating the geochemical aspects of the long term safety of a nuclear waste repository can significantly be improved by a molecular level understanding of the actinides behavior in the geosphere. In particular the interaction of radionuclides with minerals (adsorption, structural incorporation) strongly affects their mobility and retardation. In this presentation we will focus on the interaction of trivalent actinides and lanthanides with Ca-carbonates, with special focus on the structural incorporation.

Carbonates are omnipresent minerals in many rocks which are discussed as potential host for a nuclear waste repository. Furthermore, many waste repository designs include cement based components. Calcite is one of the major secondary alteration products formed during the degradation of cement over geological timescales. Actinide and lanthanide partition data derived from co-precipitation experiments indicate a high sorption affinity of these elements to calcite but a comprehensive understanding of actinide and REE uptake by calcite is not yet available. From a geochemical perspective the molecular level substitution mechanism is of key interest. Trivalent actinides and lanthanides have a similar ionic radius compared to Ca(II), the charge compensation mechanism upon substitution is unclear despite various recent studies.

We have studied synthetically Cm and Eu doped calcite, aragonite and vaterite crystals with Time Resolved Laser Fluorescence Spectroscopy (TRLFS). Particularly the Cm(III) fluorescence spectroscopy provides speciation information at very low concentrations (10^{-12} mol/L). In that sense, Cm(III) has been used here as a molecular probe to study the structural incorporation of trivalent 4f and 5f elements into Ca-carbonates. Site-selective TRLFS measurements at temperatures < 20 K show the presence of various incorporated molecular species and indicate clearly the charge-compensating role of Na^+ during the incorporation of Cm^{3+} and Eu^{3+} into Ca-carbonates.

Ra-barite solid solution formation during recrystallization in aqueous solutions

Curti, E.[1*], Fujiwara, K.[2], Iijima, K.[2], Tits, J.[1], Cuesta, C.[1], Kitamura, A.[2], Glaus, M.[1] & Müller, W.[1]
[1]Laboratory for Waste Management, Paul Scherrer Institute, Villigen, Switzerland ([*]enzo.curti@psi.ch)
[2]Geological Isolation Research Unit, Geological Isolation Research and Development Directorate, Japan Atomic Energy Agency, Tokai-Mura, Japan

High-purity synthetic barite was added to pure water or aqueous solutions containing soluble salts ($BaCl_2$, Na_2SO_4, NaCl and $NaHCO_3$) at 23 ± 2 °C. After a short pre-equilibration time (4 h), the suspensions were spiked either with ^{133}Ba or ^{226}Ra. The isotopic exchange between solid and aqueous phase was then monitored by radiometric analysis over a period of 120-406 days. The data consistently showed a continuous, slow decrease of radiotracer activity in the aqueous phase, both for ^{133}Ba and ^{226}Ra.

Mass balance calculations indicated that the removal of ^{133}Ba from solution cannot be explained by surface adsorption only, as it largely exceeded the 100% monolayer coverage limit. This was a strong argument in favor of recrystallization as the main uptake mechanism. Since complete isotopic equilibration between aqueous solution and solid was approached or even reached in all experiments, we concluded that substantial fractions of the barite initially added to the aqueous solutions had recrystallized during the experiments.

The ^{133}Ba data could be successfully fitted assuming constant recrystallization rates and homogeneous incorporation of the tracer into newly formed barite. An alternative model based on partial equilibrium of ^{133}Ba with the mineral surface (without internal isotopic equilibration of the solid) could not reproduce the measured activity data. Calculated recrystallization rates for the solutions with soluble salts ranged from 2.4 to 16 μmol m^{-2} d^{-1}, with no specific trend related to solution composition. For barite suspended in pure water, significantly higher rates (49 ± 22 μmol m^{-2} d^{-1}) were determined.

Radium uptake was determined by monitoring the decrease of ^{226}Ra activity in the aqueous solution with alpha spectrometry, after filtration of the suspensions and sintering. The Ra uptake results, in conjunction with the recrystallization data, consistently indicated formation of non-ideal solid solutions, with moderately high Margules parameters (W_{AB} =3720-6200 J/mol). These parameters are significantly larger than an estimated value from the literature (W_{AB} =1240 J/mol) [1].

Regardless of the unexpected non-ideal mixing behaviour, our results indicate that radium forms solid solutions with barite at fast kinetic rates and in complete thermodynamic equilibrium with the aqueous solutions. Moreover, this study provides essential quantitative data that can be used for the calculation of radium concentrations in environmentally relevant systems, such as radioactive waste repositories and uranium mill tailings.

Precipitation of rhabdophane ($REEPO_4 \cdot nH_2O$) from supersaturated aqueous solutions: implications for the fate of Rare Earth Elements in natural waters

Roncal-Herrero, T.[1,2*], Rodríguez-Blanco, J.D.[2], Oelkers, E.H.[1] & Benning, L.G.[2]
[1]Géochimie-Biologie Experimentale -LMTG-Université de Toulouse-CNRS-OMP, Toulouse, France ([*]roncal@lmtg.obs-mip.fr)
[2]School of Earth and Environment, University of Leeds, UK

The concentration and distribution of Rare Earth Elements (REE) in aquatic systems is strongly influenced by the dissolution/precipitation of REE bearing phosphate minerals [1]. The goal of this study was to illuminate the role of Rhabdophane (Rha) on the behavior of REE in natural waters.

Aqueous solutions supersaturated with respect to La and Nd Rha were obtained at 5, 25, 50, and 100°C and pH ~1.9 by mixing two solutions containing KH_2PO_4 and $REE(NO_3)_3 \cdot 9H_2O$ (where REE stands for La or Nd). During the experiments, the change in aqueous PO_4 and REE concentrations were followed by ICP-MS and UV-Vis spectrophotometry, while the resulting solids were characterized via powder XRD, SEM, TEM and FTIR.

The formation of Rha occurs via:

$$REE^{3+} + PO_4^{3-} + nH_2O \leftrightarrow REEPO_4 \cdot nH_2O$$

The logarithm of the ion activity product (Log (IAP)) of the reactive fluids with respect to Rha decreased rapidly after mixing tending towards equilibrium. The steady state Log(IAP) in these experiments was found to be ~$10^{-23.0}$ and ~$10^{-21.1}$ at 25°C, for La and Nd Rha respectively [Fig. 1 inset]. Analyses of the solids confirmed that crystalline La and Nd Rha nanoparticles precipitated immediately after mixing. Their initial sizes depended on temperature and REE identity, while growth in both cases was time and temperature dependent (Fig. 1). For example, over 168 h of reaction the La-Rha average particle size increased from 44 to 54 nm at 5ºC and from 54 and 105 nm at 100°C.

The initially rapid equilibration of Rha supersaturated aqueous solutions and the progressive Rha crystal growth observed in our experiments suggests that the REE concentrations of many natural waters may be buffered by Rha phases precipitating from supersaturated natural waters.

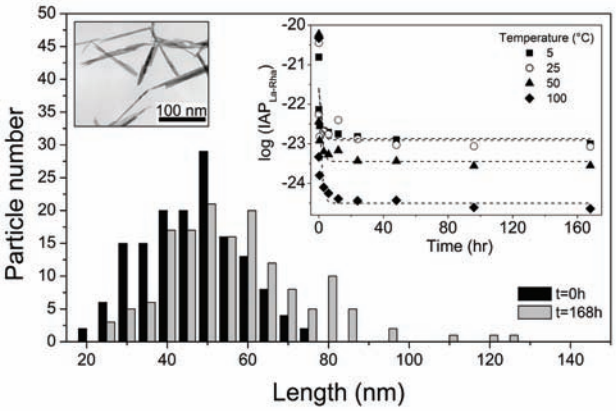

Fig. 1: La-Rha particle length distribution synthesized at T=5 ºC for times t=0 and t=168 hr. The insets show a TEM photomicrograph at T=100 ºC and t=0 hr and the evolution of Log (IAP) for La-Rha as a function of time and temperature.

Sorption and precipitation of phosphate on calcite surfaces

Stelling, J.[1*], Neumann T.[1] & Fischer, U.[2]
[1]Institut of Mineralogy & Geochemistry, KIT - Karlsruhe Institute of Technology, Karlsruhe, Germany
([*]stelling@kit.edu)
[2]Rheinkalk Akdolit GmbH & Co. KG, Pelm, Germany

Calcite is a major constituent of sedimentary rocks on the Earth surface [1] and its crystal growth mechanisms have been studied in detail in the past [2]. Moreover, the ability of calcite to adsorb phosphate from raw, sea and artificial water [3,4] has been investigated intensively to recover P as a valuable nutrient [5]. To date, understanding atomic-level processes that govern the kinetics of calcite growth with respect to foreign ions is still incomplete.

As part of the RECAWA joint project (www.recawa.de, Reactivity of Calcite/Water Interfaces,), we investigate the sorption and co-precipitation processes of phosphate on calcite surfaces from (super)saturated calcite solutions. Solutions were prepared from p.a. grade chemicals ($CaCl_2$, $NaHCO_3$) in MilliQ water (18.2 MΩ·cm), phosphate was added as H_3PO_4 or $Na_3PO_4{\cdot}6H_2O$ (50 to 500 µM/L), pH was adjusted to 8.0, ionic strength to 0.1 M (NaCl). 100 mg of precipitated calcium carbonate (PCC, SSA = 37.45 m^2/g), limestone powder (1.76 m^2/g), Iceland spar (1.6 m^2/g) or Merck $CaCO_3$ p.a. (0.2 m^2/g) powders were added as seed crystals to 20 mL calcite solution and shaken for 24 h. Afterwards, solutions were filtered and HCO_3^-, Ca^{2+}, P concentrations and pH was analysed. Relative to the starting value, the pH of the batch solution remained stable (± 0.15) during the experiments.

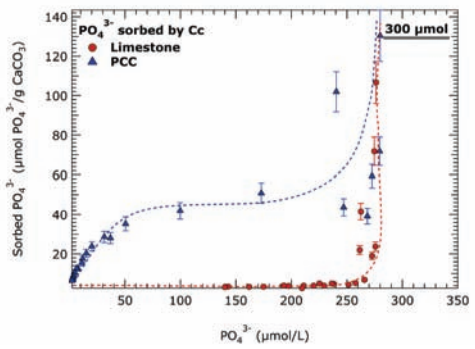

Fig. 1: Phosphate sorption isotherms of limestone (blue) and PCC (red), initial PO_4^{3-} concentration in solution 300 µmol/L.

Preliminary experimental results show that phosphate uptake is much more effective on PCC surfaces than on limestone powder surfaces. Overall decrease of phosphate ranges from 2 % to 100 % depending on the calcite powders. In contrast to limestone experimental series of, phosphate was eliminated from the batch solution of the PCC series completely. Adding high amounts to the batch solution (~25 g/L) results in a complete phosphate elimination, whereas limestone powder decreases the PO_4^{3-} concentration by max. 59% (Fig. 1). Fixation occurs not only due to pure adsorption processes. Multiple mechanisms such as precipitation and (trans)formation into stable Ca-P-compounds are involved in sorption and precipitation processes [6].

Upcoming analytical work of the experimental calcite powders includes the identification of different P fixation mechanisms for which ESEM, XRD and XAFS spectroscopy (XANES/EXAFS) is strongly required.

Nanoscale observations of calcium oxalate overgrowth onto calcite

Ruiz-Agudo, E.[*], Putnis, C.V. & Putnis, A.
Institut für Mineralogie, Universitat Münster, Germany
([*]eruiz_01@uni-muenster.de)

Calcium oxalates have attracted a significant amount of research due to their presence in kidney stones, scale deposits on sugar mill evaporators or natural patinas on calcitic stones in buildings. This has lead to the existence of a voluminous literature dealing with Ca-oxalates formation and dissolution.

An aspect that comparatively has received less attention is the precipitation of oxalates on Ca-bearing phases. In particular, very little is known about the mechanism of calcium carbonate to calcium oxalate transformation. This transformation is of particular relevance for kidney stone formation [1] or oxalate patinas development in building stones [2]. Experimental observations suggest that the growth of oxalates onto calcite follows the typical pattern of a replacement reaction (i.e. coupled dissolution-reprecipitation) where the parent calcite phase acts as a template for nucleation of the new phase. Geider et al. [1] suggested that calcium oxalate grows epitaxially onto calcite on the basis of lattice fit calculations and the observation of the regular orientation of oxalate crystals on calcite crystals. However, no details on the epitaxial relationship between the parent crystal and the overgrowth are given. The exact microscopic mechanism for this transformation remains essentially unexplored.

The present work provides a systematic in situ Atomic Force Microscopy (AFM) study of calcium oxalate growth onto calcite on changing solution composition. Whewellite ($CaC_2O_4{\cdot}H_2O$) crystals precipitated onto Iceland Spar crystals with their {100} and {010} planes parallel to {10.4} calcite faces. Growth of whewellite occurs mainly through formation and propagation of three-dimensional nuclei (Fig. 1). These observations point toward a “Volmer-Weber” mechanism of epitaxial growth, which is characteristic of weak adhesion between substrate and overgrowth. The effect of organics on this transformation has been also studied.

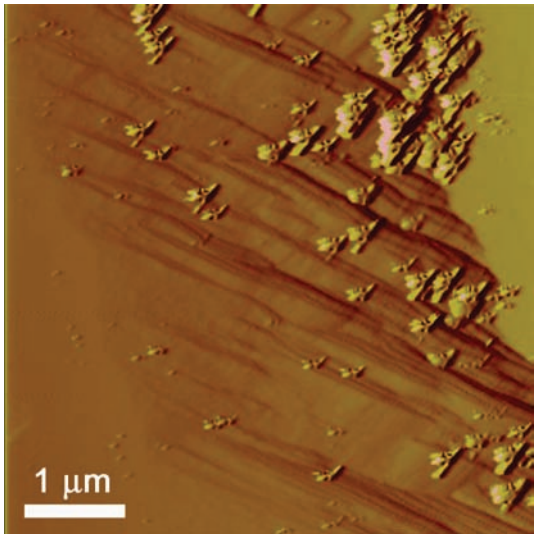

Fig. 1: Calcium oxalate overgrowth on calcite cleavage surfaces.

[1] Geider, S. et al. (1996) *Calcif. Tissue Int.*, **59,** 33-37. [2] Del Monte, M. & Sabbioni, C. (1983) *Environ. Sci. Technol.*, **17**, 518-522.

Structure and reactivity of the calcite - water interface

Heberling, F.[1,2*], Lützenkirchen, J.[1], Denecke, M.A.[1] & Bosbach, D.[2,3]
[1]Institute for Nuclear Waste Disposal, Forschungszentrum Karlsruhe, Germany ([*]Frank.Heberling@kit.edu)
[2]Helmholtz Virtual Institute, Advanced Solid –Aqueous RadioGeochemistry
[3]Institut for Energy Research 6, Forschungszentrum Jülich, Jülich, Germany

In this experimental study the calcite surface properties are characterized over a wide range of pH and p(CO_2) conditions using electrophoretic zetapotential and streaming potential measurements. In situ surface diffraction measurements at the calcite(104)-water interface are used to search for structural changes associated with the changes in the composition of the contact solution.

The zetapotential is found to be mainly determined by the calcium and carbonate ion concentration. pH plays only a minor role. The part of the 3D structure of the calcite - water interface surface diffraction measurements are mainly sensitive to does, however, not change significantly, even upon extreme changes in the composition of the contact solution. At all conditions the surface ions relax only slightly from their bulk positions, and two layers of water are observed above the surface. Water molecules of the first layer are located 2.35 ± 0.05 Å above the surface calcium ions, those of the second layer are located 3.24 ± 0.06Å above the surface, associated with the surface carbonate ions. No indications for calcium or carbonate inner-sphere complexes at flat terraces on the calcite(104) face are observed.

Based on these observations a new Basic-Stern surface complexation model for calcite is developed that describes the measured zetapotentials exclusively by outer-sphere ion adsorption.

The effect of sulphate and magnesium on the formation and stability of vaterite

Bots, P.[*], Rodriguez-Blanco, J.D., Shaw, S. & Benning, L.G.
School of Earth and Environment, University of Leeds, United Kingdom ([*]p.bots@see.leeds.ac.uk)

Vaterite (μ-$CaCO_3$) rarely forms in natural systems, as it is thermodynamically unstable with respect to calcite and aragonite [1] and it rapidly transforms in solution to the more stable phases. However, it has been shown that vaterite can be stabilized by certain inorganic (e.g. SO_4^{2-}) [2] and organic additives [3], yet a quantification of these processes is still lacking. The aim of this study was to quantify the effect of inorganic additives on the nucleation, formation and stability of vaterite.

The effect of SO_4^{2-} and Mg^{2+} on the crystallisation pathways of vaterite from amorphous calcium carbonate (ACC) was studied using synchrotron-based time resolved (seconds /frame) Small – and Wide Angle X-ray Scattering (SAXS/WAXS) on station I22 at Diamond Light Source. The reaction was quantified by mixing $CaCl_2$ and Na_2CO_3 at SO_4/CO_3 = 0 and 0.1. Equivalent off line experiments with varying SO_4/CO_3 were also carried out. Furthermore, vaterite, crystallized from a solution with SO_4/CO_3 = 25, was aged with increasing SO_4^{2-} concentrations for up to 24h. Finally, the effects of these additives on vaterite formation and its stability were studied by performing 48h long constant addition experiments.

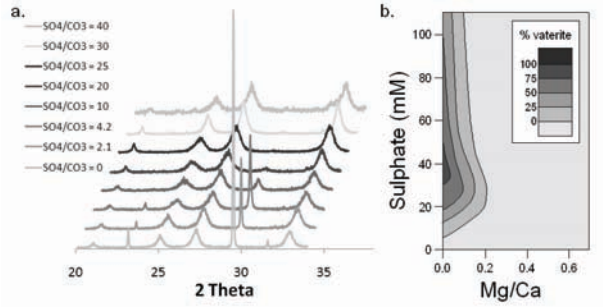

Fig. 1: a. XRD patterns from off line experiments as a function of SO_4/CO_3; b. fraction of precipitated vaterite from the constant addition experiments as a function of Mg/Ca and SO_4^{2-}.

The synchrotron SAXS/WAXS data showed that pure ACC transformed to vaterite within 10s of seconds [4]. Increasing SO_4/CO_3 to 0.1 in the initial solutions delayed the transformation of ACC to vaterite by about 25%. However, increasing Mg/Ca to 0.1 completely inhibited vaterite nucleation and promoted the nucleation of calcite. The off line crystallization data (Fig. 1a) showed that with increasing SO_4/CO_3, vaterite stability increased. Vaterite precipitated at SO_4/CO_3 = 25 (structural SO_4/CO_3 = 0.04), was stable up to 24h in a solution with SO_4^{2-} concentrations higher than 30mM. Data from the constant addition experiments (Fig. 1b) also confirmed that SO_4^{2-} promoted both the formation and stability of vaterite. Its stabilization likely occurred by the incorporation of SO_4^{2-} [2]. However, increasing Mg/Ca to 0.2 (Mg/Ca in seawater is 5.4) completely inhibited vaterite formation (Fig. 1b), which was comparable to the SAXS/WAXS results. These results show that SO_4^{2-} has a clear stabilizing effect on vaterite, while Mg^{2+} prevents its formation.

Our results show how vaterite can be formed and stabilized inorganically and give clues on calcium carbonate mineralogy in multiple environmental settings and industrial processes.

Influence of sulfate groups on the polymorphism of $CaCO_3$

Fernández-González, Á.[1*], Fernández-Díaz, L.[2] & Prieto, M.[1]
[1]Depto. de Geología, Universidad de Oviedo, Spain
([*]mafernan@geol.uniovi.es)
[2]Depto. de Cristalografía y Mineralogía, Universidad Complutense de Madrid, Spain

Calcium carbonate minerals often form in evaporitic environments. In this type of environments, the concentration of dissolved sulfate is high and calcium carbonate minerals incorporate this anion in their structures during growth. There are evidences that the presence of sulfate in the crystallization medium affects the calcium carbonate polymorph selection, promoting the formation of metastable vaterite and inhibiting the transformation of this phase into the more stable calcite [1,2]. With the aim of understanding this influence we conducted (1) precipitation and maturing experiments of $CaCO_3$ from aqueous solutions containing different SO_4^{2-}-CO_3^{2-} ratios and (2) a molecular simulation study of the effect that the isomorphic substitution of a small amount of carbonate by sulfate has on the relative energies of vaterite, aragonite and calcite.

The X-ray diffraction analyse of the precipitates sampled after different reaction times showed that, when the reaction time is short (≤ 1 hour), these precipitates always consist of a mixture of calcite and vaterite, irrespective the initial SO_4^{2-}-CO_3^{2-} ratio in the aqueous solution. However, the relative abundance of vaterite increases with the amount of sulfate in the solution. After reaction times longer than 24 hours, vaterite has totally transformed into calcite when the SO_4^{2-}-CO_3^{2-} ratio is low (≤ 1) but persists as a major phase component of the precipitate when the SO_4^{2-}-CO_3^{2-} ratio is higher. Moreover, the reaction time required for the total transformation of vaterite into calcite also increases with the sulfate content in the solution.

The computational modeling of the substitution of small percentages of CO_3^{2-} groups by SO_4^{2-} in the structures of calcite, aragonite and vaterite shows that this substitution introduces an important distortion in calcite and aragonite structures but very limited in vaterite structure. Moreover, it is energetically favorable in the case of vaterite, but unfavorable in calcite and aragonite structures.

The progressively more sluggish kinetics of the transformation of varite into calcite as the content of sulfate in the aqueous solution increases can be related to changes in the relative solubility of these two polymorphs due to the incorporation of sulfate groups in their structures. These changes are consistent with the results of our computational modeling.

Computational study of the calcium carbonate-water interface

Raiteri, P.[*] & Gale, J.D.
NRI and Dept. of Chemistry, Curtin University of Technology, Perth WA, Australia ([*]paolo@ivec.org)

Calcium carbonate is important in many fields of geology, chemistry and biology for its role in geo-sequestration of carbon dioxide and bio-mineralization. Despite its importance, the atomic mechanisms underlying the nucleation and growth of $CaCO_3$ crystals are not fully understood, either from the experimental or theoretical standpoints. In particular, the role of speciation and of hydration of the growing nucleus in the early stages of growth is completely unknown.

To gain a better insight into these processes we have developed a new force field which accurately reproduces the thermodynamics of hydration of ions and molecules as well as the dissolution enthalpies of the solid phases [1]. Molecular dynamics simulations of the aqueous interface of virtually infinite calcite layers and of nanoparticles (Fig. 1) have then been performed to study the molecular processes underpinning the calcium carbonate interfacial properties. Moreover, to address the role of bicarbonate, different approaches to simulate the proton reactivity within our classical force field framework have been explored and compared against large scale density functional theory calculations. The performance of all reactive approaches will be analysed in terms of their computational efficiency and the reliability of their description of the properties of the mineral-water interface.

Uptake of heavy metals by abiogenic calcite and aragonite from freshwater and seawater

Carneiro, J.F.*, Stoll, H.M. & Prieto, M.
Depto. de Geología, Universidad de Oviedo, Spain
(*joana@geol.uniovi.es)

In the last decades, continental anthropogenic inputs have increased the concentration of heavy metals in many estuarine and coastal areas, enhancing the potential harmful effects for organisms. One example of coastal contamination is found in the southwestern coast of Spain, where the Tinto and Odiel rivers release metals from the Iberian Pyrite Belt into the Gulf of Cadiz [1]. Several geochemical studies have focused on the sorption of divalent metals on calcite from freshwater (e.g. [2]), but few have considered the removal of metals by aragonite (with the exception of [3] and [4]). Likewise, the inorganic uptake of metals from seawater by calcite and aragonite has not been extensively studied.

The aim of this study is to compare the removal of the metals Cd, Co, Ni, and Zn from both freshwater and seawater, by sorption on abiogenic calcite and aragonite. To evaluate the significance that this uptake could have on a reduction of metal concentrations in aqueous solutions, we ran several series of batch interaction experiments. These experiments were carried out in continuously stirred reactors at ambient conditions. For each series, mineral particles (either calcite or aragonite) reacted with a metal-bearing aqueous-solution (either calcite-saturated deionised water or artificial seawater). The aqueous solutions used were enriched with 1 ppm of Cd, Co, Ni, or Zn. Aqueous samples were collected at different reaction times, for 7 to 15 days. The metal concentrations in the samples were determined by inductively coupled plasma atomic emission spectrometry (ICP-AES).

Fig. 1 shows a decrease in the concentration of Cd in solution from about 1000 ppb, at the onset of the experiment, to nearly 550 ppb, after 2 weeks of interaction. These results suggest that Cd can be effectively taken up from artificial seawater by calcite, under the experimental conditions.

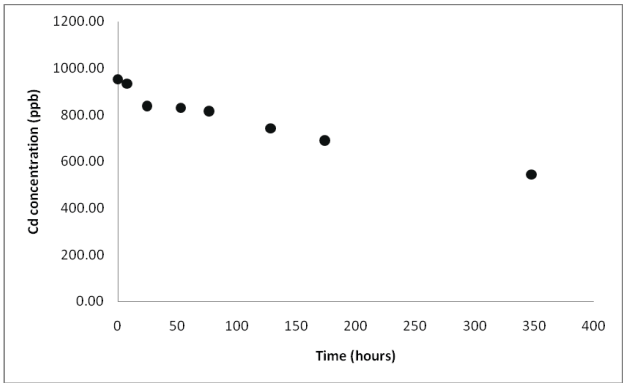

Fig. 1: Concentration of Cd in artificial seawater for different reaction times.

An experimental study of monazite dissolution in low-temperature (150 and 200°C) as a function of fluid chemistry

Čopjaková, R.[1*] & Škoda, R.[2]
[1]Czech Geological Survey, Brno, Czech Republic
(*copjakova@sci.muni.cz)
[2]Dept. of Geological Sciences, Masaryk University, Brno, Czech Republic

Low temperature (150 and 200°C) experiments concerning hydrothermal alteration of natural monazite were carried out. Monazites were treated in steel pressure vessels with PFTE liner using fluids of different compositions: distilled water, 2M solutions of $CaCl_2$, NaF+KF and NaOH in H_2O during 100 days. Quartz, plagioclase and biotite were added into the vessels to simulate natural siliciclastic sedimentary basin.

Monazite dissolution increases with increasing temperature and in relation to fluid chemistry in following order: distilled water < Cl^- fluids < OH^- fluids < F^- fluids; well documented by different degree of surface corrosion (corrosive furrows and etch pits). Newly-formed REE phases (fluorides and silicates) were observed only in experiments with F^- and OH^- fluids. F-rich fluids at 200°C caused almost total monazite destruction accompanied by growth a variety of secondary REE phases.

The newly-formed REE phases ($REEF_3$-CaF_2 s.s.) in the experiment with F^- fluids at 150°C show REE patterns similar to parent monazite. In 200°C experiments (where several secondary REE phases precipitated) was observed a conspicuous evolution in REE distribution from inner to outer zone of the newly-formed REE mineral aggregates: from steep LREE enriched chondrite normalized REE-patterns with positive Ce anomaly to relatively flatter ones often with negative Ce anomaly. This trend is probably resulted by greater HREE solubility in hydrothermal fluids ; strange behaviour of Ce can be attributed to partial oxidization of Ce^{3+} to Ce^{4+}, but only in F-rich fluids the oxidization of Ce is clearly confirmed by precipitation of Ce^{4+} rich phase, corresponding to Ce^{4+} analogue of umbite ($K_2CeSi_3O_9{\cdot}H_2O$).

The outermost part of monazite relicts overgrown by newly-formed phases leached in F^- fluids shows significant depletion of P, Th, U and Pb and enrichment in F, Ca, K and Na compared with fresh monazite. It suggests selective removal of some elements from altered monazite prior to the total monazite dissolution. Low contents of U and Pb in all newly-formed phases and altered parts of natural monazite and high contents of U in fluids (especially in OH- and F-rich fluids) confirm preferential release of Pb and U from monazite into the solution and their higher solubility in OH- and F-rich fluids.

The REE contents in solutions are quite similar for all types of fluids, the most typically 1-8 μg/l for Sm, Gd, Dy, Er and 8-25 μg/l for La, Pr, Nd and Y, except OH-rich fluids at 200°C, with the solubility of REE 10-200 times higher. Cerium contents are relatively low, the most typically < 15 μg/l, except the F^- and OH^- fluids at 200°C (120 and 3111 μg/l, respectively). The solubility of REE in fluids increases in this order: distilled water ~ F^- fluids < Cl^- fluids < OH^- fluids. All type of fluids show flat chondrite normalized REE patterns predominantly with negative Ce anomalies. Only F^- and OH^- solutions from 200°C experiments show steeper LREE enriched pattern without negative Ce anomaly. This supports nonstoichiometric monazite dissolution with preferential leaching of HREE and the highest stability of Ce in the monazite in the experiments where no secondary phases precipitated.

Molecular simulation of the aragonite-calcite polymorphic transformation induced by sulphate substitutional impurities

Fernández-González, A.[1*], Fernández-Seivane, L.[2,3], Fernández-Díaz, L.[4], Ferrer, J.[2,3] & Prieto, M.[1]
[1]Depto de Geología, Universidad de Oviedo, Oviedo, Spain

It is well known that when calcium carbonate precipitates from aqueous solutions, the presence of dissolved foreign ions in the fluid can favour the formation of metastable $CaCO_3$ polymorphs. For example, it has been stated that small concentrations of Mg^{2+} or Sr^{2+} in the growth medium promote the precipitation of aragonite instead of the more stable calcite, whereas high Mg:Ca ratios favours the precipitation of amorphous calcium carbonate (ACC). The presence of dissolved foreign anions has also been related to the formation metastable phases, like the hydrated $CaCO_3$ ikaite ($CaCO_3.6H_2O$), in the case of significant concentrations of phosphate. Moreover, SO_4^{2-}:CO_3^{2-} ratios in the fluid seem to stabilize vaterite [1]. Although the effect of some of these foreign ions on the polymorph selection of $CaCO_3$ can be attributed to specific surface effects, it can not be ruled out that the incorporation of these impurities in the crystalline structure of the precipitated calcium carbonate could also have a significant influence both on the formation of metastable phases and on subsequent polymorphic transformations of the metastable precursors. Molecular simulations methods arise as useful tools to evaluate this influence, since they can provide accurate information at the atomic scale on the possible mechanisms involved in the development of impurity-induced polymorphic transformations. In the particular case of $CaCO_3$, molecular simulation methods can unfold into a deeper understanding of the energetic and the nanoscopic phenomena affecting the aragonite-calcite limit.

In this work, the aragonite-calcite transformation induced by the SO42+-CO32+ substitution has been simulated both by first principles (DFT) and empirical potential methods [2,3]. The relaxation of the aragonite structure doped with a certain proportion of sulphate anions readily converges to a calcite-type structure. The evolution of the corresponding powder diffraction diagrams has also been simulated by Rietveld analysis techniques. The distortion of the local environment around sulphate anions occupying carbonate positions in a aragonite-like crystal structure is relaxed through structural changes, which eventually lead to the global transformation into a calcite-like structure. The application of this approach to other mineral polymorphic transformations is likely to provide a better understanding of the behaviour of key rock-forming mineral systems.

Investigating the link between topography and reactivity of mineral surfaces in solution

Godinho, J.[*] & Piazolo, S.
Dept. of Geological Sciences, Stockholm University, Stockholm, Sweden
([*]jose.godhino@geo.su.se)

In this study the reactivity of mineral surfaces in aqueous solution is investigated by analysing the changes in topography.

By studying the surface at the nano scale with confocal profilometry and SEM, as well as the composition of the liquid phase by ICP, through time, it is possible to relate the reaction rate to the presence of high energy sites on the surface (i.e. grain boundaries). The combination of these techniques allows the observation of topographic changes and the determination of its influence on the reaction rates.

A batch reactor is used, with and without stirring. The solution is kept far from equilibrium and in a range of pH from 2 to 4.

Here, we present first results of such experiments from a variety of minerals: natural and sintered fluorite, natural olivine and sintered ceria (used as an analogue for uranium dioxide i.e. nuclear waste pellets).

Crystallisation of $Ca_6Al_2O_6(SO_4,SeO_4)_3{\cdot}26H_2O$ solid solution

Jiménez, A.* & Prieto, M.
Dept. de Geología, Universidad de Oviedo, Spain
(*amjimenez@uniovi.es)

Ettringite ($Ca_6Al_2O_6(SO_4)_3{\cdot}26H_2O$) is a phase formed during the early hydration of Portland cements when sulphate is present in alkaline environments. The crystal structure of ettringite accepts numerous oxyanions, some of them radioactive and toxic. For instance, selenate (the form of selenium in alkaline medium surroundings) can be placed in the crystalline structure of ettringite by substituting sulphate groups [1]. However, the extent of selenium substitution in ettringite phase remains poorly understood. The aim of this work is to crystallise different members of $Ca_6Al_2O_6(SO_4,SeO_4)_3{\cdot}26H_2O$ solid solution and to determine its composition by X-ray diffraction.

Crystallization experiments were performed by mixing CaO (24 mmol) and stoichiometric amounts of $Al_2(SO_4)_3$, Al_2O_3, Na_2SeO_4 (Table 1) in ultrapure water in a nitrogen glove-box to minimise the CO_2 contamination. The mixture was stirred at 300 rpm during 48 hours and then it was maintained statically during two weeks at room temperature in nitrogen atmosphere. The precipitates formed during these experiments were filtered using 0.45 μm filters and analysed by powder X-ray diffraction (XRD). Two reference diffractograms of $Ca_6Al_2O_6(SO_4)_3{\cdot}26H_2O$ (41-1451) and $Ca_6Al_2O_6(SeO_4)_3{\cdot}26H_2O$ (42-224) were used to identify the pure end members as well as to calculate the structural data of the intermediate member of the solid solution.

Table 1: Parent solutions (mmol), composition and cell parameters

	$Al_2(SO_4)_3$	Na_2SeO_4	Al_2O_3	X	a	c
SSe1	4	0	0	0	11.234	21.371
SSe2	3	3	1	0.38	11.292	21.979
SSe3	2.5	4.5	1.5	0.53	11.317	21.878
SSe4	2	6	2	0.59	11.320	21.469
SSe5	1	9	3	-	11.309	22.077
SSe6	0	12	4	1	11.391	22.238

The main reflections (100, 110, 104, 114, etc.) present in the standard diffractograms have been identified in all precipitates. These reflections exhibit a continuous shift towards lower 2θ angles from the sulphate end member (SSe1) to the selenate end member (SSe6). These results confirm that different members of the solid solution have been crystallised. Table 1 shows the dimensions of the unit cell parameters (hexagonal setting) calculated using the computer program X'Pert Plus. An estimation of the solid-phase composition can be obtained from the unit cell parameter *a* (assuming Vegard's law), as shown in Table 1. As can be observed, in the case of SSe5, the value of *a* does not continue the linear trend. These results indicate that even though selenate anions can substitutes for sulphate in ettringite crystal structure, a compositional gap between $0.59 < X(SeO_4) < 1$ can not be discarded.

Stability of selenites and arsenates in oxidizing environments: Eh–pH diagrams of the systems $Me–Se–H_2O$ and $Me–As–H_2O$ (Me=Co, Ni, Fe, Cu, Zn, Pb) at 298 K

Krivovichev, V.G.[1], Charykova, M.V.[1], Yakovenko, O.S.[1*] & Depmeier, W.[2]
[1]Saint-Petersburg University, Saint-Petersburg, Russia
(*ojakovenka@gmail.com)
[2]Institut für Geowissenschaften, Universität Kiel, Germany

Since the discoveries of toxic properties of selenium and arsenic, there has been continual study of the geologic occurrence and geochemistry of these elements in oxygenated aqueous environments. Drainage from mineralized and mined areas may have high dissolved selenium and arsenic concentrations, and of major interest as the natural sources of Se and As in waters, soils and plants are likely to be the low-temperature oxidizing environments in the vicinity of ore bodies which contain Se- and As-bearing sulfides, arsenides and selenides [1].

The most selenites and arsenates were formed at chemical weathering of ores by oxygenated waters establishes conditions of increased Eh and low or neutral pH (at seasonal fluctuations of temperatures and atmospheric pressure). The interpretations are summarized on the Eh-pH diagrams, synthesized from equilibrium calculations, and reported geologic occurrences. The most recent thermodynamic data available [2] were used for the construction of diagrams from reactions which are balanced equations of Eh-pH relationships among species which are thermodynamically stable within the ranges of oxidation potential and pH considered for each reaction.

The estimation of activity of the components in natural waters which are formed out of zones natural and anthropogenous pollution by selenium and arsenic ($a_{\Sigma Se} = 10^{-9}$, $a_{\Sigma As} = 3{\cdot}10^{-8}$, $a_{\Sigma Fe} = 10^{-5}$, $a_{\Sigma Cu} = 10^{-7}$, $a_{\Sigma Zn} = 5{\cdot}10^{-7}$, $a_{\Sigma Co} = {\cdot}10^{-8}$, $a_{\Sigma Ni} = 6{\cdot}10^{-8}$, $a_{\Sigma Pb} = 10^{-8}$) and waters which are formed in an oxidation zone ($a_{\Sigma Se} = 10^{-5}–10^{-4}$, $a_{\Sigma As} = 10^{-3}$, $a_{\Sigma Fe} = 10^{-2}$, $a_{\Sigma Cu} = 10^{-2}$, $a_{\Sigma Zn} = 10^{-2}$, $a_{\Sigma Co} = 10^{-3}$, $a_{\Sigma Ni} = 10^{-2}$, $a_{\Sigma Pb} = 10^{-4}$) was done. Calculation and construction of diagrams Eh–pH was spent by means of software package Geochemist's Workbench (GMB 7.0). The used databank includes thermodynamic characteristics for 46 elements, 47 basic species, 48 redox couples, 551 aqueous species, 624 solid phases, 10 gases. Eh–pH diagrams of systems $Me–Se–H_2O$ (Me=Co, Ni, Fe, Cu, Zn, Pb) have been constructed for the average content of these elements in underground waters and for their contents in acidic waters of the oxidation zones of sulphide deposits. The formation of selenites and arsenates of Co, Ni, Fe, Cu, Zn, Pb in near-surface conditions are discussed. For the geologic purposes of this work, ionic concentrations have been considered equivalent to ionic activities.

Eh-pH stability relationships have been determined for selenites and arsenites (chalcomenite, cobaltomenite, alpheldite, mandarinoite, molibdomenite, and adamine, annabergite, symplesite, scorodite, schultenite, erythrite) and in order to interpret conditions of formation of these minerals and to compare their geologic stabilities of ore deposits.

These parameters define migration of selenium and arsenic, and their precipitation in the form of various solid phases. The understanding of mechanisms of their behavior in the near-surface conditions is one of actual problems of modern mineralogy and geochemistry and it is very important for the solving of some environmental problems.

Epitaxial growth of brushite ($CaHPO_4{\cdot}2H_2O$) on gypsum cleavage surfaces: an AFM study

Pinto, A.J.[1,3*], Ruiz-Agudo, E.[2], Putnis, C.V.[2], Putnis, A.[2], Jiménez, A.[3] & Prieto, M.[3]
[1]CREMINER, Dept. of Geology, University of Lisbon, Portugal ([*]afipinto@fc.ul.pt)
[2]Inst. of Mineralogy, University of Münster, Germany
[3]Dept. of Geology, University of Oviedo, Spain

Brushite ($CaHPO_4{\cdot}2H_2O$) can grow epitaxially on gypsum ($CaSO_4{\cdot}2H_2O$) cleavage surfaces as a result of the interaction between slightly acidic, phosphate-bearing aqueous solutions and gypsum [1]. The present study investigates the phenomenon of mutual orientation at the nanoscale, by means of Atomic Force Microscopy (AFM). The experiments consisted of placing freshly cleaved gypsum fragments in contact with slightly acidic phosphate-bearing solutions, in an AFM fluid-cell. This allowed *in situ* observation of micro and nano-topographical features on gypsum cleavage surfaces as the interaction process evolved.

The structural relationships between gypsum (space group *A2/a*) and brushite (space group *Aa*) give rise to several crystallographic peculiarities such as the induced 2-fold twining, habit polarity and topographic effects due to the coalescence of equally oriented individuals (Fig. 1).

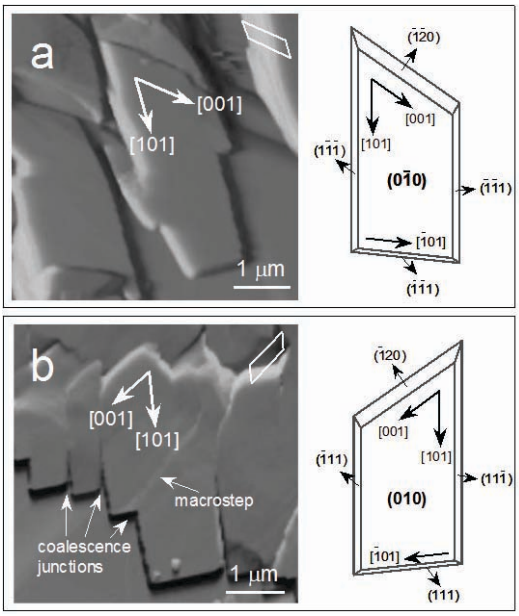

Fig. 1: AFM images of the epitaxial growth of brushite on **a)** gypsum's (0 $\bar{1}$ 0) and **b)** (010) cleavage surfaces.

The observed brushite growth is strongly anisotropic, involving a growth rate relationship of [101]>[$\bar{1}$ 01]>[010] (*Aa* space group), which leads to tabular morphologies elongated on [101]. The coupling between growth and dissolution is reflected by growth rate fluctuations due to changes in the saturation state of the solution with respect to both brushite and gypsum.

Modelling of rare earth elements adsorption onto hydrous manganese oxide using a diffuse double-layer surface complexation model

Pourret, O.[1*] & Davranche, M.[2]
[1]Dépt. Géosciences, Institut Polytechnique LaSalle-Beauvais, Beauvais, France ([*]olivier.pourret@lasalle-beauvais.fr)
[2]Géosciences Rennes, Université Rennes 1, Rennes, France

Manganese oxides are important scavengers of trace metals and especially rare earth elements (REE) in the hydrosystems. In order to better understand REE behavior, which are geochemically important tracers, modeling REE adsorption onto manganese oxide should be considered. The inclusion of Mn oxides in speciation models suffered from a lack of comprehensive set of sorption reactions consistent with a given surface complexation model (SCM). In consequence there are large discrepancies between published sorption data and predictions performed with available models. The compilation established by Tonkin et al. [1] was selected to describe surface complexation reactions for synthetic hydrous Mn oxide (HMO) using a two surface site and the diffuse double layer SCM model. The same specific surface area (i.e., 746 m^2/g), surface side density (i.e., 2.1 mmol/g) and pH_{IEP} (i.e., 2.2) were selected. Two sites (≡XOH and ≡YOH) were used with pK_{a2} of 2.35 (≡XOH) and 6.06 (≡YOH). The fraction of high affinity sites was fixed at 0.36.

Published data of REE sorption onto Mn oxides [2,3] were used to determine equilibrium surface complexation constants for lanthanide. They were modelled using the computer programs PHREEQC [4] and PhreePlot [5]. Both programs used the Nagra/PSI data base [6], which was modified to include well-accepted infinite-dilution (at 25 °C) of inorganic species.

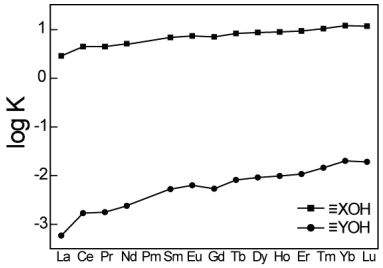

Fig. 1: REE patterns for log K (≡XOH-REE) and log K (≡YOH-REE).

The influence of pH, ionic strength and metal loading were combined and log K determined are displayed in Fig. 1. As illustrated on Fig. 1, log K globally increase from light REE to heavy REE and more specifically display a convex tetrad effect. At low metal loading, ≡YOH site type strongly express their affinity towards REE whereas at higher metal loading ≡XOH site type does. This study evidences thus heterogeneity in the distribution of the Mn oxide binding sites among REE. Eventually, as redox was not considered, Ce behavior was not correctly predicted. Indeed, Ce(III) may oxidize to Ce(IV) by oxidation scavenging with Mn oxide and such process should be further modeled.

The role of the surface fluid layer in the control of crystal growth

Putnis, C.V.[*] & Ruiz-Agudo, E.
Institut für Mineralogie, University of Münster, Germany
([*]putnisc@uni-muenster.de)

Atomic force microscopy (AFM) experiments have shown that growth on mineral surfaces can occur from solutions when the bulk composition is undersaturated with respect to the precipitating phase. As growth can only take place from supersaturated solutions, the implication is that the composition of the solution in the fluid boundary layer in contact with the surface must become supersaturated with the new phase growing at the mineral surface. This has been observed in a number of systems, including the growth of new phases on calcite cleavage surfaces, such as Ca phosphonates, and on gypsum surfaces, such as Ca phosphates, where the partial dissolution of the substrate provides ions included in the new phase. The precipitation of calcite from pure water flowing over a stressed calcite surface is a clear example of a boundary layer becoming supersaturated with the precipitating phase when the bulk fluid contains no ions included in the new phase. This can be explained in terms of the increased solubility of stressed calcite allowing the boundary layer to become supersaturated with an unstressed calcite phase which then precipitates. The thickness of the boundary layer can be deduced from the solution composition and the reacting surface area.

The concept of a boundary layer becoming supersaturated with respect to another phase, which then precipitates, is essential to the understanding of coupled dissolution-precipitation as a mechanism of mineral replacement [1]. Real-time phase-shift interferometry has been used to show the steep compositional gradient at the surface of a crystal of KBr being pseudomorphically replaced by KCl [2] and this has been used as a model system for more complex earth systems during such processes as metasomatism, metamorphism and weathering.

[6]Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität, Bochum, Germany

Ni-bearing tourmaline crystals from the Berezovskoe gold deposit, Middle Urals, Russia, are optically anomalous and show a heterogeneous biaxial optical character [1]. Domains of different optical orientation and 2*V* (from 4 to >10 degrees) correspond directly to trigonal prism |100|, |010| and pedion |001| sectors, indicating sector twinning or optical sectoral zoning. Irregular domains of different optical orientation and undulatory extinction are observed within some sectors and are attributed to strain. Crystal structure refinement was done using single crystal X-ray diffraction (R = 4.41%), with a triply primitive pseudo-hexagonal cell to mimic the hexagonal tourmaline cell [a 15.903(1) b 15.9118(8) c 7.2304(4), α 90.063(2) β 89.793(2) γ 119.742(3) V 1588.57(18)].

Compositional sectoral and concentric zoning are also observed within the crystals. The distribution of Ni, Cr and Fe in the prism sectors shows clear indication of concentric zoning. The distribution of Na and Mg is different from that of Ni, Cr and Fe. There is no obvious concentric zoning within the prism sectors, nor is there an observable difference in concentration between nonequivalent prism sectors. There is, however, a distinct concentration difference of Na and Mg between the prism sectors and the pedion sector.

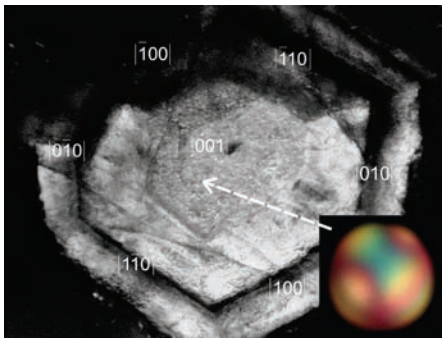

Fig. 1: A (001) section of Ni-rich tourmaline under crossed polars. The section is roughly 500 μm across. The |0-10| and |1-1 0| sectors are close to extinction while other sectors are not. Inset in lower right corner is an interference figure taken within the |001| sector.

In contrast to previous studies, the observed dissymmetrization occurs as a result of inequalities of both the hexagonal *Y* and *Z* tourmaline sites. The ordered arrangement of cations on the *Y* and *Z* sites and the correlation of optical orientation with specific sectors indicate that dissymmetrization occurred by differential incorporation of constituent elements at structurally different atomic sites at the surface of the crystal during growth.

Dissolution kinetics of tremolite in natural and biological conditions. Effect of citrate

Rozalén, M.[1*], Fiore, S.[2], Gervilla, F.[1] & Huertas, F.J.[1]
[1]Instituto Andaluz Ciencias Tierra, CSIC-UGR, Granada, Spain ([*]mrozalen@eez.csic.es)
[2]Environmental and Medical Mineralogy and Geochemistry – IMAA- CNR, Tito Scalo (PZ), Italy

The study of the degradation mechanism of asbestos under natural and biological conditions is essential to understand the clearance mechanisms of particles inhaled in the human body and the development of diseases as lung cancer or mesothelioma. The aim of this study is to evaluate tremolite dissolution rates by using soil and human-body conditions, including citrate as a proxy for organic acids in alveolar fluids.

Tremolite from Sierra Nevada (Granada, Spain) was used as a starting material. The effect of pH under Earth surface conditions was investigated using batch reactors at 25°C and buffered solutions (pH 1-8) with 0.01 M KNO_3 as background electrolyte. Aliquots of the suspension were filtered and analyzed for dissolved Si along time in order to calculate overall dissolution rates. The results show that log rate decreases linearly from -12.28 to -13.32 mol/gs when pH increases from 1 up to 5.6. The empirical rate law obtained correspond with a proton promoted dissolution mechanism:

$$\log Rate_{Si}(mol/gs) = -12.07 - 0.21pH$$

The effect of citrate on the dissolution rate was measured at 37ºC (corporal temperature) in stirred flow-through reactors by using modified Gamble's solutions at pH 4 (macrophages) and 7.4 (interstitial fluids) containing 0, 0.15, 1.5 and 15 mM of citrate. The dissolution rates calculated from Si concentration in the output solutions showed a little effect of temperature between 25 and 37°C. The results obtained point out that citrate enhances dissolution rates at both pH 4 and 7.4, although in a different grade: At pH 4 and 15 mM concentration, citrate increases almost 6 times tremolite dissolution rates with respect to citrate free solutions. At pH 7.4 the effect of similar citrate concentration is slighter, increasing 3 times dissolution rates with respect to citrate free solutions.

The overall dissolution rate has been expressed as the contribution of proton and ligand promoted dissolution mechanism and the concentration dependence can be expressed as follows:

$$\log Rate_{Si}(mol/gs) = -11.52 - 0.22\log[Cit] \text{ at pH 4}$$

$$\log Rate_{Si}(mol/gs) = -12.62 - 0.17\log[Cit] \text{ at pH 7.4}$$

These results suggest that the mechanism promoted by ligands needs to be considered in order to quantify asbestos dissolution in both soils and biological conditions. More studies are necessary to evaluate the species in solution, their interact with the mineral surface and their role in the dissolution process(es).

In-situ and ex-situ evaluations of calcite growths in laboratory and natural field experiments

Satoh, H.[1,2*], Tsukamoto, K.[2] & Ueda, A.[3]
[1]Mistubishi Materials Co., Naka, Japan ([*]hsatoh@mmc.co.jp)
[2]Tohoku University, Sendai, Japan
[3]Kyoto University, Kyoto, Japan

Recent study of growth kinetics of calcite is highly focused on underground storages of carbon dioxide. In Japan, utilization of geothermal field is considered to be a potential site for the CO_2 sequestration, because of faster dissolution and precipitation reaction than that at normal aquifers. In order to estimate the CO_2 capturable budget and its feasibility, we conducted three experiments: (1) laboratory experiment by in-situ interferometry; (2) field experiments at the surface monitoring station of the Ogachi geothermal research laboratory, Japan; (3) field experiment of on-site reacted samples recovered from GL-1000 m deep hydrothermal.

Laboratory experiment using a PSI-M (phase-shift interference microscope [1]) was performed at 22-200°C, 0.1-3.5 MPa. Normal pressure runs at 0.1 MPa were performed to determined spiral growth kinetics. Results showed growth curves of hillock as a function of supersaturation (Q/K_{sp}, e.g., [2,3]). Their growth rates showed dependency on temperature from 22 to 100°C [3], which enables estimation of spiral growth at higher temperature. Calcite growth at higher temperature showed significant enhancement of 2D nucleation.

Ex-situ runs at the surface was conducted using flow-through chambers which is connected to the recycling system comprised of CO_2-enriched groundwater (~600 ppm) and hot dry rock (~200°C) beneath Ogachi geothermal field. During 60 min, prepared hillocks of calcite showed successive growth in normal velocity of 6.5E-3 nm/s and steeper slopes than initials.

Another ex-situ runs were employed with a newly developed equipment named "Crystal Growth Sonde (CGS)" dived into deep underground hydrothermal system. After CO_2 injection (~600 ppm of CO_2), calcite formed etch-pits with a dissolution velocity of 0.17 nm/s, but after 1 day, calcite turned to grow with 2D nucleation with a velocity of 0.18 nm/s. This fast growth velocity can be recognized to be a benchmark data for CO_2-capturing at the Ogachi geothermal site. Based on the previous kinetic data [3], the Q/K_{sp} of this system could be ~1.8.

According to a recent study [4], spiral growth of calcite is inhibited in the Si-rich solution but 2D nucleation is promoted. Our in-situ PSI measurement confirmed growth inhibition in Si-rich solution (0.8 mM) at 35 °C (Fig. 1). The solution recovered by CGS at GL-1000 m was analyzed to be Si-enriched as ~4 mM. It is inferred that the calcite-precipitation could initially be initiated as spiral growth slowly due to Si-inhibition by enriched silica molecules or colloids, but lately be enhanced as 2D or 3D-nucleation growth. These growth behaviours in natural geothermal system such as CO_2-sequestration site need to be considered for better evaluation of the storage.

Insights into the dehydroxylation kinetics of lizardite and chrysotile

Trittschack, R.* & Grobéty, B.
Dept. of Geosciences, University of Fribourg, Switzerland
(*roy.trittschack@unifr.ch)

Lizardite and chrysotile represent two prominent trioctahedral 1:1 phyllosilicates of the serpentine mineral group. Lizardite ($Mg_3Si_2O_5(OH)_4$) has a conventional sheet silicate structure, whereas in chrysotile the same TO-layers are rolled to cylinders. The chrysotile structure has thus not a classical 3D-symmetry, but only rotational and no radial symmetry. Physical properties are, therefore, expected to reflect also this non-conventional symmetry.

The aim of this study is to understand the influence of special symmetry of chrysotile on the mechanism and the rate determining steps of the dehydroxylation reaction. The dehydroxylation kinetics of lizardite serves, thereby, as reference. Theoretical deprotonation and water forming schemes were compared with results of in-situ High-Temperature X-ray diffraction, in-situ IR-spectroscopy, FTIR and Differential Thermogravimetry experiments on well characterized chrysotile and lizardite samples. In-situ IR and HT-XRD experiments under ambient pressure gave starting temperatures for the dehydroxylation of lizadite between 500°C and 550°C which lies in the range of former investigations [1]. Chrysotile dehydroxylation depend on structural features like the inner and outer tube diameter which itself dictate the physical properties. The dehydroxylation starts at the outermost layers at around 450°C and 500°C, whereas innermost layers breakdown about 600°C [2]. The initial dehydroxylation product of both polymorphs is X-ray amorphous, but crystallizes after a certain time to forsterite. These phase transformations were also followed by FTIR analyses, which offer a detailed insight into the structural recombination during the dehydroxylation.

Kinetic data were calculated from two independent methods, in-situ High-Temperature X-ray diffraction and Differential Thermogravimetry techniques for different atmospheres (N_2, O_2, air, etc.). Assuming proportionality between the integral intensity of diffraction peaks and the amount of serpentine present, the reaction rate can be extracted from the rate of intensity decrease. Data from isothermal runs have been treated with the conventional Avrami method as well as the "time to a given fraction" (TGF) method. Latter one offers the possibility to discover changes in the activation energy E_a during the course of dehydroxylation [3]. The same reaction progress dependency of E_a can also be obtained by the isoconversional Friedman analysis from a series of dynamic DTG data.

Isothermal HT-XRD experiments on lizardite yielded E_a of around 340kJ mol^{-1} (Avrami method). Data treated with the TGF method showed a progressive increase of the E_a with the fraction transformed from around 200kJ mol^{-1} (α=0.1) to 340kJ mol^{-1} (α=0.9). Non-isothermal DTG analyses on lizardite with different heating rates and under a controlled nitrogen atmosphere confirmed the TGF results and enabled a much more detailed resolution of the E_a during the dehydration progress. A preliminary mechanistic interpretation of these results will be given.

[3]Kyoto University, Kyoto, Japan

Some bivalve shells contain calcite and aragonite simultaneously although aragonite is metastable at normal temperature and pressure. Previous studies showed that organic matrices in shells control polymorphs of $CaCO_3$, though it was not clear whether magnesium ions were responsible for the aragonite formation. Frequency Modulation AFM (FM-AFM) has been employed for the first time for the direct study of calcite-aragonite phase transition in the presence or absence of peptides (50μg/ml) and magnesium ions (0.05M).

A cleaved calcite surface has been grown in $CaCO_3$ solution containing polypeptide, followed by the FM-AFM observation to see the change of atomic arrangement of the surface. This AFM has a capability to resolve the arrangement of atoms during crystal growth. The images are Fourier transformed to see the symmetry of atomic arrangement of the topmost surface.

The following results were obtained:

(1) Both calcite and aragonite surface at atomic level was obtained by FM-AFM.

(2) Addition of peptide to the solution is not enough to get aragonite configuration (Fig. 1).

(3) Both peptide and magnesium ions are needed to change calcite structure to aragonite structure (Fig. 2).

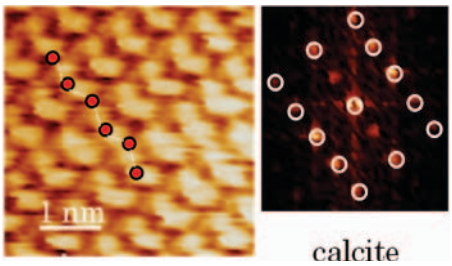

Fig. 1: Calcite surface grown from $CaCO_3$ solution containing the synthetic polypeptide without magnesium and the corresponding Fourier transformed image (right).

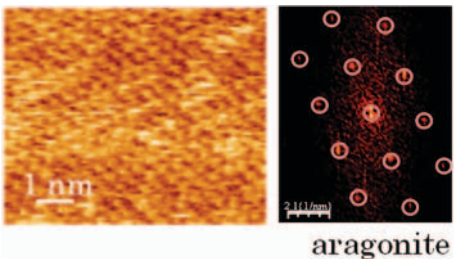

Fig. 2: The aragonite surface grown in the presence of both peptides and magnesium ions (left) and the corresponding Fourier transformed image (right).

Confocal differential interference contrast microscopy applied to studying mineral growth: the gypsum case

Van Driessche, A.E.S.[1*], Garcia-Ruiz, J.M.[1], Delgado, J.M.[1] & Sazaki, G.[1,2]
[1]Laboratorio de Estudios Cristalograficos, IACT, CSIC-University of Granada, Spain ([*]sander@lec.csic.es)
[2]The Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan

The combination of confocal differential interference contrast microscopy and atomic force microscopy is a powerful method for studying mesoscopic and microscopic step dynamics on a mineral surface. To demonstrate the usefulness of this method we studied the kinetics of gypsum crystals growing from aqueous solution as a function of temperature and supersaturation.

We found that 2D nucleation is the main step generation mechanism, even at low supersaturation. The crystallographic direction of stable steps on the (010) face are [001] and [102]. Due to the elongated morphology of the 2D islands along the *c*-axis and the frequent nucleation of multilayer 2D islands a "hills and valley" topography is formed on {010} faces.

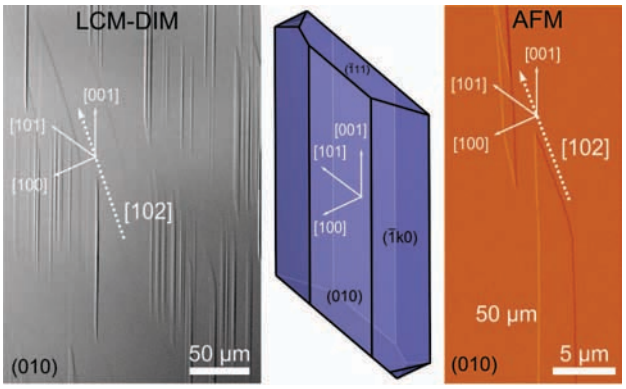

Fig. 1: Schematic representation of the structure of gypsum and the {010} face (middle image). LCM-DIM image at high supersaturation (left image) and AFM image at low supersaturation (right image) showing the crystallographic directions of steps found on the {010} face of gypsum.

The step kinetic coefficient, β_{st}, was determined in the temperature range 20-80ºC and a steep increment in the kinetic coefficient is found with increasing temperature. From these data we were able to calculate the activation energy barrier for incorporation of molecules in the crystal lattice. We found that gypsum crystals grow at low temperature in a mixed regime while at higher temperatures growth is controlled by diffusion. This is explained due to the increment of the kinetic coefficient with temperature. Overall, our results suggest that temperature govern the growth regime controlling gypsum crystallization and that measurement of the microscopic and mesoscopic step dynamics is decisive for explaining the morphology of gypsum crystals.

Simulation of the nucleation and growth of clay particles: the code Nanokin

Fritz, B.[1*], Clément, A.[1] & Noguera, C.[2]
[1]Laboratoire d'Hydrologie et de Géochimie de Strasbourg, Université de Strasbourg/EOST, CNRS, Strasbourg, France ([*]bfritz@unistra.fr)
[2]CNRS, Institut des Nanosciences de Paris, UMR 7588, Paris, France

In water-rock interaction processes, the formation of secondary phases from aqueous solutions is obviously a kinetically controlled phenomenon. Solutions producing clay phases must be oversaturated enough to favour the nucleation of new particles. This nucleation phase has a strong feed-back effect on the aqueous solution: created particles may grow or disappear as a function of the evolution of their oversaturation state in the aqueous solution.

In our attempt to model these processes we have developed a theoretical approach [1,2] combining nucleation, growth and re-dissolution of particles, embedded in a code, called Nanokin. It allows predicting the formation of populations of clay particles along a water-rock interaction process: classes of particles are described in sizes and abundances as a function of time, and the crystal size distribution can be followed.

The model has been applied to various systems [3,4] where the oversaturation state of the aqueous solution with respect to clay minerals is either due to: (1) the initial chemical composition of the aqueous solution as would be done in a laboratory approach or (2) to the alteration of a natural rock like in a geological environment. The competitive formation of simple clay phases like kaolinite and halloysite has been obtained first in both cases of oversaturation, the halloysite being generally formed on short term as a precursor of kaolinite for long term precipitation.

The effect of a temperature increase on these processes has been tested considering: (1) the simulated weathering process at 25°C of a granitic rock producing first competing halloysite and kaolinite and later Ca-montmorillonite, and (2) the hydrothermal alteration of a granitic rock at 150°C producing kaolinite and later illite [3,4]. This temperature effect was also tested in a diagenetic process: the interaction between sandstone–type sediments and sea water lead to the formation of an illitic clay together with the possible formation of albite as often described in diagenetic processes.

The model is now ready for application in systems where the formation and evolution of clay phases may play a key-role in the long-term evolution. This is particularly interesting for the simulation of weathering processes in watersheds, leading to the formation of soils, or in the prediction of long term stability of clay barriers in nuclear waste storages [6].

Crystallization and transformation of iron sulphates on polished and fractured colloform pyrite surfaces

Dimitrova, D.[1*], Mladenova, V.[2] & Hecht, L.[3]
[1]Geological Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria ([*]didi@geology.bas.bg)
[2]Sofia University "St. Kliment Ohridski", Sofia, Bulgaria
[3]Natural History Museum, Berlin, Germany

The phenomenon of sulphate formation on samples that contain colloform or spherulitic pyrite as a result of pyrite oxidation during their laboratory storage, gives us an extraordinary opportunity to study these minerals, which are highly unstable in natural conditions.

Two types of specimens containing colloform pyrite from the low-temperature Fe-Hg mineralization of the Ag-Pb Chiprovtsi deposit in NW Bulgaria have been studied: 1) colloform pyrite with quartz; and 2) colloform pyrite, cinnabar, quartz, calcite, quartz, barite, fluorite, ± ankerite and kutnohorite. Colloform pyrite contains variable amounts of As (0.66-4.77 wt.%), as well as Sb, Co, Ni and trace amounts of Tl, Ag and Au [1]. Sulphates have been formed on both types of specimens, on polished and fractured surfaces, but more abundant on the second type.

SEM study of sulphates formed on fractured surface of colloform pyrite revealed that tiny hexagonal-shaped platy crystals (coquimbite?) with slightly rounded edges start growing directly on the fine striated and cracked surface of the fibres within the spherulite. In open cracks at least two mineral phases crystallize simultaneously (szomolnokite and halotrichite or szomolnokite and coquimbite). Crystallization in cracks contributes toward their opening and further fracturing of the samples, thus increasing the surface area for oxidation, which in colloform, spherulitic and framboidal pyrite is very high. Evidences of partial dissolution like small pits (sometimes triangular-shaped) orientated along weak sites on crystal surfaces and rounded crystal edges and faces, are often observed on the newly form crystals. Transformation of one into another mineral phase occurs when the conditions change (temperature and air humidity mainly). Through partial oxidation szomolnokite may be converted to hydroxysulphate as copiapite.

The following hydrous sulphates were identified using XRD and SEM-EDS: szomolnokite ($Fe^{2+}SO_4.H_2O$), aluminocopiapite ($Al_{2/3}Fe^{3+}_4(SO_4)_6O(OH)_2.20H_2O$), coquimbite ($Fe^{3+}_2(SO_4)_3.9H_2O$), halotrichite ($Fe^{2+}Al_2(SO_4)_4.22H_2O$) and voltaite ($K_2Fe^{2+}_5Fe^{3+}_3Al(SO_4)_{12}.18H_2O$). All of them occur as well formed nano- to micro-sized crystals and aggregates: fibres (halotrichite), cubic and combinative forms (voltaite), prismatic (szomolnokite), platy and platy-sheet hexagonal (aluminocopiapite and coquimbite, respectively), rounded (effects of partial dissolution).

Pyrite oxidation in air is explained as electrochemical process requiring electron transfers to and from surface distinct cathodic and anodic sites where dissociation of the sorbed O_2 and H_2O occur as a precursor to formation of SO_4^{2-} and H^+ [2,3]. The small amounts of calcite and ankerite in the samples act as buffer neutralizing the reaction and resulting in formation of iron sulphates and gypsum as well. Arsenic from the colloform pyrite is incorporated in coquimbite, szomolnokite and halotrichite. This fact supports the idea that arsenic from As-bearing pyrite is easily released to the environment through formation of water soluble minerals. Unlike pyrite, cinnabar does not show apparent indications of oxidation.

In-situ observation by interferometer during condensation of smoke particles

Kimura, Y.[1*], Tsukamoto, K.[1] & Maki, T.[2]
[1]Dept. of Earth and Planetary Materials Science, Tohoku University, Sendai, Japan ([*]ykimura@m.tains.tohoku.ac.jp)
[2]Product Development Dept. 1, Micro-Imaging Systems Division, Olympus Corporation, Tokyo, Japan

When nanoparticles are formed directly from gas phase in homogeneously, they should be condensed under supercooling with nonequilibrium state. This situation should be common for the formation of cosmic dust particles in ejecta gas of evolved stars and possibly in a plume after energetic shock in primitive solar nebula. Therefore, nucleation and growth conditions and processes of nanoparticles must be understood to model the growth and evolution of cosmic dust particles, which are actually nanometer order. In fact, however, there is very limited quantitative data concerning a homogeneous condensation from a gas phase.

One of the best methods of producing nanoparticles in gas phase is the smoke experiment, which is termed the gas evaporation method. The gas evaporation method was developed in Japan (1963) after stimulation by investigation of Kubo, which has been known as the Kubo effect, in the field of solid-state physics [1]. When an evaporant is initiated in an inert gas, rising smoke from the evaporation source can be observed. The evaporated vapor subsequently cools and condenses homogeneously in the gas atmosphere, i.e., solid particles are obtained directly from the gas cloud. So far, only temperature distribution around a hot source in an argon gas atmosphere has been measured by thermocouple without smokes and expected the condensation and terminal growth temperature of nanoparticles under the similar experimental condition except evaporant [2]. Here, we will show a first achievement of in-situ visualization of nucleation and growth environments of smoke nanoparticles using Mach-Zehnder interferometer and attempt to determine the homogeneous condensation temperature and supersaturation of several kinds of materials in gas phase.

Figure 1 shows an example of our first smoke produced in newly constructed smoke chamber. The smoke was produced by heating of a tungsten wire with 0.2 mmϕ and 70 mm depth in a mixture gas of Ar (9×10^3 Pa) and O_2 (1×10^3 Pa). Tungsten has been evaporated as oxide at the source temperature ~1200 K, which measured by pyrometer. Evaporated oxide molecules are subsequently cooled following the convection current produced by hot source and WO_3 particles have been condensed and formed the smoke. Since there is no heterogeneous nucleation cite, solid grains were obtained homogeneously from the gas cloud. The evaporated tungsten oxide vapour is concentrated at the interface between interior WO_3 vapor rich atmosphere and outer mixture gas. Their condensation temperature can be determined from the interferogram. We analyzed the produced smoke particles using TEM and recognized the formation of WO_3 single crystal nanoparticles with 20-200 nm in diameter.

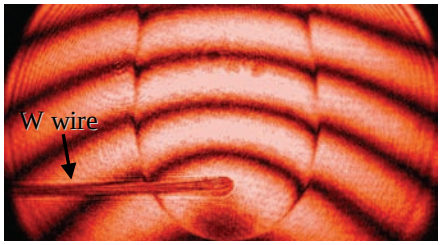

Fig. 1: Typical interferometric image of smoke particles.

Account of chemical variability and cationic exchange in the nucleation and growth of minerals in aqueous solutions

Noguera, C.[1*], Clément, A.[2] & Fritz, B.[2]
[1]INSP, CNRS-UPMC, Paris, France ([*]noguera@insp.jussieu.fr)
[2]LHYGES, CNRS-UDS, Strasbourg, France

Chemical variability and ion exchange in mineral phases are very important geochemical processes which take place in many natural systems and are related to societal questions such as contamination of soils and ground-waters, global element cycles, hydrothermal ore-forming processes, etc. They concern both major and minor ions present in most of the natural solutions in contact with mineral phases. However the full simulation of nucleation and growth of solid-solutions in aqueous media (SS/AS), including kinetic effects in the first steps of their formation and later during their evolution, still remains a challenge.

As an extension of our previous studies of the precipitation of minerals of fixed composition [1-4], we present here a formalism which describes the precipitation for SS of the $A_{1-x}B_xC$ type, with variable composition x. It is based on the classical nucleation theory, on a size-dependent (algebraic) growth law allowing growth, resorption and ripening of particles simultaneously, and on conservation laws akin to a thermodynamically closed system [5]. At all times, one obtains a full characterization of the size and composition of the population of particles, and of the AS composition as a feed-back effect. A similar formalism applies to the description of cationic exchange in particles of clay minerals during their formation as secondary minerals. However, from the simulation point of view, the challenge is to include, in the same simulation tool, several kinetic processes with largely different time scales for mineral formation and evolution: quasi-instantaneous cationic exchange near equilibrium and longer term mineral precipitation or re-dissolution.

These approaches have been embedded in the geochemical code Nanokin that we have elaborated [3-4]. We will present results for the precipitation of solid-solutions whose end-members have either similar or very different solubilities, thus allowing distinct ion partitionings and composition profiles. We will also present some first applications for Na/Ca and K/Ca exchange in montmorillonites and illites during their precipitation.

Kinetics of anisotropic evaporation of forsterite

Ozawa, K.[1*], Nagahara, H.[1], Morioka, M.[2] & Matsumoto, N.[1]
[1]Dept. of Earth & Planetary Science, University of Tokyo, Japan ([*]ozawa@eps.s.u-tokyo.ac.jp)
[2]Radioisotope Center, University of Tokyo, Japan

Congruent evaporation of a condensed substance in vacuum is one of the extreme reactions where backward reactions and transport processes in the reactant can be neglected, in which only surface processes and intrinsic nature of the substance control the reaction. We have conducted a series of evaporation experiments in vacuum for crystallographically oriented forsterite, which is one of the most important constituents of the terrestrial planets, meteorites, and interstellar dusts.

The overall evaporation rate (retreat rate of averaged surface) shows anisotropy; the rate is largest for (001), intermediate for (100), and smallest for (010) with maximum difference by a factor of four between 1500 and 1750 °C. The activation energy of overall evaporation rate below 1750°C is smallest for (010) (~620 kJ/mole), intermediate for (001) (~650 kJ/mole), and largest for (100) (~680 kJ/mole). The large activation energy for overall rate from (100) comes from the comparable evaporation rates for (100) and (001) at ~1750°C and for (100) and (010) at ~1500°C. In addition to this, a high apparent activation energy for (010) above ~1750°C diminish the anisotropy in the overall evaporation rate to within a factor of 1.5.

The intrinsic evaporation rate, which is defined to be the evaporation rate from dislocation-free surface, was estimated by analysis of time-dependence of evaporation rate and by evaluating contribution of preferential evaporation around dislocations. The intrinsic rates are smaller than the overall rates for (100) particularly above ~1700°C and for (010) above ~1600°C. The difference is attributed to preferential evaporation around dislocation, which is consistent with abrupt increase in pit density for (010) above ~1750°C and gradual increase in pit density for (100) above ~1600°C. as well as that of (100) and (010). The activation energy of intrinsic rate for (010) (~610 kJ/mol) is much lower than that for (100) (~740 kJ/mol). The intrinsic evaporation rates for (001) are better fitted by higher activation energy above ~1700°C (790 kJ/mol) and lower one below ~1600°C (680 kJ/mol).

The presence of steps with height of nanometer order and variously bunched steps on (100) and (010) at all experimental temperatures and other morphological information indicate that evaporation from the two surface takes place by lateral motion of steps (layer-by-layer mechanism). The absence of steps with nanometer-scale height on (001) above ~1650°C indicate change of evaporation mechanism from layer-by-layer to detachment of evaporation units from rough surface at ~1650°C.

We infer that rough-smooth transitioin takes place at this temperature. The temperature shows good correspondence to that of change in activation energy of intrinsic rate for (001). The temperature of rough-smooth transition is inferred to be higher than ~1800°C or not realized below melting temperature of forsterite for (100) and (010).

The lower roughening transition for (100) than for (100) is in contradiction with the prediction based on the anisotropy in attachment energy. The discrepancy is attributed to a surface kinetic process, probably selective evaporation of Mg from M1 site forming SiO_4 chains along [001], which is then broken to complete evaporation (kinetic roughening).

The structure of the feldspar-feldspathoid intergrowths in the rocks of Khibiny massif

Ageeva, O.A.*, Borutzky, B.Ye. & Karimova, O.V.
Institute of Ore Geology, Petrography, Mineralogy, and Geochemistry (IGEM) RAS, Moscow (*agolga7@yandex.ru)

We used the 4-Axis Universal Stage for study of the structure of the feldspar-feldspathoid intergrowths (often concerned as pseudoleucite) which are widespread in potassic rocks of Khibiny alkaline massif (Kola Peninsula, Russia). These intergrowths are composed of parallel or differently directed lamellas of feldspathoids (kalsilite, more rare nepheline) in giant poikilocrysts of potassium feldspar (OR). The lamellas are well formed, complanate by c-axis, and extremely elongated along plane (0001). The intergrowths often contain central isometric nepheline grains (NE) with veinlet, frontal rims or unformed kalsilite inclusions (Fig. 1a). The study showed that the optical orientation of the kalsilite (kls) of both morphological types was not accidental. In most cases it was related with orientation of the intergrowing feldspar. It could be caused by some crystal structure features of these minerals.

An examination of the crystal structures minerals drew our attention to two details: 1) An existence of channels, running through their Si,Al framework: along all axes in both the feldspathoids and along directions [001], [010], [100], [101], [110], [112], [310] in feldspar. In most examined samples the c-axis (only accessible for optical detection) of kalsilite was oriented exactly along these directions in the feldspar. One case of such orientation coincidences is demonstrated (Fig. 1b). 2) A similarity of some features of their elementary cells: the angle of monoclinicity of feldspar β=116° in plane (010) is close to the angle of feldspathoid hexagonal cell γ=120° in plane (0001). The most frequent coincidence directions in the examined samples (c-axis of feldspathoid is parallel to b-axis of feldspar) reflects parallel disposition of these planes in the intergrowths. Thus, the minerals locations in these intergrowths are related by common orientation of their crystal structure elements. A structure state of the feldspar changes from low sanidine to orthoclase and microcline. Often all these modifications are found in limits of single poikilocrysts. It was noticed a tendency to fall of structure ordering in areas the kls-lamellas concentration and near the nepheline central grains.

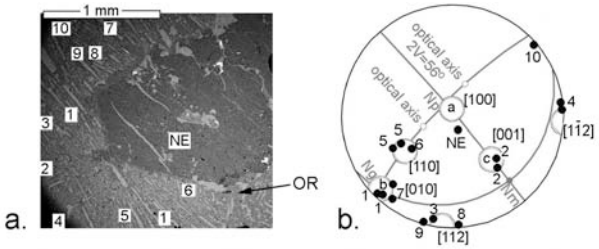

Fig. 1: a) back-scattered electron imaging: numerals mark feldspathoids of different orientations; b) their projection on the Wulff net (black points mark position of c-axis of feldspathoids), and projection of intergrowing feldspar (the circles mark the directions of its structure)

We suppose an action of ion-changing reactions through the structure channels, which results a divide into two mineral phases and an appearance of phase borders crossing the directions of their spread. It may explain the complanate (by c-axis) form of kalsilite alternating with regularly oriented feldspar. A more profound study of their growth mechanism needs to use of additional methods, including X-ray structure observations. Coming studies are directed on a detection of primary mineral (probably nepheline), stages of formation of these intergrowths in metastable feldsparization or other processes, a following collecting recrystallization, and an examination of epitaxy of the intergrowing minerals.

Superficial energy and structure of crystal-forming media

Askhabov, A.M.
Institute of Geology, Komi Science Centre, Ural Branch, RAS Syktyvkar, Russia (xmin@geo.komisc.ru)

In this work we suggest a simple way of estimation of the first amendment to superficial tension on curvature of interphase boundary.

For dependence of specific superficial energy σ from radius r of a particle the following formula is suggested:

$$\sigma = \sigma_o(1-\frac{n_S}{n}) = \sigma_o(1-\frac{2\delta}{r}),$$

where σ - specific superficial energy for flat boundary of the section. Parameter δ is treated as diameter of cluster-forming atoms, molecules or other structural units of medium, n_S - number of such units on cluster surface, n - total number of particles.

This formula in form is close to the formulas received before by Tolman within the frames of the thermodynamic capillarity theory and H.Reiss within the frames of the theory of scale units.

Accordingly, for specific superficial energy of the condensed liquid medium in which the formation of clusters (clusters of "hidden" phase or quatarons) takes place, we obtained the following expression:

$$\sigma_o^L = \frac{5.847 * 10^{-16} T}{\delta^2}, \text{ (erg/cm}^2\text{)}$$

Calculations under this formula give close to experimental values. Here from follows an interesting conclusion that knowing σ_0^L, it is possible to define diameter of cluster-forming particles (structural units). For example, for water σ_0^L = 75, 62 erg/cm^2, accordingly δ = 0,46 nanometers that corresponds to the second maximum on function of radial distribution for water. From this it follows that structural cluster-forming water unit includes 13 molecules. The optimum structure built of such quantity of molecules, is icosahedron. Similar estimations of structure give following values: for lead melt - 4, aluminum - 6, copper - 7, silver - 8, gold - 6, sodium - 9. If to interpret corresponding cluster formations in terms of polyhedrons then these are simple geometrical figures - a tetrahedron (n = 4), an octahedron (n = 6), an aligned octahedron (n = 7), a hexahedron (n = 8) etc. Actually quatarons are not steady geometrically and energetically optimized structures. These are the dynamic and usually hollow structures constantly changing their form.

Anorthoclase twins of Mount Erebus (Antarctica)

Boulliard, J.-C.
Collection des Minéraux, Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie (UPMC), Paris, France (jean-claude.boulliard@impmc.upmc.fr)

Mount Erebus volcano is well known for its anorthoclase "giant" crystals (megacrysts) and twins. So far, the albite, X-Carlsbad and Mannebach twins have been recognized. Thanks to a set of more than 400 specimens, we have improved the knowledge about the twins of this locality. Several well-known twins, not yet mentioned in this locality, have been determined. The status of the X-Carlsbad has been revisited. Two new twins have been discovered. The first one (Tazieff twin), which possesses some features of the Emfola twin, was theoretically predicted but never found. There is no mention of the second twin (Erebus twin). Statistics about the appearance of different twins have been recorded. Moreover, the study of anorthoclase twin and group habits gives rise to the opportunity to get information about several mechanisms, like the re-entrant corner effect or the oriented attachment mechanism.

Mechano-chemical effect of brucite powder in the wet super-fine grind process

Du Gao-xiang[1,2*], Xue Qiang[1], Liao Li-bing[1], Ding Hao[1] & Guo Wei-juan[1]
[1]School of Materials Science and Engineering, China University of Geosciences, Beijing, China ([*]dgx@cugb.edu.cn)
[2]Hebei Yingdu Composite Materials Co. Ltd, Xingtai, China

The mechanochemistry of brucite during wet grinding in a ball-stirred mill was studied. Raw brucite and ground brucite were characterized by XRD and FTIR. The particle size of raw brucite and ground brucite were measured. The solutions of the slurry during grinding were sampled and their Mg^{2+} contents were tested by chemical analysis. The change of Mg^{2+} content in the solution of the slurry shown that the solubility of brucite in water was increasing at the initial grinding stage, and stabilized in about 30min. The (110) peak intensity in the XRD pattern of the ground brucite decreased initially and then increased with grinding time, which was probably resulted from the recrystallization of brucite during the grinding. The FTIR absorption band of Mg-O bond for the ground brucite splits compared to that for the raw brucite, which may indicate the activation of brucite and is related to the forming of new type of Mg-O bond. Particle size measurement indicated that the mean particle size of brucite decreased and tended to be even gradually in the process of grinding.

Trace elements in titanite: chemical (ICP-MS) studies and implications for fractional crystallization

Geraldes, M.C.[1*], Janasi, V.A[2] & Tupinambá, M.[1]
[1]Faculdade de Geologia, Universidade do Estado do Rio de Janeiro, Rio de Janeiro (RJ), Brazil
([*]geraldes@uerj.br)
[2]Instituto de Geociências, Universidade de São Paulo, São Paulo, Brazil

The present study reports a titanite grains REE compositions investigation as a function of magnetic susceptibility. This study was possible due to the ICP-MS low limit of detection for trace elements, allowing for the characterization of chemical composition in titanite magnetic fractions. With exception of Nb, all trace elements and REE have increasing content from titanite fraction M(4) to fraction M(12) (see Fig 1). Variations are: Y values range from 574 ppm to 1331 ppm. U amounts increase from 75 ppm to 243 ppm. Th amounts increase from 67 ppm to 173 ppm. Pb amounts encrease from 5 ppm to 73 ppm.

LREE (La, Ce, Pr, Nd, Sm, Eu, Gd and Tb) amounts have larger enrichment than HREE (Dy, Ho, Er, Tm, Yb and Lu) from fraction M(4) to fraction M(12). Consequently LREE have the behavior similar to compatible elements, which variations are: La from 35 ppm to 594 ppm; Ce from 136 ppm to 1969 ppm; Pr from 19 ppm to 349 ppm; Nd from 70 ppm to 1259 ppm; Sm from 22 ppm to 258 ppm; EU from 11 ppm to 76 ppm; Gd from 29 ppm to 214 ppm; and Tb from 9 ppm to 44 ppm.

HREE presented smaller variation (from 49% to 342%) than LREE. The HREE content variations are: Dy from 70 ppm to 240 ppm; Ho from 20 ppm to 51 ppm; Er from 60 ppm to 128 ppm; Tm from 13 ppm to 24 ppm; Yb from 94 ppm to 147 ppm; Lu from 14 ppm to 21 ppm.

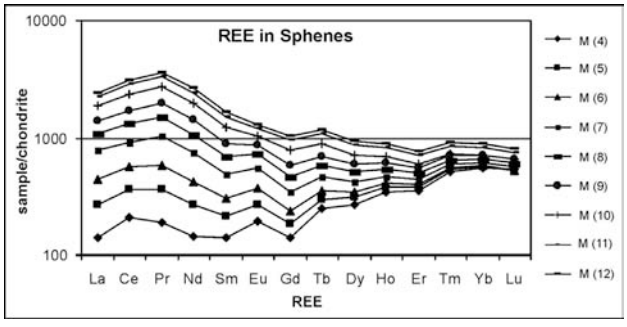

Fig. 1: Rare Earth Element patterns of titanite grains.

These results show that variations of trace elements in each titanite fractions are probably correlated to increasing amounts of these elements in the melt phase during fractional crystallization. Trace element content variations may represent part of the history of magma crystallization at the hand-sample scale, with accessory minerals playing important role in concentrating incompatible elements. As consequence, the whole rock REE pattern should be regarded as integration of a significant number of phase parameters, a fact to be taken into consideration when interpreting REE patterns in magma crystallization processes.

On the growth habit of precipitates in minerals: the normal-to-delta g principle for optimum interphase boundaries

Hwang Shyh-Lung[1*], Shen Pouyan[2], Yui Tzen-Fu[3] & Chu, Hao-Tsu[4]
[1]Dept. of Materials Science and Engineering, National Dong Hwa University, Hualien, Taiwan, ROC
([*]slhwang@mail.ndhu.edu.tw)
[2]Dept. of Materials and Optoelectronic Science, National Sun Yat-sen University, Kaohsiung, Taiwan, ROC
[3]Inst. of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC
[4]Central Geological Survey, Taipei, Taiwan, ROC

Minimization of interfacial energy is the dominant factor governing the equilibrium habit, *i.e.* orientation and morphology, of a precipitate in the parent crystal. The existing models on optimum interphase boundaries have established criteria, which minimize the lattice misfit and/or the strain energy, by comparison of the dimensions of two interpenetrating lattices. Based on a detailed analytical transmission electron microscopy study of two precipitate-matrix systems with different degrees of structural similarity in oxygen sublattices, *i.e.* hematite in rutile of an eclogite from the ultrahigh-pressure (UHP) Kokchetav terrane and magnetite in clinopyroxene of a garnet-clinopyroxenite from the UHP Sulu terrane, here we report that the optimum interphase boundary and the equilibrium habit of a precipitate in these structurally complex systems can be defined from the special geometry characteristics of diffraction patterns along specific zone axes. AEM results show that the precipitate in a parent crystal, either with or without a similar oxygen framework, always poses a specific crystallographic relationship with the differences of **g**-vector pairs (Δ**g**s), *i.e.* misfits of diffraction-spot pairs, of two structures aligned in the same direction, and that the precipitate would exhibit a growth habit plane normal to the Δ**g**s. This new insight into the interfacial energetics controlled mineral growth can be understood by the coherency of lattice planes in the interphase boundary, and rationalized by the normal-to-Δ**g**s principle originally developed for structural transformations in alloys with simple close-packed structures [1, 2]. The normal-to-Δ**g**s principle is formulated to calculate the optimum interphase boundaries in several mineral systems and gives results comparable to other models, yet in a more straightforward manner. This alternative approach can be readily applied in interphase boundary modeling of minerals and sheds light on the growth habit of mineral precipitates as a potential geothermobarometer of metamorphic rocks.

Genesis of a unique stalactite formed in a tunnel under the River Danube (Budapest, Hungary)

Kármán, K.[1,2*], Fórizs, I.[1], Tóth, M.[1], Németh, T.[1] & Szabó, Cs.[2]
[1]Institute for Geochemical Research, Hungarian Academy of Science, Budapest, Hungary ([*]anitszirk@hotmail.com)
[2]Lithosphere Research Lab, Eötvös University, Budapest, Hungary

Carbonate minerals were measured growing on the concrete tunnel under the Danube River. The examined tunnel is made of ferroconcrete. It crosses the river in the depth of 10-12 m below the bottom of the Danube at Budapest (Hungary). Inside of the tunnel two pipes carry the drinking water towards the capitol. The tunnel consists of cylinder shaped concrete elements. On several localities there are white, yellow or amber coloured dripstone formations. In these locations the water is leaking and forms stalactite or rarely stalagmite.

Five stalactite, one stalagmite and one concrete samples have been taken for X-ray diffractometric, stable C and O isotopic and optical microscopic analyses. We would have liked to know the origin of these formations.

The mineralogy of the concrete: quartz >> plagioclase, K-feldspar, calcite > phyllosilicate, gypsum. The stalactites proved to be almost pure calcite (with sporadic gypsum in tiny amount). The stalactites are very porous and brittle formations. Their stable C and O isotopic compositions ($\delta^{13}C$, $\delta^{18}O$) show very significant differences between the samples (Fig. 1), which is uncharacteristic for natural dripstones formed in one cave. The $\delta^{13}C$ (-19.2 to -30.7 ‰ vs. VPDB) and the $\delta^{18}O$ (+4.7 to +14.0 ‰ vs. VSMOW) values show exceptional depletion comparing to natural dripstones in Hungary ($\delta^{13}C$ = -4 to -11 $[‰]_{VPDB}$; $\delta^{18}O$ = (+19.5 to +25.5 $[‰]_{VSMOW}$; [1]), but they are highly similar to those of carbonate growths on concrete structures [2,3]. This observation indicates that the studied stalactites cannot be deposited from the regionally ascending old groundwater of high TDS. There is a very good linear correlation between the $\delta^{13}C$ and $\delta^{18}O$ values (see Fig. 1), which may suggest a strong kinetic isotope fractionation. Although the details of processes forming carbonate growth on concrete structures significantly depleted in ^{13}C and ^{18}O are not clearly understood, our observations indicate that the interaction between the water and concrete material plays an important role in the formation of the studied stalactites, which may shorten the life-time of the tunnel.

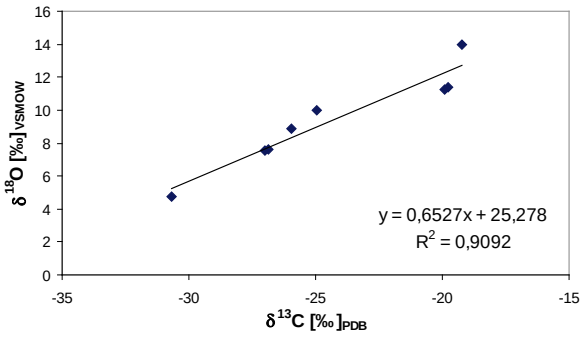

Fig. 1: $\delta^{13}C$ and $\delta^{18}O$ values in the stalactites. The good linear correlation may indicate a strong kinetic isotope fractionation.

Surface specific growth on olivine in acidic saline solutions

King, H.E.[1*], Satoh, H.[2,3], Tsukamoto, K.[2] & Putnis, A.[1]
[1]Institut für Mineralogie, University of Münster, Germany ([*]hking_01@uni-muenster.de)
[2]Dept. of The Earth and Planetary Science, Tohoku University, Sendai, Japan
[3]Mitsubishi Materials Corporation, Japan

Understanding the dissolution of olivine has important implications for a variety of areas including weathering and predicting the rate of in-situ carbon dioxide sequestration in peridotites. There are large discrepancies between laboratory determined and natural dissolution rates, which are attributed to the formation of secondary phases that armour the reactive surface. For olivine, phases such as amorphous silica [1] and hematite [2] have been previously observed during experiments at temperatures above 90°C. The majority of dissolution experiments are stirred to prevent the formation of such phases, however, the use of powdered olivine creates more reactive surfaces than would be expected in nature. The presence of parting in natural peridotites can expose specific surfaces to fluids and thus control olivine dissolution [3]. To study the rate of dissolution at different surfaces we have used real-time phase-shift interferometry (PSI, [4]). Solutions were based on a 0.1 M NaCl solution which was acidified using 0.1 M HCl to pHs between 4.7 and 1. Flow rate through the sample cell was 40 µL/min (105 µm/s). Surfaces formed when olivine crystals are broken result from conchoidal fracturing and thus are not suitable for PSI measurements due to the high surface curvature. Therefore, surfaces used in our experiments were cut from natural euhedral forsteritic olivine crystals with well defined faces from the Sapat region, Pakistan and chemically polished using hydrofluoric acid.

We observed that the dissolution increased with decreasing pH in agreement with previous dissolution studies [5]. Dissolution rates showed minimal variation with surface orientation with the exception of dissolution at pH 3 and 1 on the (021) surface. On this surface we also observed the growth of a new phase. The precipitates are a maximum size of 0.3 µm in width and present everywhere on the surface, including at etch pit sites. Thermodynamic calculations performed using PHREEQC show that the super saturated phases in the system were amorphous silica, sepiolite or talc. Raman spectroscopy was conducted to identify the precipitate. The dominance of olivine peaks could mask additional precipitate peaks. However, the spectra have some peaks which are not associated with olivine or other phases commonly associated with olivine as accessory minerals. These peaks do not correlate with those of talc or the broad peaks which are characteristic of sepiolite. Experiments of Mg-silicate growth at low temperatures typically precipitated an amorphous Mg-rich phase rather than sepiolite or talc at low pH [6]. Therefore, the phase is expected to be an amorphous hydrated Mg-silicate phase that forms from the dissolution of olivine and nucleation of the new phase at the olivine surface. The presence of the new phase appears to have limited passivating effect on the overall dissolution of olivine.

Mixed crystal formation by direct growth and isomorphic replacement in aqua solutions

Kryuchkova, L.Y.* & Glikin, A.E.
Dept. of Crystallography, St.Petersburg State University, St.Petersburg, Russia (*2106@list.ru)

Mixed crystal formation is featured by a permanent exchange of isomorphic components between the crystal and solution that is the universal mechanism for an inherent regulation of a crystal composition. [1,2]. The exchange proceeds either in itself or in a combination with growth (or dissolution). It is realized by simultaneous acts of epitaxial growth and dissolution distributed along the surface chaotically in a form of spontaneously alternating micro-spots, which sizes vary in the range of orders 0.1–100 micrometers. The spots walk randomly (including appearance and disappearance) all along the surface. The boundary solution acquires an inhomogeneity of a corresponding distribution and change. Overgrowths cover these surface mosaics protecting them from a homogenization. In their turn, the covers undergo the same micro-processes, and new covers bury them in a non-homogenized state, etc. As a fundamental result, mixed crystals consist of coherent blocks, which compositions vary in wide ranges gravitating to discrete values determined by specific metastable equilibria.

Mass precipitates show similar picture of crystal distribution in isomorphic composition. The distributions are characterized by a bimodality, which corresponds with a bimodality of crystal sizes [2]. The absence of intermediate fractions emphasizes size bimodality in some cases. Crystals of the smallest and biggest fractions (<10 and >100 microns respectively) are of a similar composition enriched by one of the components (which can be either more soluble or less soluble in different systems) while their abundances are brought together in intermediate fractions. Supercooling change causes a displacement of the distribution maxima without an influence on the general picture of distribution and more remarkable on the total composition of the precipitate. Thus the ratio between isomorphic compounds does not depend of growth rate immediately. Such a discrete distribution can be also interpreted in terms of composition gravitating to specific metastable equilibria.

Metastable equilibria were established between solid solutions and liquid solutions supersaturated by isomorphic substances and determined as a characteristic feature of such systems. Supercooling stops crystal dissolution causing stoppage of salting-out and growth of crystal substance with other composition. Crystals of two kinds of the isomorphic ratio can be in the equilibrium that is the reason of the compositional distribution peculiarities. Those spots on the monocrystal surface and individuals of precipitates, disposed randomly within suitable liquid portions, survive while the others dissolve.

Redox-controlled element migration during subsolidus syntheses of Fe-Ti oxide samples

Langner, R.[1,2] & Lattard, D.[1*]
[1]Institut für Geowissenschaften, Universität Heidelberg, Germany (*Dominique.Lattard@geow.uni-heidelberg.de)
[2]Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität Bochum, Germany

Synthetic Fe-Ti oxide samples are useful to study the physico-chemical properties and phase relations of titanomagnetite (Tmt_{ss}), ilmenite-hematite (Ilm_{ss}) and pseudobrookite (Psb_{ss}). In most cases such samples have been synthesised at 1 bar and sub-solidus temperatures in gas mixing furnaces. The run products are polycrystalline aggregates, either single or multi-phased. Ideally, each phase should have a constant composition within each crystal as well as over the whole sample, and in multi-phased run products the crystals should be equally repartitioned over the sample. In fact, chemical and textural heterogeneities frequently occur, especially near the surface of the sample. The present study aims at identifying the processes controlling these heterogeneities.

The starting materials were mixtures of TiO_2 and either Fe° or Fe_2O_3 or both. The reagents were weighted, ground and homogenized in an agate mortar and pressed to cylindrical pellets of a few mm in diameter and height. They were fired at 1300°C at $fO_2 = 10^{-6.9}$ (ΔNNO = -0.2; established by a CO/CO_2 mixture) for various, short run durations (0.25 to 20 h). The runs were terminated by drop-quench into water. Three different bulk compositions were chosen, with Ti/(Ti+Fe) of 20, 33 or 53 atom%, which, at equilibrium, yield single phase Tmt, Tmt_{ss} + Ilm_{ss} and Ilm_{ss} + Psb_{ss}, respectively.

When the starting materials are made up of TiO_2 and Fe° (Type III), i.e. are strongly reduced, the run products display at least 3 concentric shells. The outermost shell (100 to a few hundred µm thick) consists only of Fe-rich oxides (magnetite or Tmt ± wüstite), in the other shells the bulk Fe/Ti steadily decreases towards the pellet centre. The outer shell is dense; the inner shells are more porous. These concentric shells appear already after short run durations (0.25 h), whereby the innermost shell consists of Fe°+Psb_{ss}+Rutile, i.e. is still in a reduced state. This implies that Fe must have migrated over hundreds of µm towards the surface at the very beginning of the high-temperature experiment, before fO_2 was equilibrated throughout the pellet.

When the starting materials are mixtures of TiO_2 and Fe_2O_3 (Type II), i.e. strongly oxidized, the run products display a monomineralic Ti-rich, porous outer shell that directly surrounds the central part of the pellet with the equilibrium assemblage. Since this concentric structure pattern also appears in short runs, it points to inward migration of Fe at the beginning of the experiments. It is not clear whether Ti may have also migrated in the opposite direction.

With both types of starting materials, the concentric structures remain, even after long run durations. With starting material Type II, the phase compositions re-equilibrate according to the fO_2 of the gas mixture throughout the whole pellet. With starting material Type III, however, disequilibrium assemblages persist in core regions over long run durations.

With mixtures of TiO_2, Fe° and Fe_2O_3 as starting materials (Type I) the formation of concentric shell is generally avoided, provided the original oxidation state is close to that established by the gas mixture. Already after 1 h run duration the phases have the desired chemical compositions in all parts of the pellet.

Our results show that redox-controlled element migration over hundreds of µm rapidly takes place (within a few minutes) in solid state, high-temperature reaction processes. It induces compositional gradients within the synthetic samples, which persist even if the phase compositions re-equilibrate later on.

Tracing nucleation and growth of forsterite from amorphous thin films

Oehm, B.[1], Lattard, D.[1*], Burchard, M.[1], Dohmen, R.[2], Chakraborty, S.[3] & Langenhorst,F.[4]
[1]Institut für Geowissenschaften, Universität Heidelberg, Germany ([*]Dominique.Lattard@geow.uni-heidelberg.de)
[2]Dept of Earth Sciences, University of Bristol, UK
[3]Institut für Geologie, Mineralogie und Geophysik, Ruhr Universität Bochum, Germany
[4]Bayerisches Geoinstitut, Universität Bayreuth, Germany

Observations of accretion disks of Young Stellar Objects have revealed dust of crystalline Mg-silicates, in particular of forsterite (Fo), which is assumed to result from high temperature annealing of amorphous cosmic dust particles. We are performing annealing experiments to obtain kinetic parameters of the crystallization that are necessary for the numerical modeling of accretion disks.

We use thin films obtained by Pulsed Laser Deposition (PLD) on Si (111) wafers. The thin films are completely amorphous, chemically homogeneous (on the Mg_2SiO_4 composition) and with a continuous and flat surface. They are annealed for 1 to 260 h at temperatures in the range 973-1073K in a vertical quench furnace and drop-quenched on a copper block. To monitor the progress of crystallization, the samples are characterized by AFM, SEM and TEM imaging, and IR spectroscopy.

After short annealing times (e.g. 2.5 h at 1073 K) AFM images reveal elliptical features, approx. 1 µm in diameter, with a central elevation and surrounded by a lowering of the surface. TEM images show that these features represent nucleation sites in an amorphous matrix. The IR spectra still show the broad bands of Si-O stretching modes typical of the amorphous, unprocessed silicate thin film

After e.g. 6 h of annealing at 1073 K, AFM and SEM images show circular and square features both with a central elevation. IR spectra show a few weak bands that can be assigned to crystalline Fo (bending and stretching of tetrahedra).

With increasing annealing duration planar faces appear in the former pyramidal features and the surrounding matrix evolves into domains with spherolitic appearance. IR spectra of these samples display typical bands of crystalline Fo. After longer annealing, AFM images picture the further growth of the planar faces towards idiomorphic crystals and SEM imaging shows increasing surface roughening.

The quantitative evaluation of the surface roughness of AFM images point to three evolutionary stages during annealing. The quantitative evaluation of IR spectra reveals that the Fo peaks continuously grow with increasing annealing time up to a certain duration (e.g. 64 h at 1073 K) but that no significant change appears for longer run durations.

AFM imaging proves to be a sensitive tool to detect the very first signs of crystallization and to trace its further evolution.

Experimental screening of the morphology of gypsum crystals

Ossorio, M., Van Driessche, A.E.S.[*], Garcia-Ruiz, J.M.
Laboratorio de Estudios Cristalográficos, IACT, CSIC-University of Granada, Spain ([*]sander@lec.csic.es)

Gypsum (calcium sulfate dihydrate, $CaSO_4.2H_2O$) is the most abundant sulfate mineral throughout natural earth systems and is also present in a wide range of industrial processes (e.g. construction material, fertilizer) where the morphology and size of the crystals determines the final characteristics of the product. But despites its importance in natural and artificial processes neither the growth nor equilibrium morphology of gypsum crystals are properly understood. Therefore we are currently working on identifying the factors that influence the mechanisms of nucleation, growth and, finally, the morphology of calcium sulfate in both natural and laboratory environments.

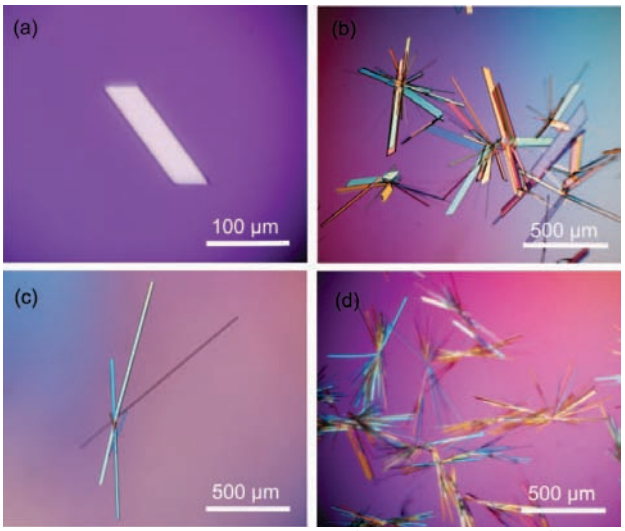

Fig. 1: Representative morphologies of gypsum crystals at different temperatures and initial supersaturation, a) 4ºC, b) 20ºC, c) 40ºC, d) 60ºC.

A series of crystallization experiments were conducted to identify the key parameters that control the growth morphology of gypsum crystals. It was found that both temperature and supersaturation have the most significant effect on the growth morphology of gypsum. This influence is explained in terms of changing growth kinetics and mass transport with varying temperature and increased nucleation at higher supersaturation.

Reactivity of iron oxide nanoparticles

Erbs, J.J.[1], Burrows, N.D.[1], Yuwono, V.M.[1], Berquo, T.[1], Banerjee, S.K.[1], Lowry, G.V.[2], Reinsch, B.C.[2], Gilbert, B. & Penn, R.L.[1*]

[3]Lawrence Berkeley National Laboratory, Berkeley, CA, USA

Iron oxide nanoparticles are a major source of reactive surface in many natural systems. These nanoparticles are dynamic from the perspectives of size, phase, morphology, reactivity, aggregation-state, and available reactive surface area. We quantify the kinetics of reactions between iron bearing nanoparticles and model pollutant molecules (e.g., carbon tetrachloride and 4-chloronitrobenzene) in order to elucidate the link between the physical and chemical properties of the nanoparticles with their reactivity in aqueous systems. Furthermore, we employ low temperature magnetic susceptibility, which provides a sensitive tool for detecting aggregation state for particles (prepared with and without organic coatings) in the dry state. Finally, using cryogenic transmission electron microscopy (cryo-TEM), the nanoparticles can be directly characterized in their aqueous environment, enabling in situ characterization of aggregative state. Results enable comparisons of reactivity with varying particle size, aggregation, composition, and other properties.

Following electron transfer pathways and products in iron oxide nanoparticles

Gilbert, B.[1*], Katz, J.E.[1,4], Zhang, X.[2], Attenkofer, K.[2], Zhang, H.-Z.[4], Rosso, K.M.[3], Banfield, J.F.[4], Falcone, R.[5] & Waychunas, G.A.[1]

[5]Dept. Physics, UC – Berkeley, CA, USA

Iron oxide and oxyhydroxide nanoparticles are high-surface area minerals that are widespread in the environment. Because of the ferric/ferrous iron redox couple, these nanophases are important participants in natural redox cycles. In particular, when reducing conditions develop in soils and sediments containing iron oxide nanoparticles, the consequent changes in geochemistry and mineralogy are tightly coupled to the fate of electrons transferred to the nanophase minerals. Electron transfer and iron reduction can cause a diverse range of consequences including nanoparticle dissolution or phase change as well as secondary transformations of species such as adsorbed contaminants. Figure 1 depicts a general scheme for the fate of electrons transferred to an iron oxide nanoparticle.

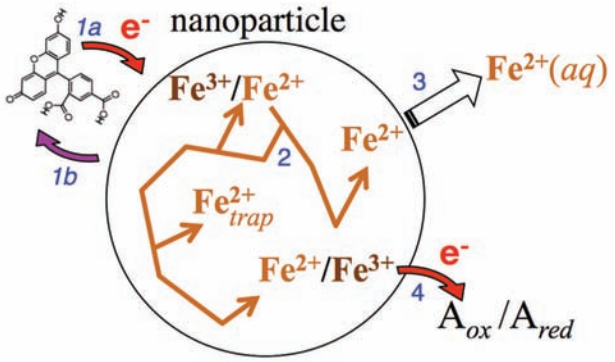

Fig. 1: Scheme depicting possible fates of an electron transferred to an iron oxide nanoparticle from a surface-adsorbed electron donor. **1a** and **1b** = forward and back electron transfer, respectively; **2** = electron mobility within nanoparticle; **3** = dissolution of ferrous iron; **4** = reduction of adsorbed electron acceptor, **A**.

The reaction products depicted in Fig. 1 are amenable to straightforward identification and quantification but transient intermediate species such as structural ferrous iron sites within the nanoparticle are inaccessible to conventional observation. The identification of transient species and measurement of their lifetimes is an important step in determining mechanisms that control the rates and yields of competing processes

We are studying the fate of ferrous iron sites created by electron transfer to ferric iron oxide nanoparticle surfaces. By adsorbing photoactive electron donor molecules to the nanoparticle surfaces, iron redox dynamics can be followed at the nanosecond timescale using X-ray spectroscopy. Our spectroscopic measurements of the chemical state and lifetime of transient ferrous iron species may be interpreted by aid of classical molecular dynamics predictions of local structure changes and *ab initio* simulations of electron mobility within iron oxides. Because nanoparticles contain a diversity of structural sites and defects, our ability to derive accurate molecular–scale models of electron transfer will be aided by complementary studies of ferric-iron containing cluster compounds.

Reactive ferrous iron in titanomagnetite ($Fe_{3-x}Ti_xO_4$) nanomaterials

Pearce, C.I.[1*], Qafoku, O.[1], Liu, J.[1], Arenholz, E.[2], Heald, S.M.[3], Felmy, A.R.[1], Ilton, E.S.[1], Droubay, T.[1], Henderson, C.M.B.[4] & Rosso, K.M.[1]

[2]Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, USA

[3]Argonne National Laboratory, Argonne, IL, USA

[4]Daresbury Laboratory, Warrington, UK

Magnetite is a key ferrous-iron-containing mineral phase present in contaminated sediments, including at the Hanford nuclear processing site, WA, USA [1]. Magnetite can contain isostructural multivalent metal impurities and Ti(IV) is a common substituent. The resulting titanomagnetites ($Fe_{3-x}Ti_xO_4$) form a magnetite (x=0) to ulvöspinel (x=1) solid-solution series. Ti(IV) substitution is charge compensated by increasing Fe(II), and this 'tunable' Fe(II)/Fe(III) ratio affects redox reactivity with respect to the reduction of polyvalent metal contaminants such as Tc(VII).

Compositionally controlled $Fe_{3-x}Ti_xO_4$ materials were synthesized as model systems to investigate rate controlling factors in heterogeneous reduction, such as surface passivation and Fe(II) resupply: (i) thin films were deposited by pulsed laser deposition to produce crystallographically oriented, defined surfaces; (ii) bulk powders were synthesized at 900°C; and (iii) aqueous nanoparticle suspensions were synthesized under ambient conditions to produce high surface area material for batch studies. Fe(II), total Fe and total Ti content were measured by acid digestion and ferrozine/ICP-MS. *In situ* XRD, Mössbauer spectroscopy, XANES/EXAFS, and *ex situ* TEM, XPS and XMCD were also used to determine Fe(II)/Fe(III) ratios in the bulk and at the surface. Information on local coordination, bond distances and magnetic ordering allowed discrimination of different reactive ferrous iron pools, including Fe(II) in octahedral and tetrahedral sites and sorbed Fe(II). Bond lengths and charge and spin distributions calculated from first principles were used to aid interpretation. XAS confirmed that Ti(IV) entered octahedral sites in bulk titanomagnetite powders, up to x=0.94. Fe(II) increased with Ti-content, but only entered tetrahedral site when $x \geq 0.4$. XMCD showed the sensitivity of the micron-sized bulk particle surfaces to redox conditions [2]. Nanoparticle titanomagnetite accepted Ti(IV) into octahedral sites with concomitant increase in lattice Fe(II) up to x=0.35; higher x values yielded amorphous Fe(II)/Ti(IV) phases on the surface. Fe(II) release from the nanoparticles into solution increased systematically with Ti-content. At pH 8, Fe(II) release kinetics were initially fast, followed by slower apparent reabsorption of Fe(II) for $x \leq 0.35$. Reaction with Tc(VII) yielded exponentially decaying reduction kinetics with rates increasing with Ti-content. In preliminary studies, x=0 films, but not x=1 films, reduced Tc(VII) due to more facile passivation of the latter by pre-oxidation.

These collective results suggest a condition-sensitive dynamic exchange of reducing equivalents between highly interactive surface-associated Fe(II) and less accessible bulk lattice Fe(II), the relative proportions of which relate to the structural disorder and electron density redistribution caused by Ti(IV) substitution. Contaminant reduction kinetics are found to strongly depend on the availability and relative proportions of these different Fe(II) pools.

Zero-field and in-field ^{57}Fe Mössbauer spectroscopy applied for study of iron oxide phases

Tuček, J.[1,2*] & Zbořil, R.[1,3]

[1]Nanomaterials Research Centre, Faculty of Science, Palacky University, Olomouc, Czech Republic ([*]jiri.tucek@upol.cz)

[2]Dept. of Experimental Physics, Faculty of Science, Palacky University, Olomouc, Czech Republic

[3]Dept. of Physical Chemistry, Faculty of Science, Palacky University, Olomouc, Czech Republic

^{57}Fe Mössbauer spectroscopy is a very sensitive experimental technique which allows monitoring the changes in the local environment of the iron atoms in the crystal lattice. Hyperfine parameters acquired from the spectral line positions, such as the isomer shift, δ, the quadrupole splitting, ΔE_Q, and the hyperfine magnetic field, B_{hf}, provide important information on the electronic density, its symmetry and magnetic properties at the ^{57}Fe Mössbauer probe nucleus. The method also yields valuable material characteristics from the widths of the spectral lines, their relative intensities, asymmetry of the spectrum, and temperature dependence of the hyperfine parameters. The valence and spin states of iron, quantification of non-equivalent iron sites in the crystal lattice, co-ordination of iron in its individual positions, level of ordering and stoichiometry, type of the magnetic ordering, orientation of the magnetic moments in external magnetic fields (*i.e.*, spin canting, spin frustration, spin nonlinearities), magnetic anisotropy, and magnetic transition temperature can be derived from the temperature-dependent zero-field and in-field Mössbauer spectra.

In this contribution, we present how Mössbauer spectroscopy is a powerful tool to study various physico-chemical properties of iron oxides and to distinguish between different crystalline polymorphs of iron oxides [1]. In particular, we show its advantages when investigating and explaining various magnetism-related physical phenomena occurring in the nanosized iron oxide materials [2,3]. A stress is devoted to in-field Mössbauer spectroscopy which brings light in some questionable areas concerning physical phenomena occurring in nanosized iron oxides and enables more precise determination of quantitative phase composition of the mixture samples based on different magnetic response of different iron oxide polymorphs when exposed under an external magnetic field. In this context, a particular attention is, for example, focused on the stoichiometry issue of magnetite and maghemite and possibilities of distinguishing between maghemite, hematite and amorphous Fe_2O_3. Some future perspectives of Mössbauer spectroscopy in the area of iron oxides are also discussed with regard to our recent research results.

Novel methods for the synthesis of magnetite nanoparticles with special morphologies and textured assemblages

Nyirő-Kósa, I.[1*], Rečnik, A.[2] & Pósfai, M.[1]
[1]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary ([*]kosaili@gmail.com)
[2]Jožef Stefan Institute, Ljubljana, Slovenia

Controlling the sizes, shapes and compositions of magnetite nanoparticles have become an important issue because of the technological applications that require magnetic nanoparticles with specific material properties. There are several methods for synthesising octahedral or irregularly shaped magnetite nanoparticles with sizes from ~5 to ~120 nm. In a previous study we investigated the influence of various inorganic co-precipitation processes on the sizes and shapes of nano-sized magnetite particles [1]. In the present study we synthesized magnetite crystals at low temperature by using organic compounds, including Fe(II) oxalate, ethylene glycol (EG) and tetraethylene glycol (TEG), in order to investigate their effects on the physical and chemical properties of the crystals. In all synthesis routes the magnetite crystals formed from precursor materials (sulfate or oxalate green rust) that have special morphological and textural features. The intermediate and the final products were studied using transmission electron microscopy (TEM), selected-area electron diffraction and X-ray powder diffraction.

TEM images show that magnetite nanoparticles produced under different synthesis conditions have different shapes and sizes. Crystals precipitated from Fe(II) oxalate have regular octahedral shapes. The mean particle size is 100 nm. In a synthesis route that used $FeSO_4$ as the starting material and TEG as an additive, the crystals are rod-shaped and elongated along [110]. The crystals are arranged in hexagonal-shaped clusters that have straight edges, indicating that the shape of the precursor crystal (sulfate green rust) has been conserved. Using a different amount of TEG, large rounded polycrystals of magnetite formed with irregular edges, heterogeneous contrast and a porous structure. Particles synthesized with the addition of EG instead of TEG have similar morphologies but show homogeneous contrast, suggesting that no pores are present and the particles have approximately constant thickness. The 270 nm-sized particles consist of few nm-sized crystals that attach to one another in the same crystallographic orientation, producing a diffraction pattern characteristic of a single crystal.

Our results indicate that octahedral magnetite crystals can be produced from Fe(II) oxalate in a simple co-precipitation process at low temperature. By using different kinds and amounts of polyols, various types of particle morphologies and nanocrystal textures can be produced, including hexagonal-shaped clusters of elongated crystals and porous and solid, rounded polycrystalline aggregates. Some of these products could find technological applications, for example, porous magnetite grains could be used as drug carriers.

High-temperature transformation of nanocrystalline Fe- and O-based minerals

Filip, J.[*], Blechta, V., Janata, M. & Zboril, R.
Centre for Nanomaterial Research, Palacký University, Olomouc, Czech Republic ([*]jan.filip@upol.cz)

Iron oxides (hematite α-Fe_2O_3, maghemite γ-Fe_2O_3, magnetite Fe_3O_4), hydroxides ($Fe(OH)_3$), oxyhydroxides (goethite α-FeOOH, akaganéite β-FeOOH, lepidocrocite γ-FeOOH), hydrated oxide-hydroxides (ferrihydrite $5Fe_2O_3 \cdot 9H_2O$) and oxyhydroxysulfates (schwertmannite $Fe_{16}O_{16}(SO_4)_2(OH)_{12} \cdot nH_2O$) commonly forms micro- to nano-sized crystals. Aside from their unique magnetic, physico-chemical (e.g., sorption of various metals, [1]) and catalytic properties [2], they could easily be transformed into nanoparticles with specific properties [3]. We report on results of controlled and well reproducible thermally-induced solid-state transformation of all abovementioned synthetic and natural minerals under reducing atmosphere (hydrogen/forming gas) and compare it with transformations performed in air and inert atmosphere. For in-situ monitoring of high-temperature transformation we employed X-ray reaction chamber XRK900 (Anton Paar, GmbH) installed on conventional X-ray powder diffractometer. Raw and transformed material was further characterized with Mössbauer spectroscopy, BET surface area analyzer, scanning and transmission electron microscopy and SQUID magnetometer.

Generally, the HT reductive transformation of Fe(III) oxides/hydroxides/oxyhydroxides proceed towards more stable Fe(III) oxides, further to Fe(II) or mixed Fe(II)-and-(III) oxides and subsequently ends with formation of metallic α-Fe (bcc structure) nanoparticles (Fig. 1). Employing isothermal treatment we could easily control the particle-size of all particular phases formed as a result of HT transformation of any precursor.

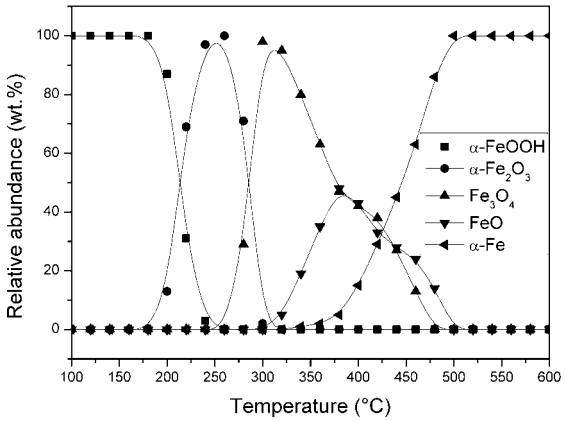

Fig. 1: Reductive transformation of goethite under hydrogen atmosphere.

Morphological study of transformed material demonstrates that the newly-formed nanoparticles or aggregates remain in the form of precursor material. Moreover, the surface properties could be modified using of controlled air-intake procedure (i.e., passivation [3]) and/or utilizing suitable surfactants and polymers [4]. The resulting nanomaterials were tested as potential catalyst for decomposition of hydrogen peroxide and as suitable agents for surface and/or ground water treatment.

TiO_2 nanoparticles: structure, properties, reactivity

Ponaryadov, A.
Institute of Geology of Komi SC UB RAS, Syktyvkar Russia
(alex401@rambler.ru)

Titanium minerals are interesting due to their structure and properties and the most important source of titanium, a strategic metal in modern industry. The structure, composition, and properties of nanodisperse structures of these minerals are of great interest. However several studies showed that synthetic analogues of natural oxide forms had fundamentally new structural features and physical-chemical properties. The structuring of nanodisperse forms of titanium minerals occurred due to many various geological processes that determined their genesis.

At the same time, nanosize implies isolation of the laws of formation of structures and properties of titanium minerals as compared with macrohomologs. The study of special conditions of surface reactions with the participation of organic molecules on the nanostructured titanium minerals draws attention due to potential programming of the form, dimension, texture, and even crystalline structure during crystal growth.

We have successfully synthesized TiO_2 nanoparticles with tubular structure using soft chemical treatment of commercially available anatase with sodium hydroxide solution [1]. The obtained samples have been characterized by nitrogen adsorption isotherms, XRD, TEM, UV and IR spectroscopy. Also fractal surface dimension (FSD) has been calculated. Chemical reactivity of surfaces of nanostructured systems has been studied with several test reactions including preferential CO oxidation.

According to XRD nanostructured samples do not show the crystal structure of initial material. Noticeable widening of peaks is present due to formation of nanosize particles. On TEM images titanium dioxide nanotubes of spiral type are clearly observed.

The specific surface area calculated by BET method from nitrogen adsorption isotherms enlarged from 87, for initial anatase powder, to 221 m^2/g for TiO_2 nanotubes [2]. According to obtained FSD values the surface of nanstructured samples became smoother.

CO conversion on nano-TiO_2 was studied in temperature region 323–673 K by IR spectroscopy using Nicolet Impact 400 spectrometer. Self-supporting wafers of the samples were heated up to 673 K in situ in IR cell for 1 hour at He, cooled to room temperature and diffusion reflectance spectra of the wafer were determined in the presence of 1.8%O2/3.29%CO/He flow.

The reaction of CO oxidation on active surface sites was studied. We obtained more than 60 % CO conversion instead of 11 % on regular form of titanium dioxide [2].

Thus, nanostructured titanium dioxide is considered to be a specific substance form, which physical and chemical characteristics differ from regular anatase. New geotechologies could be based on these unique properties.

An efficient, selective and low cost method for the adsorption and separation of Lanthanum Rare Earth Metal Ion using Iron (II) sulfide coated on magnetite nanoparticles

Bagheryan, S.
Islamic Azad University - Aligudarz Branch, Aligudarz, I.R.Iran (syamak.bagheryan@gmail.com)

A novel iron sulphide adsorbent using magnetite embedded with nanosized Fe_3O_4 was prepared and applied to separate lanthanum (III) from aqueous solution. This adsorbent combines the advantages of magnetic nanoparticle with magnetic separability and high affinity toward rare earth metals, which provides distinctive merits including easy preparation, high adsorption capacity, and easy isolation from sample solutions by the application of an external magnetic field. The effect of pH, contents of loaded iron sulphide nanoparticles, ionic strength, contact time, and temperature on adsorption capacity of the magnetic beads was investigated. Complexation, ion exchange and electrostatic interaction were all believed to play a role in lanthanum adsorption on magnetic beads. We hope that this procedure will be applicable for mineral processing and economically mineralization.

Synthesis and aging of nanocrystalline FeS

Csákberényi-Nagy, D.[1*], Maróti, B.[1], Rečnik, A.[2], Samardžija, Z.[2] & Pósfai, M.[1]
[1]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary ([*]dorottka@gmail.com)
[2]Jožef Štefan Institute, Ljubljana, Slovenia

Nanocrystalline iron sulfides typically form in anoxic marine sediments. The iron sulfide initially forms as disordered mackinawite (FeS) that converts to greigite (Fe_3S_4) [1], which, in turn, converts to pyrite (FeS_2) [2]. In order to better understand the structural, morphological and compositional changes associated with these transitions, we studied synthetic iron sulfides that were precipitated from hydrous solutions at room temperature. The products were studied using scanning and transmission electron microscopy, selected-area electron diffraction and X-ray powder diffraction.

Freshly precipitated iron sulfide is typically poorly crystalline, and forms aggregates of disordered, curved sheets (Fig. 1a). The sheets consist of 3-6 layers that are structurally likely similar to the tetrahedral iron sulfide layers that occur parallel to (001) in mackinawite. However, their spacings are significantly larger (5.4 to 5.5 Å) than d(001) in crystalline mackinawite (5.03 Å). As the material is aged in solution, the spacing between the individual layers decreases and the particles adopt a distinctly crystalline, platy shape (Fig. 1b). After ten months aging, the structure of the platy crystals is consistent with that of greigite. In the course of transition from poorly crystalline FeS to greigite, ordered mackinawite was never observed. Samples that were cured in an autoclave at 200°C transformed to greigite within a few hours, but the mechanism of transformation appeared to differ from that in the aged samples, since the products included both larger greigite crystals and sheets of poorly crystalline iron sulfide.

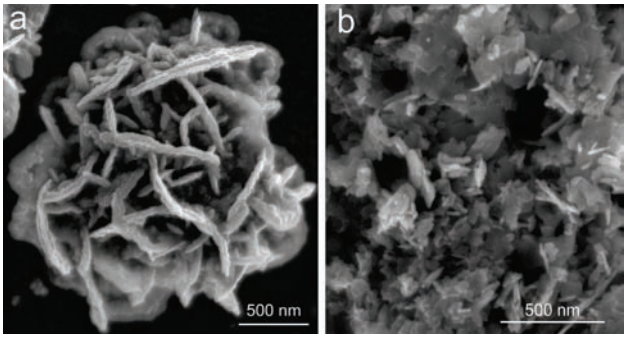

Fig. 1: Scanning electron microscope images of nanocrystalline iron sulfides (a) immediately after precipitation, and (b) after aging in solution for 10 months.

Our results indicate that while the crystallinity of iron sulfide increases during aging, the transformation from poorly ordered sheets to greigite platelets results in a reduction of the sizes of distinct morphological units. Iron sulfides can act as sinks for trace metals either by coprecipitation or adsorption both in marine sediments and in contaminated environments; however, our results suggest that the incorporation or adsorption of metals may vary with the age of the precipitate because of the complex structural and morphological changes during aging. Further studies are in progress on the incorporation of trace elements in iron sulfides.

Chrysotile and imogolite: Quantum mechanical *ab initio* study of structure and energetics

Demichelis, R.[1*], Noel, Y.[2], D'Arco, P.[2] & Dovesi, R.[1]
[1]Dipto. di Chimica IFM, Università di Torino and NIS – Nanostructured Interfaces and Surfaces – Centre of excellence Torino, Italy ([*]raffaela.demichelis@unito.it)
[2]Institut des Sciences de la Terre de Paris (UMR 7193 UPMC-CNRS), UPMC - Paris Universitas, Paris, France

A recent implementation in the CRYSTAL code of the helical symmetry exploitation in quantum mechanical simulation of nanotubular systems allows the investigation of inorganic nanotubes at the *ab initio* level, using rich Gaussian Type basis set and hybrid functionals, with a relatively reduced computational cost [1-4].

Single-walled chrysotile ($Mg_3Si_2O_5(OH)_4$) and imogolite ($Al_2(OH)_3SiO_3OH$) nanotubes with different radius and chirality were studied with hybrid B3LYP functionals and Gaussian-type basis sets (6-31G* for chrysotile, larger VDZ-type for imogolite). Details regarding the calculation costs and the efficacy of the adopted strategy are presented (see Table 1).

Table 1: Effect of the point symmetry exploitation in the simulation of chrysotile [2]

	Radius, Å	N_A	N_{AO}	N_R	t_{SCF}, s	t_{GRAD}, s
[001] slab	∞	18	236	1	1033	9801
chrysotile	35.13	864	11328	48	1901	12025

N_A, N_{AO}, N_R: number of atoms, atomic orbitals, helical operators in the unit cell; t_{SCF}, t_{GRAD}: cost of a single SCF step and of the gradient calculation. (1CPU - Intel Xeon, 1.86GHz, RAM 8Gb - B3LYP).

The stability with respect to the ideal 2D-layers (lizardite mono-layer for chrysotile, hypothetical structure containing a gibbsite-like hexagonal layer linked to asilanolic unit for imogolite) is investigated and the role of hydrogen bonding (HB) and Si-O bonds in the stabilization of imogolite tubes is discussed.

Different rolling polarities (chrysotile) and directions (imogolite) are explored. Chrysotile results less stable than the flat layer for all the radii within the range 20-35 Å, whereas all the considered imogolite tubes are more stable than the flat reference structure. Both the explored rolling directions of imogolite (zigzag and armchair) present a minimum energy structure, which seems to be the result of three main factors: SiO_4 rigidity, HB setting (zigzag only), and electrostatic repulsion among apical oxygen atoms (inner wall of the tubes).

HBs and orientation of the silanolic group inside the tube play an important role in stabilising imogolite. The zigzag minimum energy structure (10,0) is 10.6 kJ/mol per formula unit more stable than the armchair one (8,8), the difference being due, at least partially, to the formation of hydrogen bonds in the inner wall of the tube. Two curves are observed in the zigzag case, whose minima, both at n=10, are separated by 2.01 kJ/mol per formula unit. These two structures are extremely similar, the main difference being the orientation of the OH unit pointing inside the tube.

The influence of synthesis condition on the supermolecular structures of silica. Mechanism of self-assembly of the structural units of opal-like materials

Kamashev, D.V.
Komi SC UB RAS, Institute of Geology, Syktyvkar, Russia (kamashev@geo.komisc.ru)

The problems of silica supermolecular matrix synthesis arouse recently a certain interest. It is connected, on the hand, with the fact that such structures can be used in the synthesis of noble opal analogues, on the other hand they are the most convenient examples for modeling the processes of supermolecular crystallization. The problems of study of supermolecular structures generation arouse a certain interest, since recently they find a more broad application in different spheres of chemistry, physics, including their application as matrices for nanocomposite materials. The available data on the mechanism of formation of supermolecular structures and their components is insufficient which connected with certain difficulties of their analysis.

In the present work, on the basis of experimental data, we considered the influence of different physical and chemical conditions of supermolecular structures synthesis on the sizes and morphology of resulting silica particles, and also the features of their precipitation into well-ordered structure. On the basis of the obtained results we suggested the model of spherical particle structure.

The formation of monodisperse silica spheres was based on Stober-Fink method [1], which we improved [2]. Three series of experiments were conducted. The first series was conducted under 18°C, all the preparation of tetraethyl ortosilicate came to its preliminary purification through distillation. The second series was conducted like the first one but under 8°C. The third series was conducted using TEOS processed with combined method [2], in concentration interval (0.04÷4.75) mole/dm^3 for NH_3 and (1.5÷31.8) mole/dm^3 for H_2O, with the constant concentration of tetraethyl ortosilicate of 0.28 mole/dm^3 and of the temperature at 18ºC. Just in this series we were able to obtain monodisperse silica spheres in the wide ratio of the system components: (0.2÷0.8) mole/dm^3 for NH_3 and (2.75÷6.4) mole/dm^3 for H_2O and hence in the wide size range of 235-765 nm. At lower temperatures and also beyond, the suggested concentration interval the disturbance of both monodisperses and of spherical form of particles occurred.

The oscillation of dependence of particle sizes on the concentration of the system components: TEOS-C_2H_5OH-NH_3-H_2O along with the discreteness of sizes of resulting particles let us suppose the following mechanism of spherical particle structure. According to concepts of cluster self-organization of matter at nanolevel [3], ultradisperse particles of the size, typical for opal balls, are composed of much smaller particles than mentioned above 10 nm. The sizes of these particles depend on the satiety of solution and in amorphous state can reach about 2.4 nm. Accordingly all the compact amorphous formations can be formed resulting from hierarchical aggregation. In the first case, when clusters are located around the central one, cluster aggregation of the 1st hierarchical level is formed. In the same way the cluster of the 2nd level is formed, etc. Thus, we interpret the formation of silica spheres as the process of hierarchical self-organization of matter at nanolevel.

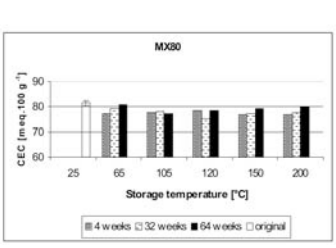
Response of clays on their long-term thermal treatment in open and closed systems

Valter, M.* & Plötze, M.
Institute for Geotechnical Engineering, ClayLab
ETH Zurich, Switzerland (*martin.valter@igt.baug.ethz.ch)

Clays are used in various applications. In many of them it is necessary to preserve their unique properties for long periods of time, e.g. in radioactive waste disposal. The presented work is focused on time dependent changes in different properties of various clays during long-term thermal treatment under near field relevant conditions. The clays under investigation are: Na-bentonite MX-80, Ca-bentonite Calcigel, Na-smectite Cloisite, vermiculite, illite and kaolinite. The clays are stored at temperatures between 50 °C and 200 °C. One group of samples is treated in an open system and the other group in closed containers with different water saturation states. Changes are expected in such parameters like cation exchange capacity and layer charge but also in related properties. Furthermore, physical parameters will be analyzed, e.g. the surface area, swelling behaviour and the thermal conductivity.

First results for MX-80, Calcigel and Cloisite show different responses on thermal treatment. The CEC of MX-80 and of Calcigel decreases during the first 4 - 32 weeks of heating. However, with longer heating the CEC gains back even at higher temperatures (Fig. 1). Cloisite, on the other hand, shows a weak but opposite tendency. The MLC of the smectites changes insignificantly and without obvious trends even after more than one year of heating.



Sample	MLC
MX80 original	0,29
Week 4_Temp. 65°C	0,28

_T150°C	0,27
_T200°C	0,27

Fig. 1: Evolution of CEC and mean layer charge of MX-80 during thermal treatment (open system).

The development of CEC cannot be explained (only) by changes in MLC. Presumably, cations in the interlayer/ ditrigonal cavities in the tetrahedral sheet are stronger bound thus preventing their exchange. Beside possible edge effects, a further process can be the formation of interlayers which are no longer accessible for the exchanging Cu-complex solution, e.g. due to occurring cementations or clay mineral transformations, i.e. formation of hydroxy-interlayered clay minerals. The evolution of water vapour adsorption is the same for all investigated clays: the adsorption ability decreases with increasing temperature but independent from heating time. XRD and FTIR investigations, the study of water uptake and swelling behaviour will give further insight to explain this phenomenon.

Thermal stability and phase transition of natural Na- and Ca-montmorillonites from China, an *in-situ* XRD study under non-ambient condition

Wang Heijing[1*], Zhou Jian[2], Li Ting[1], Wang Mingzhen[1] & Fan Erping[1]
[1]School of Earth and Space Sciences, Peking University, Beijing, P. R. China (*hjwang@pku.edu.cn)
[2]Chinese Academy of Geological Sciences, Beijing, P. R. China

Two natural specimens of Na- and Ca-montmorillonite (Mnt hereafter) were collected from NW and central China [1] for physical properties research [2]. SEM and EDS analyses reveal flake-like habits of both Na- and Ca-Mnts with formulae of $K_{0.1}Na_{0.40}Ca_{0.08}(Mg_{0.54}Al_{1.44})_{1.98}(Al_{0.19}Si_{3.81})_4O_{10}(OH)_2$-$xH_2O$ and $Ca_{0.20}(Fe_{0.13}Mg_{0.72}Al_{1.40})_{2.25}(Al_{0.40}Si_{3.60})_4O_{10}(OH)_2$-$xH_2O$, respectively. The *in-situ* XRD technique was used to investigate the thermal stability and phase transition of these two typical specimens under non-ambient conditions. From room-temperature to 900°C the XRD patterns were measured at 5, 10 and 25°C intervals depending upon the gaps of phase transitions. Deconvolution technique was used to quantitatively measure the ratio of 6-water Mnt to 4-water Mnt and that of 4-water Mnt to paragonite- and margarite-like micas.

With increasing temperature from room condition to 900°C, both Na- and Ca-Mnts dehydrate and change into 9.6-9.7Å mica and finally collapse into glass. Na-Mnt dehydrates from 6-water Mnt into 4-water one in a range of 90-135°C and from 4-water Mnt into paragonite-like mica in range 175-240ºC, whilst Ca-Mnt dehydrates from 6-water Mnt into 4-water one in range 40-85°C and from 4-water Mnt into margarite-like mica in 150-350°C respectively. At a little bit higher than 875°C, both paragonite- and margarite-like micas entirely collapse into black glass and yellow glass, respectively.

There exists a "step" relation between the position of "first basal reflection" of Mnts and corresponding temperature, in which there are three plateaus and two slopes. The first plateau is the stable section of 6-water Mnt, the second plateau renders that of 4-water Mnt and the third one is that of 9.6-9.7Å mica respectively, whilst the first slope indicates the transition from 6-water Mnt into 4-water one and the second slope describes the transition of 4-water Mnt into 9.6-9.7Å mica, respectively. With the help of regression analysis four equations were derived for the two slopes as:

$$d_{6/4\text{water-Na-Mnt}}(Å) = -0.461\ T(ºC) + 66.77 \quad (1)$$
$$d_{4\text{water-Na-Mnt/mica}}(Å) = -0.269\ T(ºC) + 64.958 \quad (2)$$
$$d_{6/4\text{water-Ca-Mnt}}(Å) = -0.197\ T(ºC) + 26.259 \quad (3)$$
$$d_{4\text{water-Ca-Mnt/mica}}(Å) = -0.028\ T(ºC) + 18.385 \quad (4)$$

There exist a series of correlations between the amount (integrated intensity percentage) of 6-water specimen in total Mnts, amount of 4-water specimen in the mixture of Mnt and 9.6-9.7Å mica and corresponding temperature:

$$T(°C) = 134.36 - 0.435M_{6/4\text{water-Na-Mnt}}(\%) \quad (5)$$
$$T(°C) = 83.84 - 0.477M_{6/4\text{water-Ca-Mnt}}(\%) \quad (6)$$
$$T(°C) = 239.98 - 0.661M_{4\text{water-Na-Mnt/mica}}(\%) \quad (7)$$
$$T(°C) = 153.85 - 0.384M_{4\text{water-Ca-Mnt/mica}}(\%) \quad (8)$$

Assuming that the situation of natural Mnts in air-dried condition could represent their thermal stability of formation, the Na-Mnt from NW China and the Ca-Mnt from central China would originate in a temperature range of 135-175°C and 85-150°C respectively.

De-hydroxylation of kaolinite to metakaolin – a molecular dynamics study

Sperinck, S.*, Raiteri, P., Marks, N. & Wright, K.
Nanochemistry Research Institute, Dept. of Chemistry, Curtin University of Technology, Perth, Australia
(*shani.sperinck@postgrad.curtin.edu.au)

Kaolinite, $Al_4[Si_4O_{10}](OH)_8$, is a 1:1 dioctahedral phyllosilicate material and is the main component of the kaolin group of minerals. Calcining kaolinite at temperatures between 450ºC and 750ºC produces metakaolin – a 2-dimensionaly ordered, highly pozzolanic state that is used in the food-processing industry, oil shale processing, and ceramics and as a feedstock for geopolymer cement. The transformation is characterized by a complete de-hydration of the structure, loss of crystallinity and a concomitant change in aluminium coordination from octahedral to tetrahedral.

This transformation of kaolinite to metakaolin has been investigated using molecular dynamics (MD) simulations with an empirical force field that accurately produces the experimental kaolinite structure. Starting from the kaolinite structure (Fig. 1) we performed a series of NPT runs with increasing levels of de-hydroxylation to understand the effects on the structure of kaolinite and the change in aluminium coordination. Our study shows, for the first time, the atomic mechanisms underpinning the loss of crystallinity, which occurs during the de-hydroxylation of kaolin to metakaolin (Fig. 2).

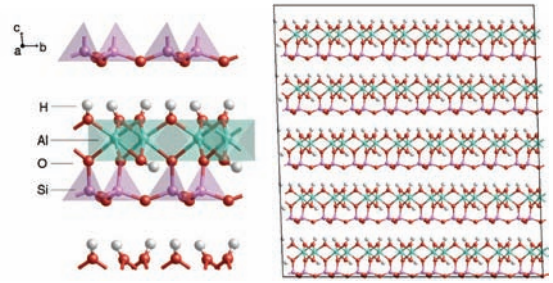

Fig. 1: Layered structure of kaolinite (left) and the initial simulation cell prior to de-hydroxylation (right).

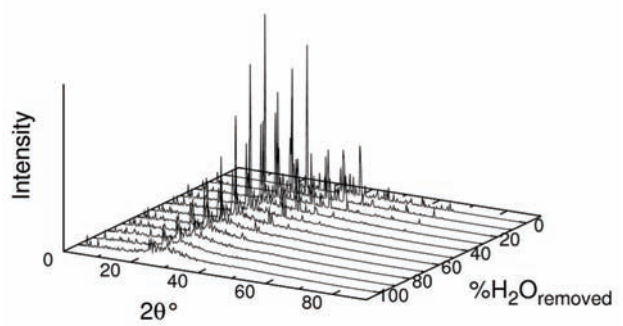

Fig. 2: Simulated x-ray diffraction data showing the loss of crystallinity.

Intercalation and dynamics of hydrated Fe^{2+} in the vermiculites from Santa Olalla and Ojén (Spain)

Lerf, A.[1*], Wagner, F.E.[2], Poyato, J.[3] & Pérez-Rodríguez, J.L.[3]
[1]Walther-Meissner-Institut, Bayerische Akademie der Wissenschaften, Garching, Germany
(*anton.lerf@wmi.badw.de)
[2]Physik-Department, Technische Universität München, Garching, Germany
[3]Instituto de Ciencia de Materiales de Sevilla, Consejo Superior de Investigaciones Científicas-Universidad de Sevilla, Spain

Whereas the uptake of Fe^{3+} into vermiculites and smectites via ion exchange is notoriously difficult and accompanied by the deposition of iron oxyhydroxides on the external surfaces of the phyllosilicate particles [1], the insertion of Fe^{2+} is much easier. To reduce the tendency towards oxidation one can carry out the ion exchange under nitrogen or one can use Fe^{2+} salts (e.g. gluconate) which are less sensitive to oxygen. The vermiculites were treated twice for one hour with freshly prepared Fe^{2+} solutions. Afterwards the solid was washed at least five times with deaerated water and dried. The samples so obtained were stable against oxidation for months when stored in closed vessels (no special protection against air).

The Mössbauer spectrum at room temperature (Fig. 1) looks like the typical spectrum of a vermiculite. Just the peak at ~2.5 mm/s belonging to the quadrupole doublet of the Fe^{2+} site gets slightly broader towards higher quadrupole splitting and increases in intensity slightly.

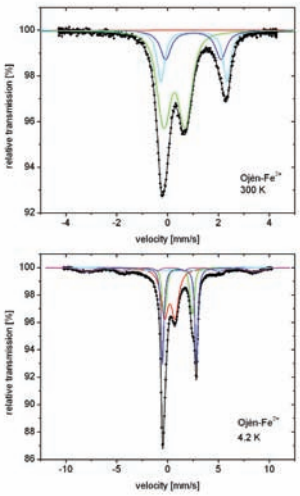

Fig. 1: Mössbauer spectra of the Fe^{2+} intercalated Ojén vermiculite at room temperature (top) and at 4 K (bottom). Dots are the data points, the solid lines marks the individual components as obtained from the fit to the data points.

At 4 K the right of the peak at 2.5 mm/s (Fig. 1) increases dramatically in intensity and the quadrupole splitting of this new site (~3.3 mm/s) can be assigned to the hydrated Fe2+ ions. The dramatic increase in intensity as a function of temperature is mainly due to a strong rise of the Mössbauer-Lamb factor at low temperature, indicating that the Fe2+ ions, which are highly mobile at room temperature, are frozen in definite lattice sites at low temperature. We will discuss also the temperature dependence of the rise of the Mössbauer-Lamb factor with increasing temperature.

High-pressure phase transitions in serpentines

Bezacier, L.*, Caracas, R. & Reynard, B.
ENS Lyon, CNRS, Lyon, France (*lucile.bezacier@ens-lyon.fr)

Serpentines are formed by interaction of water with basic to ultrabasic rocks under conditions that range from shallow (<10 km) ocean floor hydrothermal systems to intermediate depths (150-200 km) of subduction zones. Several Raman and X-ray diffraction data on various serpentine varieties at pressures up to 10 GPa [1-3] suggested phase transformations that were recently confirmed by single-crystal X-ray diffraction on antigorite [4]. DFT calculations on lizardite [5] suggested phase transformation at higher pressures.

We performed first-principles calculations on lizardite using the generalized gradient approximation (GGA) of the density functional theory as implemented in the ABINIT package based on plane waves and pseudopotentials. We compute the lattice dynamical properties, the phonon frequencies and the atomic displacement pattern of the vibrational modes within the density functional perturbation theory.

Results of DFT calculations are compared with former and new high-pressure Raman spectroscopic data and with X-ray diffraction data. They show good agreement on phase transitions observed below 10 GPa. Consequences for serpentine seismic properties and detection in subduction zones are discussed.

High-pressure transformations in kaolinite

Welch, M.D.[1*] & Crichton, W.A.[2]
[1]The Natural History Museum, London, UK
(*mdw@nhm.ac.uk)
[2]European Synchrotron Radiation Facility, Grenoble, France

Polytypic transformations are a key aspect of the crystallography and stability of sheet silicates. However, their physical significance in natural systems at high *P* is largely unexplored.

Kaolinite, $Al_2Si_2O_5(OH)_4$, is a hydrous sheet-silicate of considerable geological, industrial and technological importance. While numerous studies of its ambient and near-ambient stability and geochemistry have been made, almost nothing is known about its *P* response. Recent modelling of kaolinite stability by *ab initio* methods [1,2] has predicted a sequence of polytype stability as a function of *P*: kaolinite ("kaolinite-I", polytype 11a of [1])→ "kaolinite -II" (polytype 5a or 7a of [1])→ "kaolinite -III" (polytype 18 of [2]). Unlike kaolinites I and II, kaolinite–III has trifurcated interlayer H-bonds that arise from the operation of an unusual layer stacking vector and the production of a new kind of polytype.

We have studied the behaviour of Keokuk kaolinite (space group *C*1) to 8 GPa at 298 K using synchrotron X-ray powder diffraction and a diamond-anvil cell [3]. Two transformations were encountered: kaolinite-I → kaolinite -II at 3.7 GPa and kaolinite-II → kaolinite -III at 7 GPa. The two high-*P* phases were identified from calculated diffraction patterns based on the model polytype structures listed by [1,2]: kaolinite-II is the 5a polytype of [1], and kaolinite-III is the one-layer model 18 polytype of [2]. Thus, experiment has confirmed the predictions of *ab initio* modelling.

Both transformations involve layer translation without rotation. Kaolinite I↦II involves the removal of unfavourable vertical cross-interlayer Al-Si superpositions, and so is analogous to the 2.7 GPa transformation in dickite [4]. Kaolinite II→III involves the formation of a new kind of polytype, which has a very different hydrogen-bonding topology and layer stacking from kaolinites I and II. Kaolinite-III can be quenched to ambient conditions from 7.8 GPa. Its ambient density of 2.77 g/cm^3 is 6% higher than those of kaolinite-I, dickite and nacrite; thus, it is a significantly collapsed structure.

Bulk and linear moduli for kaolinites I and III were obtained from compression curves of the EoS study. Unit-cell parameters were obtained by refinement of powder diffraction patterns and fitted to a 2nd-order Birch-Murnaghan EoS (K' = 4).

Kaolinite-I: K_0 = 59.7(0.7)GPa, K_a = 88.6(3.5)GPa, K_b = 85.4(2.8)GPa, K_{001} = 34.6(0.5)GPa.

Kaolinite-III: K_0 = 50.2(1.5)GPa, K_a = 63.3(4.1)GPa, K_b = 54.8(1.6)GPa, K_{001} = 38.2(1.2)GPa.

The higher compressibility (lower K_0) of kaolinite-III is due to softening parallel to the polyhedral sheets.

Trioctahedral micas: relationships between crystal chemistry and magnetic behaviour

Affronte, M[1], Brigatti, M.F.[2], Malferrari, D.[2*], Marcelli, A.[3] & Pini, S.[2]
[1]Dipto. di Fisica, Università di Modena e Reggio Emilia, Modena, Italy
[2]Dipto. di Scienze della Terra, Università di Modena e Reggio Emilia, Modena, Italy ([*]dmalf@unimore.it)
[3]Istituto Nazionale di Fisica Nucleare, Laboratori Nazionali di Frascati, Italy

This study is aimed at verifying the factors affecting magnetic susceptibility χ variation in micas in relation to: I) Fe content; ii) Fe^{2+}/Fe^{3+} ratio; iii) occurrence of Fe in tetrahedral and octahedral sites, outlining possible ordering effects.

Other aspects considered in our study will involve: i) eventually observed variation in magnetic properties for samples showing similar chemical composition, but occurring from different areas and different crystallization environments; ii) possible influence of strong magnetic anomalies over magnetic properties of samples therein occurring.

All these aspects were thus addressed by characterizing samples belonging to phlogopite – annite, tetra-ferri-phlogopite – tetra-ferri-annite and polylithionite – siderophyllite series. Some samples, representative of the whole sample set, were then selected for magnetic susceptibility characterization. Some of them also required calorimetric analyses, in order to better describe and understand their behaviour.

Other experimental methods used in this investigation include: electron microprobe, structure resolution by X-ray single crystal methods, X-ray absorption spectroscopy, with a particular attention to the understanding of the XANES region.

Main results demonstrate that: i) magnetic phenomena associated with maxima of magnetic susceptibility could be observed at low temperature (T<10 K) and weak magnetic field (10 Oe); ii) magnetic properties depend not only on the total Fe content. Samples where Fe is mostly in octahedral coordination are predominantly ferromagnetic, strongly depending on the $[6]Fe^{2+}/([6]Fe^{2+}+[6]Fe^{3+})$ ratio, which was observed to increase with Curie-Weiss θ constant (ranging from 13 to 24 K and from 4.4 and 5.2 K for samples showing higher and lower $[6]Fe^{2+}/([6]Fe^{2+}+[6]Fe^{3+})$ ratio, respectively). In tetra-ferri-phlogopite, dominant interactions were observed to be anti-ferromagnetic, as shown by a negative Curie-Weiss θ constant value (-25 K). Furthermore Curie-Weiss constant (θ) and the temperature value giving the maximum in the magnetic susceptibility (Tm) seem to be dependent not only on the mean number of Fe atoms in octahedral coordination (Z) per unit cell, but also on its ordering. Tm linearly depends on several structural parameters as well, e.g., the tetrahedral rotation angle α.

Effect of temperature on Hg-cysteine complexes in vermiculite and montmorillonite

Malferrari, D.[1*], Brigatti, M.F.[1], Marcelli, A.[2], Chu, W.[3] & Wu, Z.[2,3]
[1]Dipto. di Scienze della Terra, Università di Modena e Reggio Emilia, Modena, Italy ([*]dmalf@unimore.it)
[2]Istituto Nazionale di Fisica Nucleare, Laboratori Nazionali di Frascati, Italy
[3]Beijing Synchrotron Radiation Facility (BSRF), Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, P.R. China

This work describes the influence of temperature on two Hg(II)-cysteine modified clay minerals with different layer charge (*i.e.*, vermiculite and montmorillonite) by using chemical analyses, thermal analyses coupled with evolved gas mass spectrometry (TGA-MSEGA), synchrotron-based X-ray absorption spectroscopy (XAS), and X-ray powder diffraction (XRPD) techniques. These two latter techniques were applied on samples heated "*in situ*" up to 900°C. Hg binds cysteine by the thiol group with Hg–SH bond lengths similar in both clay minerals, thus suggesting their independence from layer charge. On the contrary, the thermal behaviour of the adsorbed organometallic complexes is strictly layer charge dependent, as evidenced by decomposition temperatures, which are commonly lower in montmorillonite than in vermiculite. Results from X-ray absorption near edge structure (XANES) spectroscopy evidence a nearly completely Hg removal in montmorillonite at temperature values ranging from 600 to 700°C, unlike in vermiculite where Hg is still present at these temperatures.

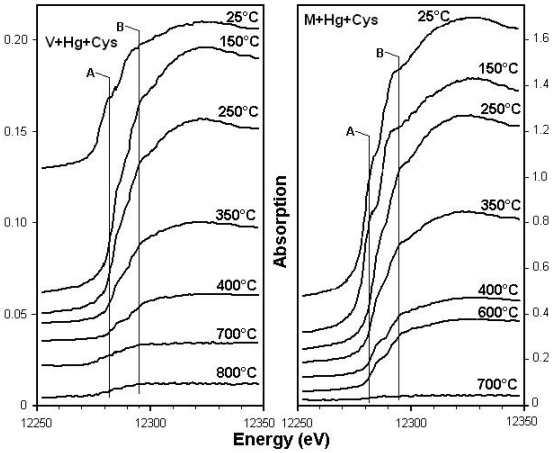

Fig. 1: XANES spectra of Hg-Cysteine treated vermiculite (left side) and montmorillonite (right side) vs. temperature.

Kinetics of Zn-Al hydrotalcite structure reconstruction process

Zimowska, M.*, Napruszewska, B.D., Dula, R., Mucha, D. & Serwicka, E.M.
Institute of Catalysis and Surface Chemistry, Polish Academy of Sciences, Krakow, Poland (*nczimows@cyf-kr.edu.pl)

The unique ability of anionic clays known as „memory effect" allows for the reconstruction of the layered structure of calcined hydrotalcite-like samples. In view of this, our intention was to investigate the kinetics of structure reconstruction of the zinc-aluminum hydrotalcite type samples calcined at 450 °C for 3 hours. Hydrotalcite-like samples (Htl) with atomic ratio of Zn:Al = 3:1, synthesized by standard co-precipitation method at a constant pH=7, using either Na_2CO_3 and NaOH, or $(NH_4)_2CO_3$ and NH_3 (aq) for precipitation and control of pH. The precipitates were calcined at a desired temperature and subsequently exposed to humid air at room temperature.

XRD analysis of the starting materials confirmed that the synthesized samples possessed Htl structure, mainly with carbonates as compensating anions. The presence of some nitrate anions was evidenced with the EGA and FTIR results. Nitrate contribution was, at least in part, associated with $Zn_3(OH)_4(NO_3)_2$ phase whose traces were observed in both samples (especially in the solid synthesized with Na_2CO_3 and NaOH). XRD patterns of calcined samples showed strongly amorphous materials, with poorly crystalline ZnO as the only identifiable phase. The reconstruction process was carried out at controlled humidity (94%) and temperature (295K) conditions.

Already after 10 days in all calcined samples strong reflections originating from recovered Htl structure were observed. The progress of reconstruction was investigated over a period of up to 150 days. In all samples, independently of the applied preparation method, the position of d_{003} reflection was constant and appeared at 0.755 nm, which shows that, as expected, a carbonate form of Htl was formed upon reconstruction. Even after the longest applied treatment (150 days), not all of the ZnO phase was consumed. Analysis of the XRD patterns suggests that in the first place reconstruction occurs at the expense of the finest ZnO grains. Apparently, their high surface energy is responsible for facile rebuilding of the Htl lattice at the beginning of experiment.

Noteworthy, crystallinity of the reconstructed phase was better than that of the starting Htl. This is also illustrated by SEM images, which show the changes in grain morphology at different stages of the reconstruction experiment.

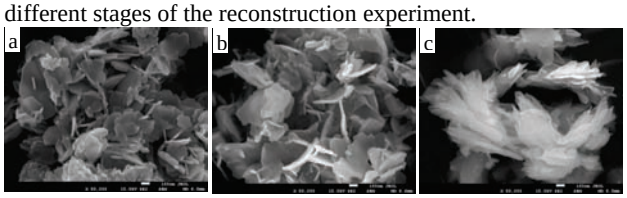

Fig. 1: SEM images of a) fresh Zn-Al Htl precipitated with Na_2CO_3 and NaOH, b) calcined at 450°C, c) after the reconstruction.

Deformation and lattice preferred orientations of antigorite serpentine

Reynard, B.[1*], Bezacier, L.[1], Van de Moortèle, B.[1] & Hilairet, N.[2]
[1]ENS Lyon, CNRS, Lyon, France ([*]bruno.reynard@ens-lyon.fr)
[2]GSECARS APS, University of Chicago, Chicago, IL, USA

Antigorite is the major component of serpentinites in subduction zone context. Its presence and deformability likely control the downdip extent of the seismogenic zone and exhumation processes. Lattice preferred orientations (LPO) of serpentines induce a strong anisotropy of various properties in serpentine bearing-rocks. For example, seismic anisotropy is potentially extreme in serpentinites and may allow their seismic detection as well as the determination of the deformation pattern at the plate interface and in the mantle wedge. LPO of antigorite had so far been obtained only by X-ray diffraction techniques. We have applied EBSD to the measurement of the LPO of antigorite in a naturally deformed high-pressure serpentinite. This technique is very sensitive to sample preparation that can lead to surface amorphization in the case of serpentine. A polishing procedure is described that avoids amorphization and allows accurate EBSD measurements with optimized experimental conditions in a variable pressure SEM. Results indicates that deformation leads to LPO characterized by extremely strong c-axis clustering perpendicular to the foliation, as expected for a layered silicate. In the foliation plane, a significant clustering of the a-axis is observed and tentatively attributed to intracrystalline deformation mechanisms. These data suggest that antigorite deforms mostly by gliding along the basal plane of the layered phyllosilicate structure, but that gliding may occur along directions favoring a-axis alignment. EBSD appears to be a reliable method for determining phyllosilicate LPO in deformed rocks, with potential applications for determining anisotropy of properties like seismic velocities or thermal and electrical conductivities. Applications concerning seismic anisotropy are shown. Comparison with deformation in experimentally deformed antigorite is in progress and will be presented.

Influence of clay microfabrics on petrophysical properties of clay stones and bentonites

Klinkenberg, M.[1,2,3*], Dohrmann, R.[2], Kaufhold, S.[2] & Siegesmund, S.[3]
[1]present address: Institute of Energy Research (IEF-6), Research Centre Jülich GmbH, Jülich, Germany ([*]m.klinkenberg@fz-juelich.de)
[2]Technical Mineralogy, Sedimentology, BGR/LBEG, Hannover, Germany
[3]Geowissenschaftliches Zentrum der Universität Göttingen, Germany

Claystones and bentonites are currently being investigated as potential host rock and geotechnical barrier, respectively, for radioactive waste disposal. For this application, the hydraulic conductivity, swelling properties, water uptake, rheological and mechanical properties are important. The Opalinus Clay (Mont-Terri, Switzerland) and the Callovo-Oxfordian clay stone (France) are the most frequently studied clay stones. One goal is to develop a numerical model being able to predict the mechanical behaviour of clay stones under repository-like conditions.

The results of this study show that Opalinus Clay and Callovo-Oxfordian clay stone behave different with respect to the dependence of mechanical strengths on the carbonate content. The failure strength of Opalinus Clay decreases with increasing carbonate content, while it increases for Callovo-Oxfordian clay stone [1]. For the investigation of the microfabrics, scanning electron microscopy of polished sections and image analysis were used. Opalinus Clay shows large elongated carbonate grains of shell fragments, whereas Callovo-Oxfordium clay stones show a homogeneous distribution of fine-grained and more isometric carbonates. The most important result of this study is that not only the carbonate content, but also the microstructure (grain size distribution, shape, spatial distribution, and intergrowth of carbonates) affects the mechanical behaviour of the claystones. The microscopy and image analysis techniques proved to be an excellent tool, which can be employed in model development.

Furthermore, the microfabric of 38 bentonites was investigated. During genesis bentonites undergo continuous maturation from glass to smectite. Almost all bentonites show glass relict structures. The microfabric of the bentonites, particularly the intergrowth with relict volcanic glass may have an additional influence on relevant geotechnical properties. Based on the optical characterisation, a model of maturation was developed, containing five alteration-classes. The following petrophysical properties of bentonites were determined and compared to the microstructural characteristics namely density, porosity, BET-surfaces, abrasivity of bentonite suspensions [2], electrical conductivity, and water uptake capacity [3]. The results show that all these properties are affected by the microfabric.

Relationship between morphological preferred orientations and landslides

Bortolotti, D., Brigatti, M.F., Elmi, C., Malferrari, D.* & Pattuzzi, E.
Dipto. di Scienze della Terra, Università di Modena e Reggio Emilia, Modena, Italy (*dmalf@unimore.it)

Crystals orientation in polycrystalline natural compounds may be either completely random or else follow preferred directions, which reflect physical processes in which the materials have been involved during the solidification and / or after the solid state had been reached.

The preferred orientation can be divided into two main groups: i) preferred orientation of the crystal lattice (LPO, lattice preferred orientation) and ii) grains preferred orientation (i.e., morphological preferred orientations, MPO). Frequently there is a close relationship between these two groups. Geological processes that determine the formation of LPO are, for example, tectonic (regional) compressive movements; on the other hand MPO can be induced also by local stress (i.e., gravitational movements). While tectonic (regional) compressive movements may produce LPO even on already lithified rocks, usually, MPO are induced only on not-lithified and incoherent rocks.

The preferred orientation cab be observed: i) macroscopically (the rock structures) ii) microscopically, grains orientation and morphological textures of the rock according to the classic concept of optical microscopy, iii) with diffraction methods (i.e., X-rays and neutrons diffraction), to study both LPO and MPO when, this last, cannot be studied via optical methods because, for example, of a very small grain size.

This research will investigate MPO via X-ray diffraction only. We collected, and kept oriented, samples in several landslide areas. In particular samples were collected both in the active crumbling area and at the landslide margin. Samples were analyzed for texture using X-ray diffractometer equipped with a phi-chi Eulerian cradle. We analyzed the preferred orientation of the hkl reflections: i) (001) and (060) in smectiti and illite; ii) (001) and (100) in caolinite; iii) (24-1) in plagioclase.

Preliminary investigation demonstrated a direct correlation between the number of MPO and the amount of clay minerals. Texture measurements on samples collected in the crumbling area agree with other morphological field measurements, providing, in addition to the main direction of the landslide, also the vertical module, thus probably defining the preferential path for interstitial fluids migration. Only in one case we could observe preferred orientation in a sample coming from a margin of a landslide, data which could testify a past movement (paleo-landslide) or else a quiescent landslide.

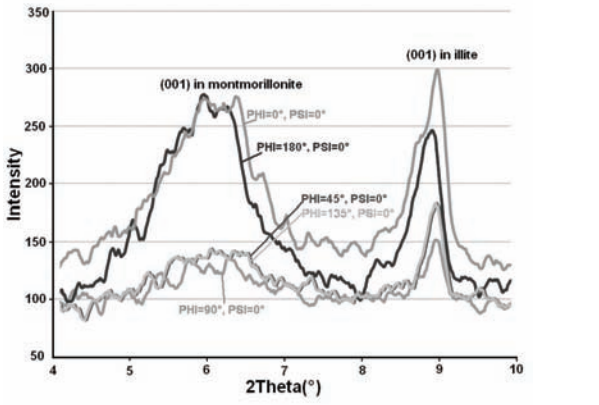

Fig. 1: Intensity variation of (001) in montmorillonite and illite varying sample orientation.

The influence of scaly fabric on the illitization reaction in faulted claystones

Dellisanti, F., Pini, G.A. & Valdrè, G.*
Dept. of Earth and Geo-Environmental Sciences, University of Bologna, Italy (*giovanni.valdre@unibo.it)

A closely-spaced fabric, related to the interlacing of striated and polished shear planes, is commonly defined as scaly fabric in the geological literature. A tens-of-meters-wide belt characterized by pervasive scaly fabric occurs in claystones of the Northern Apennines foothills, south of the town of Bologna, in a shallow-level fault zone. The shear planes are arranged in different oriented sets defined hereafter as R, P, R' and D planes, following the terminology after Tchalenko (1968) [1].

Microscopical observations (SEM) show a significant increase of parallel orientation of the clay platelets ("face to face" arrangement) on the surfaces and in the proximity of shear planes, leading to development of clavage domains and porosity decrease. Despite, far from the shear planes in the undeformed domains (microlithons), the clay particles show a more open texture with a "edge to face" disposition, due to a more disordered arrangement of the clay particles.

A systematic mineralogical study performed by XRD on the less than 2 micron grain-size fraction has evidenced a progressive illitization of smectites and mixed layer illite/smectites (I/S) along shear planes and cleavage domain associated. The progressive change from smectites-rich I/S into illite-rich I/S was also confirmed by microchemical EDS data, which showed an enrichment in K^+.

The studied claystones were sampled in absence of significant mechanical compaction and clay mineral diagenesis and the alignment of clay platelets and illitization occurred in shallow burial conditions and very low thermal maturity (< 60°C) [2]. Moreover, the illitization reaction in the scaly cleavage domain is isothermal and probably driven only by K^+-rich fluid circulation.

The progressive transition from smectite-rich I/S to illite-rich I/S is due to enhanced fluid migration, which is preferred within the scaly cleavage domains because enriched in oriented phyllosilicates (P-domains), whereas the circulation is inhibited in microlithon cores because of disordered arrangement of clay particles. The anisotropic fabric is caused by tectonic strain, which produces flattening and extension of clayey rocks leading to a volume decrease and consequent fluid expulsion. This tectonic dewatering mechanism involves chemical changes within the microstructural domains favouring progressive illitization of clay particles.

[1] Tchalencko, J.S. (1968) *Tectonophysics*, **6**, 159-174. [2] Dellisanti, F. et al. (2008) *Int. J. Earth Sci.*, **97**, 601-616 .

Experimental shear test of montmorillonite: the role of water on geomechanical behaviour of smectite

Dellisanti, F., Pini, G.A. & Valdrè, G.*
Dept. of Earth and Geo-Environmental Sciences, University of Bologna, Italy (*giovanni.valdre@unibo.it)

In order to investigate the role of the interlayer water molecule of Ca-montmorillonite on the geomechanical behaviour, a cycle of controlled experimental shear deformations on natural and structurally modified Ca-montmorillonites have been performed and correlated to structural and morphological analysis. Experimental shear tests were performed on five types samples: (1) a natural Ca-montmorillonite; (2) the same montmorillonite after heating for three hours at 80°C; (3) at 250°C; (4) at 335°C, and (5) after inducing defects in the tetrahedral and octahedral sheets. The five samples have been shear-tested by a specifically built shear box apparatus under 19.6 MPa condition of normal pressure. All samples, before and after the shear deformation, have been analysed by SEM and XRD.

The shear-deformed samples were cohesive and presented striated and polished shear planes along the displacement surfaces imposed by the experimental apparatus. The shear planes were arranged in sets disposed at low angle with respect to the principal shear surface, which correspond to R, P and D planes, [1,2]. The disposition of planes and the lustrous aspect of the surfaces are quite similar to the ones observed in natural examples. In our experiments striations are not related to ploughing by coarse grains or asperities because we have deliberately used montmorillonite with homogeneous composition and granulometry. XRD and SEM analyses indicated that in the vicinity of the shear planes the clay platelets appear preferentially orientated and with a “face to face” arrangement, whereas in zones far from the shear planes the platelets present a lower degree of orientation and an “edge-face” disposition. The shear strain also produced a reduction of structural ordering and an increase of both lattice defects and microstrain in the mineral. Moreover, natural montmorillonite presented a typical strain softening behaviour and the geotechnical parameters (cohesion and internal friction angle) of overconsolidated clayey rocks

The cohesion and compaction of the material are essentially related to the capability to release what is called “absorption water”, whereas the development of striated shear planes has to be attributed to the role of interlayer water. The last hypothesis is supported from the experiments carried on the same material heated up to 80°C (to desorb completely the water), which showed only scaly cleavage and striations. Samples heated up to 250 and 335°C, which have almost completely lost the interlayer water molecules, did not show neither development of scaly cleavage nor striations on the principal shear surface. However, they showed a very moderate strain hardening behaviour. Defective montmorillonite with disorder in the tetrahedral and octahedral sheets (hindering absorption and release of water, as described by [3], presented, as expected, a strain hardening behaviour without any striations and scaly cleavage. The general strain softening behaviour of natural montmorillonite can be explained by the presence both absorption and interlayer water that allow the sliding of clay platelets along the TOT layers. However, the montmorillonite, which contains defects and disorder is hindered to a deformation by a sliding mechanism and therefore does not develop shear planes and alignment of clay platelets.

Adsorption properties of clays in teaching of Environmental Chemistry

del Hoyo Martínez, C.[1*] & Queiruga Dios, A.[2]
[1]Dept. of Inorganic Chemistry, University of Salamanca, Spain ([*]hoyo@usal.es)
[2]Dept. of Applied Mathematics, University of Salamanca, Spain

In the last fifty years, environmental issues has required the study of air pollution, water and soil to prevent and remedy the adverse effects of waste originating from anthropogenic activity and the development of new energies and new materials. The teaching of this discipline has been marked by lectures on general lines, materials, disciplines, who explained biased objects of reality, but often forgot the task of reconstruction and integration of such visions. Moving from that model, otherwise quite static, to a dynamic relational model, would in our view, a real revolution in education. This means taking a systematic approach to complex both in interpreting reality and in favor when learning. Children relationships are as important or more than single objects, and it is to discover fundamental organizational principles of phenomena we seek to interpret or in other words, find the pattern that connects. Thus, we must work on relationships and also take into account the relation between the observer and the observed. Educate about relationships means that studies should always be considered within a framework of probabilities, not absolute certainties.

This model of systemic thinking, dealing with complexity, is a possibility to bring coherence to our educational work, because the complexity is not taught, complexity is live, so that complex thinking is extended (and fed) in a form educate complex. It is the task of teaching to help people move from level to level of decision reviews. This means that systems thinking should be extended in a local action, action that engages the individual and the environment. So we must work with our students helping them to understand, in this case, environmental problems from their daily reality, where the real subject of study.

Environmental Chemistry has emerged as a discipline of free choice for pupils attending chemical engineering which has been assigned 4.5 credits theorists. The chemical engineer's professional profile within the current framework is defined as a professional knowledge as a specialization technical / functional, working in a learning organization and the formation of which enables him to continuous improvement and innovation.

There are different materials used in the adsorption and immobilization of chemical contaminants, most of which remain under patent, so they do not know the procedures and products used, but in all cases the safety and / or biodegradability of materials used is an important issue in their choice for environmental applications. Regarding the materials, safe and low cost, clays and clay minerals must be mentioned, because their colloidal properties, ease of generating structural changes, abundance in nature and low cost make them very suitable for absorption of chemical contaminants. We proposed to use these materials to show the different aspects for the study of the Enviromental Chemistry.

Minerals in context: the Earth, rocks, and society

Dutrow, B.L.
Dept. Geology & Geophysics, Louisiana State University, Baton Rouge, LA, USA (dutrow@lsu.edu)

Minerals are the fundamental building block of our Planet and are the heart of a geoscience education. Yet, there is an increasing perception that a foundation in mineral sciences is no longer relevant, nor critically necessary for a comprehensive geosciences education. Teaching *"minerals in context"* provides a powerful approach for engaging students in the exciting, important and socially relevant field of mineralogy.

At Louisiana State University, U.S.A., this is accomplished in three different classes ranging from the required mineralogy course through elective advanced courses. For our first core curriculum course in mineralogy, the context of minerals is Planet Earth and the approach focuses on teaching minerals from the core to the crust. Systematic mineralogy is introduced via elements in the core and proceeds outward increasing in mineral complexity as one proceeds to the crust. With this emphasis, crystallographic concepts are woven into the discussion of minerals as they are encountered. For example, mantle minerals provide a backdrop for teaching polymorphic phase transitions in context of their environment in the transition zone. Further, relevance can be given by connecting to deep-focus earthquakes. Crystal chemical concepts are reiterated once crustal minerals are described. This approach sets the stage for the multitude of complexity found in crustal minerals both in terms of environment, chemistry, and structure. Here, numerous connections are made with reference to minerals in our lives as well as minerals as key indicators of environmental conditions. Such an approach emphasizes the central focus of mineralogy and its linkage to other disciplines.

For the advanced level, two approaches continue to focus on teaching minerals in context: minerals as fingerprints of geologic conditions (in the course Petrologic Mineralogy) and minerals in our lives (course: Earth Materials and the Environment-EME). Petrologic mineralogy continues to explore the crystal chemistry and structure of minerals in the context of deciphering tectonic evolution; that is, minerals as geochronometers, geothermobarometers and/or as provenance indicators. In this course, students complete a semester-long research project where they chemically analyze minerals in order to determine derivative information such as P-T, age, or source. In contrast, for the EME course, minerals are explored as both problems and solutions in the context of societally relevant issues. These range from various health effects (e.g. asbestosis, silicosis), to solutions for global warming (e.g. carbon capture and sequestration) and nuclear waste (e.g. material templates for encasement, geologic barriers), to requirements for our standard of living (e.g. metals, rare earth elements, PGEs). Such a context not only raises awareness of the critical nature of our science and its importance to government policy but also provides opportunities for improving critical thinking skills as related to the development of public policy dealing with these issues. In both cases, students appear to engage more fully in the material because it relates to their lives and opens their eyes to potential career goals and their everyday lives.

Volcanic petrology in six weeks

Nicholls, J.
Dept. of Geoscience, University of Calgary, Alberta, Canada
(nichollj@ucalgary.ca)

At the University of Calgary students have to learn igneous petrology in six weeks. I've heard of similar reductions in time allocated to mineralogical science courses at other universities. Responses to the reductions included: provide an overview, teach everything anyway, or teach through special projects. An overview provides little depth. Covering everything leaves students frustrated and feeling inadequate. Projects are great but students don't reach an appreciation of the many different faces of igneous petrology.

Several decades ago, the goal of a geology program was a student who could work at a professional level in any geologic setting. Today, many students specialize; they expect to work at the professional level in the energy industry, on problems of climate change, or on problems of environmental remediation, to name but a few popular career fields. Prospective employers often share their expectations. Most students graduating with geoscience degrees will never look at an igneous rock as a professional geoscientist. Why then, do they need to learn about igneous rocks? This is the first of three important questions that geoscience educators must answer if they expect to keep igneous petrology in geoscience curricula.

Igneous petrology is integral to geoscience. Igneous events sporadically intrude themselves into our lives, often with a vengence. Those who graduate with a degree in geoscience will be expected to assess the events for themselves, their families, and their communities. If they cannot, their reputations will suffer along with the reputations of the departments granting their degrees and along with the reputations of the faculty in those departments.

Second question: supposing these arguments convince the powers that be to keep igneous petrology in the curriculum, what should be included in a six-week course? At a minimum, geoscience graduates should be able to assess articles on igneous phenomena in popular science magazines such as *National Geographic*, *Scientific American*, *American Scientist*, *Elements*, and *Earth*. I recently reviewed several issues of these magazines and compared their contents to the material I had taught in igneous petrology a decade ago. Two features stood out: (1) Articles were almost always about volcanic, not plutonic, events and products; (2) The articles were devoid of rock names, textural descriptions, rock compositions, and theoretical petrology, for example thermodynamics and phase diagrams. The articles focused on the effects eruptions had or could have on society and civilization. I would leave out plutonic rocks and theoretical petrology. Six weeks is not enough time to do justice to all three aspects. Geologic context, texture, mafic index, silica activity, alumina activity, and chemical composition would be emphasized. If students know something about these features for any particular volcanic rock they will know a lot about its nature and can infer much about the processes that formed it.

Third question: how can a six-week course in volcanic petrology enhance the degree of an undergraduate who plans a specialized professional career?

Graduating students should be able to discover the geologic context of a volcanic rock, describe its textural features, identify the critical minerals it contains, and become familiar with its chemistry. With this background, they should be able to read and assess mass media accounts of volcanic activity, take part in geoscience outreach programs where they could talk about volcanic phenomena with confidence and without misconceptions, and they should be able to write accounts of volcanic phenomena suitable for popular science magazines.

Teaching mineralogy for geology students at the Eötvös L. University, Budapest, Hungary

Buda, Gy.
Dept. of Mineralogy, Eötvös L. University, Budapest, Hungary
(buda@ludens.elte.hu)

Teaching mineralogy at the Eötvös L. University began in 1774. The separate Department of Mineralogy was established in 1849. From this time several text-books were available based on Dana's Mineralogy or Klockmann and Ramdhor text-books. After World War II., geology training started and students of geology received detailed and specialised mineralogy during the first and second semester. Due to the demand of students of geology several university notebooks and textbooks were published. The last one was the textbook of Koch S and Sztrókay K. I (first published 1955, last one in 1986 in two volumes). These lectures and text-books, besides the well known general mineralogy (crystallography, X-ray crystallography, crystal chemistry, physical properties of minerals etc.), dealt with systematic mineralogy. The systematic mineralogy part, written by Sztrókay, differs from the previous text-books. It is based on crystal chemistry and the sequence of mineral classes reflects Sztrókay's concept [1].

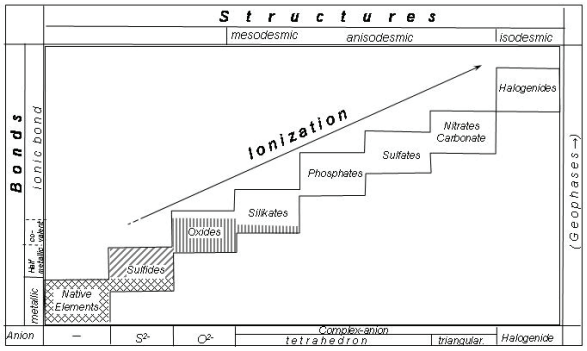

Fig. 1: Sequence of mineral classes by K. Sztrókay (1982).

He started with metallic (native metals and sulphides), followed by covalent (oxides) and more and more ionic bonds (silicates, phosphates, sulphates, borates, carbonates, nitrates, halogenides) and finished with the molecular structures of organic minerals. When describing the individual mineral species, Sztrókay included crystal structure, lattice parameters etc., but also emphasized the diagnostic features and gave information on genetics and localities needed for geologists. Unfortunately the two levels (BSc, MSc) of the new Bologna-system radically decreased number of the lectures of mineralogy. Basic knowledge of natural sciences by secondary school students is becoming poor and consequently there is now little chance to make them understand principles of mineralogy. There is a greater chance that mineralogy as one of the main subjects for students of geology shall disappear from the geology curriculum in Hungary.

[1] Sztrókay, K.I. (1962) *Über die Grundprinzipien einer zeitemässen Systematik des Mineralreichs*. I. Teil. Ann. Univ. Scien. Bp. de R. Eötvös Nom. Sec. Geol. Budapest, **5**, 139-149.

Teaching of crystallography and gemmology at the "Museum of Unique Crystals", Sofia, Bulgaria

Kostov, R.I.
Dept. of Mineralogy and Petrography, University of Mining and Geology "St. Ivan Rilski", Sofia, Bulgaria
(rikostov@gmail.com)

The newest mineralogical museum in Bulgaria is devoted to the famous collector and donator of Bulgarian origin – Mr. Ilia Deleff, who in the past decades worked for preservation of the mineral heritage on the planet. Mr. Deleff (Brazilian citizen, born 1921 in Bulgaria) is a well known collector of phenomenal giant and rare minerals. In 1983 Mr. Deleff exhibited for the first time in the world his collection with giant crystals in the National Museum of Natural History in Paris. In 1987 in Sofia was opened to the public the "Earth and Man" National Museum, where the main and central part constitutes the remarkable collection of Mr. Deleff of unique giant quartz crystals and other minerals from Brazil [1]. In Bulgaria Mr. Deleff made also several donations with minerals from Brazil to the University of Mining and Geology "St. Ivan Rilski" in Sofia, which can be seen in the newest mineralogical museum – Museum of Unique Crystals "Ilia Deleff". In the museum are exhibited rare crystals and minerals from Brazil in the following sections: crystal flowers of nature; parade of phenomenal crystals; treasures of Minas Gerais; gem pegmatite minerals; mineral wealth of Brazil; world of agates; the noble amethyst; the quartz palette; rock crystal fairy; nature and art. Special ascents at the museum are the "Amethyst Room" and the "Rock Crystal Cave".

The Museum of Unique Crystals (MUC) at the Rectorate is open to the public and for social events as the most representative museum among the other academic museums (geological and paleontological; mineralogical and petrographical) at the university. Since its opening in November 2007 the MUC serves also as a place for lectures and education in mineralogy and crystallography for the bachelor degree [2] and in gemmology for the bachelor and master degrees [3]. Impact in the teaching process is made on the richness of crystal habits of minerals [4], mainly quartz varieties of different size, perfection and colour, as well as some gem minerals as topaz, beryl, tourmaline, kunzite and feldspar. As Bulgaria is not so rich of gem and decorative minerals [5] compared to Brazil, the exhibit allows a broad enrichment of the knowledge of different common and rare mineral species. The main hall is used for presentations and scientific films, including for scientific conferences. Students and other visitors of the museum are assisted in their mineralogical research also by a gem and mineral shop.

Interactive Wolfram Mathematica demonstrations and physical models for studying crystal structures

Kabai, S.
Uniconstant Co., Budapest, Hungary (unico@t-online.hu)

From Version 6 on (launched on May 1, 2007) the computer software Wolfram Mathematica is capable of showing interactive graphics, which can be used preferably to study crystal shapes and structures. In this paper selected demonstrations are shown that are related to crystal structures (Fig. 1-3). In the last part the modeling with polystyrene blocks is introduced. The blocks are cut out with the proprietary machine of the author, and then sticked together (Fig. 4) (http://demonstrations.wolfram.com/search.html?query=kabai).

IMACS: an international Master programme entirely devoted to clays

Patrier Mas, P.[1], Petit, S.[1*], Christidis, G.[2], Ferreira da Silva[3], G., Rocha, F.[3], Blanchette, C.[4], Detellier, C.[4] & Mexias, A.[5]
[1]Université de Poitiers, UMR 6269 CNRS HydrASA, Poitiers, France ([*]sabine.petit@univ-poitiers.fr)
[2]Technical University of Crete, Chania, Greece
[3]University of Aveiro, Portugal
[4]University of Ottawa, Canada
[5]Federal University of Rio Grande Do Sul, Porto Alegre, Brazil

Most existing Masters Courses dealing with clays focus on a single discipline or domain in which Clay Science does not necessarily constitute the main part of the course (Earth Sciences, Civil and Geotechnical Engineering, Materials Science, Environmental and Life Science, Chemistry and Chemical Engineering). However, Clay Science is a multidisciplinary endeavour, combining geology, mineralogy, crystallography, with physics, geotechnology, and soil mechanics together with inorganic, organic, physical and colloid chemistry and biochemistry. The IMACS (International Master in Advanced Clay Science) is the first multi-disciplinary programme that brings together the widely-distributed knowledge of clay science.

IMACS is an integrated 2 years master programme developed by five universities: the University of Poitiers (France), the Technical University of Crete (Chania - Greece), the University of Aveiro (Portugal), the University of Ottawa (Canada) and the Federal University of Rio Grande Do Sul (Porto Alegre – Brazil). AIPEA is an associated member of this consortium. The French Clay Group (GFA) also supports IMACS.

The teaching language is English. During the first year, basic knowledge on clays is provided, followed by a four month master project, which completes the first year programme. The second year incorporates two elective specialization options in the following fields: 1) Environment, soil and geological systems, 2) Geomaterials and civil engineering – Assessment and processing, 3) Advanced clay – nanomaterials, and 4) Healing minerals. The master thesis (6 months) completes this second year and can be carried out at any of the partner research laboratories. The completion of the curriculum is rewarded by a multiple Master Degree.

The IMACS programme was approved by the European Commission under a very competitive application scheme as an Erasmus Mundus Joint Master programme in July 2009 and it will open in September 2010. Erasmus Mundus is a cooperation and mobility programme in the field of higher education supported by the European Commission. This programme offers financial support for high-quality joint master courses, attractive scholarships/fellowships for both Non European and European student candidates and short-term scholarships for Non European and European academics to carry out research or teaching assignments as part of the joint masters project. Free language training in the local languages is offered by the five higher education institutions. Moreover, the programme makes available a range of services and facilities (e.g. visa request, accommodation, insurance, bank account opening, social and cultural activities among many others…) to the students.

This Masters Course is open to students holding a BSc (or a degree equivalent to 180 ECTS) or an academic equivalence based on professional experience, and a fluent understanding of the English language.

ERASMUS MUNDUS

Teaching clay science and technology within a Geological Engineering Master program: Bologna Process implications

Rocha, F.
Geosciences Dept., Geobiotec Unit, University of Aveiro, Portugal (tavares.rocha@ua.pt)

Aveiro University (AU) was created in the mid-70's, establishing a Geosciences Department, the first in Portugal of its kind with the purpose of integrating the various areas regarding Sciences of the Earth, including the Engineering Science as well as the Geophysical Science. Teaching of clays and clay minerals deserve, since the beginning, particular attention in the Geological Engineering graduation program. Clay-related matters were teached within disciplines like Industrial Minerals, Ceramic Raw Materials and Crystallochemistry and Diffraction, but two very important steps were fulfilled first in 1986 with the inclusion, on the Geological Engineering graduation program, of a new discipline called Clays, entirely focused on clay science and technology, then in 1994 with the creation of the master degree in Industrial Minerals and Rocks (1994), offering clay formation within disciplines, such as Geology of Industrial Minerals, Exploration and Exploitation, Industrial Applications, Technologies, Mineral Economy.

The implementation of the Bologna process caused significant changes in the courses offered at AU. In the scope of Master Degrees, apart from the recreation of a master degree in Geological Engineering, the Department of Geosciences of the AU launched in conjunction with the Department of Geology of the Science Faculty of the University of Porto, a master degree in Geomaterials and Geological Resources, both offering several clay-related disciplines.

Recently, some advanced training courses (ATC), in which the Geosciences Department will play an important role, were put forward: (1) Strategies for the Protection of Lands, (2) Strategies for the Evaluation of contamination, (3) Rehabilitation of Lands; (4) Hydrogeophysics. The first three are strongly articulated among them and involve formation on clay science and technology. They are all related to fields of study aimed at an audience with a wide range of training in scientific and technological areas. The ATC does not confer degrees, but the approval in this type of training can be credited in other post-graduate, including doctoral programs.

ERASMUS IP: a simple and effective way for European teaching co-operations, the example of the ADVANCECLAY IP series (2008–2010)

Tóth, E.[1*], Weiszburg, T.G.[2], Pop, D.[3], Raucsik, B.[4] & Tombácz, E.[5]
[1]Eötvös Museum of Natural History, Eötvös Loránd University, Budapest, Hungary ([*]zsike@abyss.elte.hu)
[2]Dept. of Mineralogy, Eötvös Loránd University, Budapest, Hungary
[3]Mineralogical Museum, Babeş-Bolyai University, Cluj-Napoca, Romania
[4]Dept. of Earth and Environmental Sciences, University of Pannonia, Veszprém, Hungary
[5]Dept. of Physical Chemistry and Materials Science, University of Szeged, Szeged, Hungary

The Eötvös Loránd University (Budapest) has a long tradition in coordinating and hosting LLL ERASMUS Intensive Programmes (IPs) in the field of mineral sciences. The first IP took place in 2000 in Budapest, and since then, each year a 10-day international summer course was organized. Originally, the application and funding was coordinated from Brussels, but recently, applications have to be submitted in the host country of the IP. The application and the financial administration procedures of the ERASMUS IPs are relatively simple and they are really effective in enhancing international co-operations. In such training- and instrumentation-demanding fields like mineral sciences, IPs can further the usage of well equipped laboratories and fill up the gaps in university teaching programmes that originate from the lack of instrumentation.

We present our experience in the new, host country application system, through the ADVANCECLAY IP series, running in the years 2008–2010, in the hope to raise interest in organising similar events in other countries in the future. A specialty of the Hungarian IPs is that it is not only a tutorial event with lectures, practicals and labs, but students can present their results in the poster session and thus in a friendly environment they can experience how professional conferences work and how one shall prepare, and present a poster.

The ADVANCECLAY 1 IP took place in 18–29 July, 2008 in Budapest, on the topic "Dioctahedral Clay-Related Layer Silicates", with the participation of 23 teachers and 38 students, from 9 partner universities. It was the most classical summer school, with lectures, some practicals and a field trip.

The ADVANCECLAY 2 IP was held in 23 August – 2 September, 2009, in Budapest and Pécs (South Hungary), on the topic "Economic and Environmental Importance of Clays", with the participation of 13 teachers and 54 students, involving 6 partner universities. Here the emphasis was more laid on field activities: mine, factory and industrial plant visits.

The ADVANCECLAY 3 IP is scheduled for 27 August – 7 September, 2010, in Szeged, at the University of Szeged. The topic of the school is "Colloid Properties of Clays and Environmental Applications", with the participation of 63 students and 15 teachers, involving 11 partner universities. The main goal of the school is to amalgamate the mineralogical and chemical theoretical background of clay studies, with a large number of lab practicals.

Educational projects in Earth Sciences at University of Miskolc (Hungary)

Hartai, É.[*] & Földessy, J.
Institute of Mineralogy and Geology, Faculty of Earth Sciences & Engineering, University of Miskolc, Hungary
([*]foldshe@uni-miskolc.hu)

The Institute of Mineralogy and Geology, Faculty of Earth Science & Engineering has been coordinating several EU-co-funded educational projects. At the moment the Institute runs three projects of this kind.

The "EURO-AGES" (European Accredited Geological Study Programs) project aims at developing a qualification framework for geology, based on learning outcomes rather than input factors on the European level, thereby increasing transparency of the Earth Sciences qualifications and ultimately facilitating academic and professional mobility across Europe. The coordinator of the project is the ASIIN Consult GmbH Germany, the partners are from Belgium, Hungary, Spain and Sweden. The project moreover will provide important reference points for quality assurance and related recognition issues focused on learning outcomes. In this sense the project will add value to the implementation of the 2005 Directive on Recognition of Qualifications.

The project titled "Telkibánya Field Training Park" is being implemented in Hungarian-Slovakian cross-border cooperation. Telkibánya is a significant ancient mining town with outstanding medieval monuments of industrial history. In the frame of the project the partners create a joint field education centre in the area of the explored epithermal gold-silver mineralization. Besides setting up the infrastructural background, new teaching materials in English are worked out for field programs in geology, geophysics, mineralogy, geochemistry, ore exploration, mining, geotechnics and environmental engineering. Demo-courses for Hungarian and Slovakian participants at different levels (students at BSc, MSc, PhD, teachers of geography and environmental sciences, civil participants) are also organized as a part of the project. The training park is also offered as a scene for field programs for other universities as well.

The third project focuses on the development of teaching materials for the BSc program in Earth Science Engineering. The main aim is that beside the traditional contact hours, using multimedia tools, new, practice-oriented teaching materials are created for 16 courses in Hungarian and in English, which will be modern, on-line accessible and interactive. As the results of the project, the BSc in Earth Science Engineering program will be harmonized with the similar programs at other European universities, the international education facilities will be widened and the foreign job opportunities will be more favourable.

New approach in mineralogy and crystallography education by application of complex symmetry structures in old Eurasian ethnomathematics of Scythian, Xiongnu and Chinese archaeological finds of Ukraine, Russia, Mongolia and China

Bérczi, Sz.
Institute of Physics, Eötvös University, Budapest, Hungary
(bercziszani@ludens.elte.hu)

The crystallographic structure of minerals can be described by the symmetries of the crystal lattice. Complex structures contain more than one space symmetry group for the arrangement of different atoms in their positions in the unit cell. For example in the garnet structure (pyrope) the AlO_6 octahedral and the SiO_4 tetrahedral units form a subsystem, and the position of the Mg atoms also can be given well visible in a coloured subsystem.

Over the classical group theoretical approaches there are other methods to help forming the spatial view and visuality of the students. Some technological structures triggered development of 2D complex crystallographic structures, which were discovered even in the 2500 years old Eurasian ornamental arts. Within this work, we collected several of them from the complex structures found on archaeological finds in royal tombs of Scythians (Kul Oba, Ukraine; Pazyryk, Russia), Xiongnu Huns (Noin Ula, Mongolia;) and Chinese (Urumchi and Mawangdui, China) (These studies are also called ethnomathematics).

This educational course uses both symmetry and cellular automata principles in forming the operations of complex patterns and structures (From symmetry to cellular automata). From friezes double friezes, woven 2D symmetry patterns and the two types of complex (composite) plane symmetry patterns are generated. Complex patterns of Coxeter-type [1], and Curie-type [2,3] are shown in archaeological finds. Coxeter-type colored groups of cm/pm and cmm/pmg occur at Pazyryk. The multilayered structures of Scythians (Kul Oba, cmm//pmm//cm) and Xiongnu Huns (Noin Ula, p4m//cm//p1) and Chinese (cmm//cm, Ürümchi) are the Curie-type variants. Even Curie-type multilayered structures with complex unification of four different patterns were found among the later steppe structures (Afrasiab, today Samarkand, Uzbeghistan) with p4m//cm//pm//pg structure.

Complex symmetry patterns help the spatial imagination and make more complete and vivid the rigid mathematical background, and also demonstrate that ancient masters of technologies were rich enough in intuitive structural knowledge to give ideas even for the recent time crystallographers.

Formal and non-formal learning about minerals and mineralogy. A case study

Gomes, C.S.R.[1,3*], Gomes, E.M.C.[2,3] & Rola, A.S.[3]
[1]Centre for Geophysics (CG), University of Coimbra, Portugal,
[2]Geosciences Centre (GC), University of Coimbra, Portugal,
[3]Earth Sciences Dept., University of Coimbra, Portugal
([*]romualdo@dct.uc.pt)

Minerals have been precious materials for the development of civilizations and societies since the Prehistoric Times. First, the naturalists and the collectors, and then the Museums of Natural History have played an important role in the advancement and dissemination of Mineralogy. Moreover Museums have also been important as learning environments of Mineralogy. The purpose of this study is to present two examples of the teaching and learning of Mineralogy, considering the Mineralogy teaching experience at the Mineralogical and Geological Museum and at the Earth Sciences Department of the University of Coimbra in a non-formal and formal way respectively. A greater interest in minerals has been shown by teachers of Secondary Schools in the last decade. They often come to the Museum with their students. This interest may be related to the inclusion of the geological issues in the national curricula. Moreover, some scholars in the Department of Earth Sciences and in the Mineralogical and Geological Museum have developed some practical activities for the learning of minerals in a perspective of Education for sustainability in a non-formal way. These activities have been made to enable an active learning by participants, for example, by solving exercises and by handling minerals and rocks samples and everyday objects made from minerals. The participants, especially young boys and girls, aged 10 to 14, sometimes with their parents or their teachers, also have an opportunity to learn about minerals, as far as their classification, composition, diversity, occurrence, and use as a geological resource is concerned. Some activities also included the microscopic observation of minerals. Very often, the participants had a poor initial knowledge on these issues, but they developed good performances during activities and, ultimately, they evaluated them as important to very important [1]. Similar activities have also been developed within the framework of master courses for training teachers of Secondary Schools. In this case, materials for teaching minerals are being developed by master students who are attending the specific curricular units such as, Observation and Experimentation in Geosciences and Didactics of Geosciences II. In the last two years, 22 master students have made didactic materials to teach minerals in various perspectives, including the study of minerals as an important resource and the importance of minerals in the urban dust composition. At the end, these activities are significant not only because they contribute to the teacher training but also because they constitute potential activities to be developed in secondary schools in a classroom context or in the lab. Besides, school visits to the Museum are also an excellent opportunity to use these didactic materials. These two cases are examples of activities to promote learning about minerals and about their importance at different levels of education. We emphasize the learning and teaching minerals in a perspective of a *Sustainable Development.* These activities have been a success and they contribute to competence development of the participants, especially as far as the knowledge of mineralogy, geological resources and their uses and environmental implications is concerned. The promotion of these competences leads to a better understanding of minerals and to a greater discussion and participation performances.

Joint European educational programs in mining, environmental and mineral sciences - Hungarian aspects

Mádai, F.*, Ormos, T. & Hartai, É.
University of Miskolc, Faculty of Earth Sciences & Engineering, Miskolc, Hungary (*askmf@uni-miskolc.hu)

The safe, sustainable and cost-efficient supply of primary and secondary raw materials is an indispensable base of a prosperous society. Against this background the European Geotechnical and Environmental Course (EGEC) as a part of the Erasmus Mundus Minerals and Environmental Programme (EMMEP) is a two-year MSc course to educate future managers and leaders in the European and worldwide mineral extractive industry. Other two coursef of the EMMEP are the European Mining Course (EMC) and the European Mineral Engineering Course (EMEC). The whole program is implemented by a consortium of six European universities with strong engineering background: TU Delft, University of Exeter (Camborne School of Mines), TU Helsinki, TU Wroclaw, University of Miskolc, and RWTH Aachen. The Erasmus mundus program leads to a double MSc degree in Minerals and Environmental Engineering. Students who complete the program have the advantage of excellent international employment opportunities.

The course is a two-year 120 ECTS programme in English. The consortium offers a unique curriculum with mineral resource and environmental courses in a combination which is not available at a single European institution. Entry requires a Bachelors' degree in natural resource engineering, or an equivalent discipline. The study plan comprises four semesters. Two semesters are reserved for an 8 months joint curriculum at 4 universities. The remaining two semesters are spent at the two universities awarding the double degree. Non-European candidates have the opportunity to get a scholarship from EU, which covers all their expenses during the four semesters.

The Faculty of Earth Science and Engineering, University of Miskolc takes part in the EGEC program. In 2010-2011 the following courses are offered: Environmental Risk Assessment, Environmental Bioprocessing, Environmental Geology and Environmental Geophysics (two month, 4 ETCS each). In the 3rd semester the students can study Groundwater Flow, Geotechnical Engineering, Engineering/Mining Geophysics, Mine Waste Geochemistry, Mineral Processing Tailings Management and Utilization, Numerical Methods in Geotechnics (four months, 5 ETCS each). In the last semester students have to take part in project works, and they should complete their thesis works.

Last year, in the frame of EGEC program there were participants from China, Chile, Namibia, Sierra Leone, Ethiopia, India, Pakistan, Iran, Nepal, and from a number of European countries, together with Hungarian students. In June 2010 the University of Miskolc and the Delft University of Technology awarded the master double degree in Miskolc for absolvents from Pakistan and Namibia.

The program is strongly supported by the industry (near 50 multinational firms, including the worldwide leading mining companies). The participating universities and the additional institutions and companies are in co-operation in the FEMP (Federation of European Mineral Programs). This has proven to be one of the most important factors of its success. A choice of internships and job opportunities are offered to participating EU and non-EU students. Further information is available at www.emmep.org

MINSPEC – the first Marie Curie Chair of Excellence in mineralogy (2006–2009)

Nasdala, L.* & Tillmanns, E.
Institut für Mineralogie und Kristallographie, Universität Wien, Vienna, Austria (*lutz.nasdala@univie.ac.at)

This contribution summarises the activities and impact of the Marie Curie Chair of Excellence for Mineral Spectroscopy (project no. MEXC–CT–2005–024878; acronym MINSPEC). It has made an outstanding contribution to the advanced-level teaching and training of mineralogy students, both in Vienna and on a European scale. This chair was established at the Institut für Mineralogie und Kristallographie, Universität Wien, Austria, for a three-year time period (April, 2006 – March, 2009). MINSPEC was the third Marie Curie Chair at all awarded to a host organisation in the country of Austria, and it was the first Europe-wide in the field of mineralogy.

In the framework of its Human Resources and Mobility (HRM) Activity, the European Commission funds, among others, a limited number (ca. 15/year) of temporary university chairs. The establishment of Marie Curie Chairs, part of the Marie Curie Excellence Promotion and Recognition program, aims at improving the university education in disciplines where the needs of an emerging research are not met by the existing, limited training opportunities. MINSPEC's main focus were mineralogical micro-spectroscopy techniques, in particular those that use light for sample excitation (i.e., Raman, infrared absorption, optical absorption, and photoluminescence).

The project's objectives have been accomplished convincingly. The host institute has strengthened its position as one of the internationally leading places for competent training in mineralogical light spectroscopy; an enormous amount of international recognition was gained. The dissemination of spectroscopy-related knowledge and data was improved, and it is being centralised by the chair's www pages (especially the "Spectroscopy Links"). The establishment of a European Centre for Mineral Spectroscopy at the host institute was initiated.

Activities included the training of graduates, Ph.D. students, and researchers; both at the host institute and at other institutions. One diploma and three Ph.D. projects were supervised by the chair-holder, and three more Ph.D. students from other countries were co-supervised during four-month periods which they spent at the host institute. On-site spectroscopy training was also provided to 28 short-term visitors (graduates, Ph.D. students, and researchers) from institutions in 13 countries. At the Universität Wien, the chair-holder taught 19 classes plus one field trip. In addition, three one-week short courses held at the host institute were organized, which overall gathered 94 participants (coming from 19 European countries, Russia, Israel, the U.S.A., Thailand, and Australia) and 15 invited international lecturers. External teaching and training was provided through lectures at universities in Germany, Slovakia, Slovenia, the United Kingdom, France, Spain, Greece, Norway, Russia, Thailand, and Australia; and a two-day short-course in Ljubljana, Slovenia, which was attended by 36 participants.

Associated was the research project "Micro-spectroscopy of radiation-damaged minerals". This and a broad range of additional research topics was dealt with, motivated by the goal to involve the supervised Ph.D. students in a large variety of analytical problems. Results led to important contributions to the understanding of radiation effects in minerals. Scientific co-operation with 51 institutions worldwide was conducted. Research results were presented in 20 papers in peer-reviewed journals (8 more were submitted by the time of the end of the project) and 34 conference presentations, five of which were invited. The Universität Wien has finally decided to maintain the chair beyond the temporary EU funding period, as permanent full professorship for mineralogy and spectroscopy.

Using in-situ produced cosmogenic ^{10}Be in quartz to constrain deglaciation histories of Romania

Gheorghiu, D.[1*], Fabel, D.[1] & Xu, Sh.[2]
[1]Dept. of Geographical and Earth Sciences, University of Glasgow, Scotland, UK ([*]Delia.Gheorghiu@ges.gla.ac.uk)
[2]Scottish Universities Environmental Research Center (SUERC) – AMS, Glasgow, Scotland, UK

Detailed knowledge of the climatic and environmental development during the Late Devensian and Holocene stems mainly from investigations in western and northern Europe, with only fragmentary evidence from regions situated in eastern and/or southeastern Europe. To fully address the temporal and spatial variability of Late Glacial climate fluctuations, and their impact on the environment, more palaeoenvironmental data are needed from different latitudes and altitudes.

The Rodna Mountains were glaciated in the past; however, there are no constraints on the timing, extent and dynamics of this glaciation in the northern part of Romania. The former ice extent of two major glacial advances (Late Devensian and Younger Dryas) was reconstructed based on mapping and surveying of glacial features. The morphostratigraphy of the area suggests two episodes of glaciation: an older one during the Late Devensian, and a subsequent smaller glaciation. Field evidence suggests that during the Devensian glaciation, ice reached lower elevations (~ 750 m) in Rodna Mountains than previously suggested. The relative chronology was supplemented with surface exposure dating using the *in situ* produced cosmogenic nuclide ^{10}Be in quartz, which provides a preliminary chronology for ice retreat. Two boulders were abandoned about 36.8 ± 1.0 ka at an elevation of ~ 850 m. Glacial erratics and bedrock samples (n = 27) provide a good chronology for deglaciation during the Late Glacial, suggesting that ice retreated into the corries between 18.1 – 13.2 ka (1100 – 1800 m altitude). Final deglaciation took place in the corries at about 12.5 - 11.2 ka (n = 8).

Continuing field and laboratory analysis will further constrain spatial and temporal limits of glaciation allowing ice masses and palaeoenvironmental conditions to be reconstructed within the Rodna Mountains. Comparison with the other glaciated areas in NW Europe (Scotland) will provide new insights into the past climatic gradient across Europe.

Nanomineralogy – modern challenges and perspectives

Koneev, R.I.
Dept. of Mineralogy and Geochemistry, Faculty of Geology, National University of Uzbekistan, Tashkent, Uzbekistan (rkoneev@yahoo.com)

The swift development of nanosciences and nanotechnologies in XXI century caused an appearance of new scientific directions – nanomineralogy, nanogeochemistry and others. The nature has been used nanotechnological methods in different geological processes long before the human. All minerals passed the stage of nanostate (during crystallization or destruction) and modern methods of research allow determining those signs: fullerenes of schungite, opal nanostructures, "invisible" gold in sulfides and etc. Study of ores from different deposits by sound methods had shown that the majority of elements with *n*ppm – *n*ppb clarks and industrial content (Au, Bi, Te, etc.) form nanoassemblages withing the matrix of macrominerals. Nanominerals form during the processes of natural nanotechnologies "upwards" – from the atom to nanocrystal or on "gel-sol" technology. Weathering, dispersion in fault zones and other processes form nanoparticles of minerals in the "upwards" technologies.

There are very difficult questions for nanomineralogy:

- Are lows of nanotechnologies of artificial materials applied to the processes of natural nanotechnologies?
- Are the sizes of nanominerals limited by 1-100 nm interval or their size might be bigger?
- Could be nanominerals of fullerenes type with symmetry axes of the 5 order considered as crystals?
- How size effects affect on stoichiometry, physical and other properties of nanominerals?
- Is it necessary to differentiate the lows and rules of mineral formation in macrosystems from the processes with participating of nanoparticles and nanominerals?

The possibilities of nanominerals and nanoparticles formation in the nature are various: anthropogenic, explogenic and other processes; the crystallization from heterogenic, colloid systems; decay and separation of admixture from heavy solutions, diffusion and localization of elements in the defects of structure, decay of unstable isotopes and unstable compounds, weathering and so on. The problem of the development of new terminology and methods of research became actual one.

The decision of listed and other problems opens new perspectives of the decision of theoretical and practical questions of ore formation. For example why are hydrothermal deposits confined to the fault zones, different breccias, black shales? Is it possible that the explanation of it is that powdered, carbonaceous nanomaterial initiates different chemical reactions and sorbs elements from the solutions, creating industrial concentrations during non optimal thermodynamic parameters due to high surface energy. The analysis of nanoassemblages creates new basis for the search, typification, evaluation of perspectives and technological properties of noble and rare metals deposits.

Definition of bio-minerals

Miura, Y.
Yamaguchi University, Yamaguchi, Japan
(dfb30@yamaguchi-u.ac.jp)

Defining bio-minerals related with both astrobiology and life activity is required for the following factors: 1) Combined mixture of life-materials between inorganic (minerals) and organic compounds (used both as INOG). 2) Material state changes of gas-liquid-solid (VLS) phases by continuous dynamic reaction, where solid includes minerals. 3) Space and time (ST) factors, significant for dynamic processes of water from Earth planet [1-5].

Almost all life materials are combined with the following two materials: 1) Inorganic (IN) materials of mineral crystals with carbonates, phosphates and oxides in composition, with cyclic materials (called as "fossil" as some state IN with relatively long cyclic system), where carbon (C), hydrogen (H) and phosphorous (P) together with minor elements (Fe, Ni, Mg, S, Cl, Mn, Cr, Co, Cu, and Zn [2]) found in bone and shell etc. are richer in carbonaceous meteorite than in terrestrial rocks as the cosmic abundances based on silicon (10_6) [5-7]. 2) Organic (OG) materials with carbon-bearing organic materials in composition, with cyclic materials (some state OG with relatively short cyclic system), where carbon-based organic compositions of RNA and DNA found in the life cell and blood are characteristic for active reactions with short periods in life, which is changed to solid-state (to minerals). In this sense, life materials are considered to be "combined materials of inorganics (minerals) and organics (used as INOG)", which differ in composition and activity (with short (IN) and long (OG) periods of "inorganic fossil" [6,7]).

There are two processes on material changes of life activity as follows: 1) *VLS State changes:* Life activity (in human, animal and plants etc.) shows cyclic system of the following three VLS states: a) Vapor state V (like gases of oxygen and carbon dioxides). b) Liquid state L (like liquids of cell and blood etc.). c) Solid state S (like solids or minerals of bone and shell etc.). 2) *State changes for cyclic system:* Life activity (in human, animal and plants etc.) is required dynamic changes of materials by the VLS state change for overall cyclic system of the following phenomena: a) Birth and death (used as BD in life activity). b) Formation and destroy (used as FD in inorganic fossil, any minerals and rocks). In this sense, life materials reveals "dynamic VLS activity with carbon, hydrogen, oxygen and nitrogen (CHON), which produces "dynamic mini-cycle materials" on "the water-air-planet of the Earth with the VLS".

Astro-life materials are largely required to be considered to be dimensions of space and time (ST) as follows: 1) In close space and short time (to the Earth of the Solar system): a) Time: short period (from second to year). b) Space: localized space (from nm to km). 2) In deep space and long time (in the cosmic space): a) Time: long period (from year to light-year). b) Space: localized space (from km, a.u. to lightyear distance). In this sense, life materials can be "discovered" not only in the Earth Planet (of the solar system), but also in deep space if there are similar dynamic and cyclic systems of three states.

MINCALC-V5 a non EXCEL based computer program for general electron-microprobe mineral analyses data processing

Bernhardt, H.-J.
Ruhr Universitaet, Bochum, Germany
(heinz-juergen.bernhardt@rub.de)

The electron-microprobe today is a routine instrument for quantitative analyses in the micrometer scale applied in many fields of science among these Geology and Mineralogy. Besides tabular or graphical presentation of the analyses, structural formula and end-member calculations are needed to complete analyses evaluation. This may include the calculation of not measurable elements like H or Li and the separation of e.g. Fe^{2+} and Fe^{3+}. Mineral specific programs [1] or EXCEL sheets [2] are normally used for this purpose. Only few more general programs [3] exist, which are not really flexible and easy to modify and adapt to specific problems.

MINCALC-V5 combines the following features: **a)** Input filters for various probe output files are implemented in order to convert them to MINCALC-files for further use. The original files remain untouched. **b)** Long time storage and fast retrieval of analyses data as needed in a multiuser microprobe laboratory. **c)** Analyses files normally contain the results of several mineral species, therefore simple and very versatile analyses selection options are provided as numerical filters, analyses similarities, definable keys (e.g. mineral or sample name), plots and manual selection. **d)** Complex structural formula and end-member calculations using a simple programming language inside the program is possible (e.g. *Al_t= FILL Si with Al to 3;* meaning: if Si is less than 3, then fill the position of Si with Al up to 3 or less if not enough Al is present; then store the result as Al_t). Programs may be stored for further use. **e)** Plots of all measured and computed variables can be made in terms of histograms, line plots, X-Y-plots and triangular plots. It may be requested to show additionally all variables linked with the plot point specified using the mouse curser. **f)** The program user is completely free to define the output sequence of tables. All results may be printed, stored or transferred to the clipboard. Thus, also communication with other programs can be managed. **g)** A formula data base is available to simplify mineral identification; the user may search for any element combination also with exclusion of defined elements. **h)** To compare measured analyses with theoretical values, the weight-% of end-members or end-member combinations are calculable. **i)** MINCALC files may be merged to very long files (tested with 12000 analyses composed of more than 300 single files). Applying the above mentioned keys it easy to select e.g. a certain mineral species from a certain sample or from several samples and use a predefined program to compute required parameters. The advantage is to minimize the number of needed files. **j)** When two reference points are defined, the x-y-microprobe coordinates of measured points may be transformed to optical- or scanning-microscope coordinates.

Radium isotopes in the hot-spring sediments, Karlovy Vary (Carlsbad, Czech Republic)

Goliáš, V.[1*], Řanda, Z.[2], Tříškala, Z.[1], Vylita, T.[3], Strnad, L.[4], Šebek, O.[4] & Supiňková, T.[1]
[1]Inst. of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University in Prague, Czech Republic ([*]wiki@natur.cuni.cz)
[2]Nuclear Physics Inst., Academy of Sciences of the Czech Republic, Řež, Czech Republic
[3]Mineral Water Bureau of Karlovy Vary, Czech Republic
[4]Laboratories of Geological Inst., Faculty of Science, Charles University in Prague, Czech Republic

The curative thermomineral waters in Carlsbad are Glauber-type ($Na\text{-}HCO_3\text{-}SO_4\text{-}Cl$), highly gaseous ($CO_2$) with TSD about 6.4 g l^{-1} and up to 73°C hot. Its outflow is 30 l s^{-1} of water and 100 l s^{-1} of gaseous phase.

In all hydrothermal system is strong sinter precipitation, mainly caused by the *Cyanobacteria* life cycle metabolites [1]. Calcite and aragonite are both present. The Hot-spring sediments are a big problem for the spas thermal water supply system (Fig. 1).

Fig. 1: The historical pipeline (1920-1935) filed up by aragonite sinter.

Due to the highly radioactive host rock (Carlsbad granite) also the water and its precipitates (sinters) have increased radioactivity caused mainly by radium isotopes. The recent types contains up to 3.29 Bq g^{-1} ^{226}Ra and 0.87 Bq g^{-1} ^{228}Ra. The sinter type that is in full contact with gaseous phase reach specific activities up to 26.03 Bq g^{-1} of ^{210}Pb as the radon long-term deposit. The autoradiography shows a quite homogenous distribution of radioactivity sources. The radioactivity of the fossil Hot-spring sediments is very low due to radium decay.

The both of aragonite and calcite types have an increased content of Be, Ba, Fe, Mg, Pb and Sr (ICP-MS and ICP-OES results).

The radium content in carbonate sinters is not bond with sulphate phase (radiobarite) as in the other cases [2]. As the results of the sequential leaching is the main portion of radium in HCl-leachable fraction in both of aragonite and calcite types. We suppose that the radium and also ^{210}Pb are present as a substituent in the structure of the aragonite–witherite-cerrusite phases, and it can be also incorporate in the calcite structure [3] in the case of calcite-type sinters.

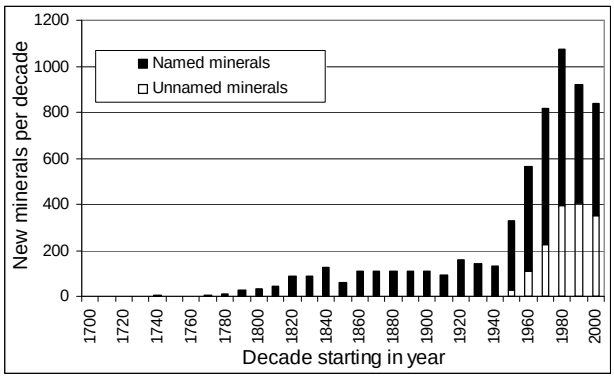
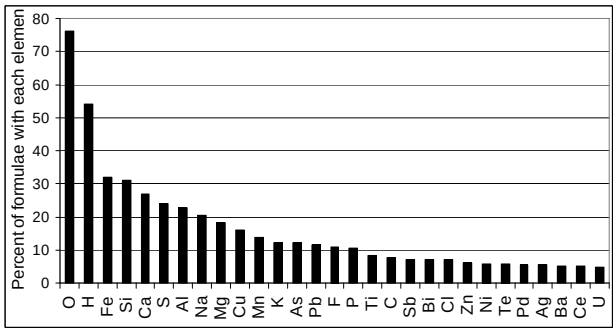
A census of mineral species – 2010

Higgins, M.D.[1*] & Smith, D.G.W.[2]
[1]Sciences de la Terre, Université du Québec à Chicoutimi, Québec, Canada ([*]mhiggins@uqac.ca)
[2]Dept. of Earth & Atmospheric Sciences, University of Alberta, Edmonton, Alberta, Canada

This census of minerals is a 'snapshot' of the state of the population of named and valid unnamed species – how it is growing and the characteristics of its members. This study is based on the very substantial MinIdent-Win mineral properties database. The availability of such data compilations put us in a position to see a broad view of mineral properties, and their variations, much more easily and more accurately than at any time in the past. Using histograms and graphs we can show the variations in such parameters as symmetry, density, indices of refraction, birefringence, reflectance, hardness, as well as the population of the major mineral divisions. Additionally, it is possible to explore in detail similar variations within major mineral groups such as the amphiboles. This poster will explore a substantial range of such variations and present the results in a series of simple diagrams. The following are examples of the results of this compilation.



The number of new minerals described per decade increased fairly steadily to ~150 until the 1950s, when it accelerated to peak at over 1000 in the 1980s. The decrease since then may reflect maturity in the subject, or stricter controls on new mineral naming. Unnamed minerals make up 23% of the total, but ~40% of new minerals defined since 1980.



The formulae of minerals reflect their major element compositions and mineral major divisions. O is the most common element, in 76% of formulae, followed by H (53%). Although other elements abundant in the crust are well-represented in mineral formulae, there are minor or trace elements that are over-represented amongst minerals, such as As, Pb, Sb, Bi, Te, Pd, Ce, U, *etc*.

Ca-rich plagioclase formed with hot CO_2 gas

Miura, Y.
Yamaguchi University, Yamaguchi, Japan
(dfb30@yamaguchi-u.ac.jp)

Anorthite, the Ca-rich plagioclase, is considered to be formed by continuous silicate crystallization at magmatic high-temperature condition. Recently, carbon-bearing anorthite mineral has been found separately in cavities of basaltic rocks from Shimonoseki, Yamaguchi, Japan [1,2].The main purpose of the paper is to elucidate the conditions of anorthite formation by hot carbon dioxides (CO_2) -rich condition by mixing with carbon-bearing calcite during dynamic explosion processes of volcanic process.

Significant amounts of carbon are found in Ca-rich plagioclase minerals, which occur only on phlogopite plates (as shown in Fig. 1), from some cavities in volcanic basalts from Shimonoseki, Yamaguchi, Japan [1,2].

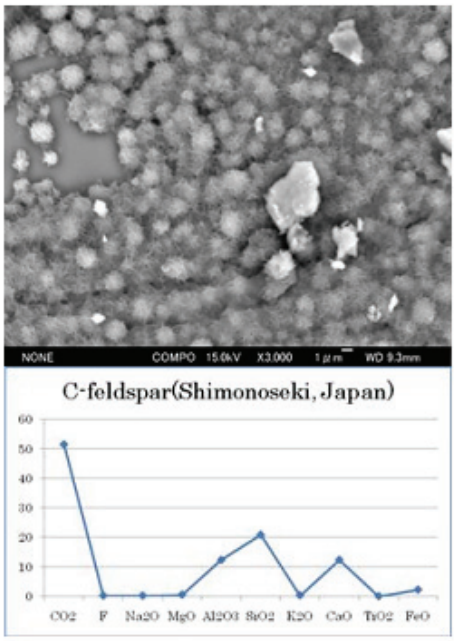


Fig. 1: Electron micrograph (FE-ASEM) of fine carbon-bearing anorthite minerals found on phlogopite plates in cavities from Shimonoseki, Yamaguchi, Japan [1,2]. Bar is 1μm in size.

Carbon is considered to be transported from the buried limestone which is broken by normal magmatic melting of basalt with few Na and K elements. The present results are similar with those found by studying anorthite formation at various volcanic rocks on the Earth (Nagahama-Hamada, Mishima-Hagi, Miyake-Jima and Sakura-Jima, Japan) and at impact breccias of the lunar anorthites on the Moon [3].

The present study is summarized as follows: 1) Ca-rich plagioclase can be formed separately from Ca-rich limestone and silicate-rich wall rocks with carbon dioxides condition at explosive magmatic intrusion. 2) Fine carbon-rich anorthite plagioclases are found in the smaller basaltic intrusion with buried limestone at Shimonoseki-Yamaguchi, Hamada-Shimane and Mishima-Hagi, Japan, whereas large carbon-bearing anorthites with hot carbon dioxides are found in active volcanoes of Miyake-Jima in Japan. 3) The present results will be applied for studyind carbon-bearing impact breccias on the Moon and Mars.

Advanced Mineralogy in Mexico: results and future research

Ostrooumov, M.
Dept. of Geology and Mineralogy, University of Michoacan, Morelia, Mexico (ostroum@umich.mx)

Nature endowed Mexico with enormous metallic and non-metallic mineral resources. This has been proven many times as a result of the immense field of study that mineralogists have undertaken in the country. However, in spite of the extensive research, at the end of the XX century scientists paradoxically have still not appropriately explored the Mexican territory from the mineralogical point of view [1,2].

In the last few years, European specialists have implemented an approach that may be called Advanced Mineralogy [3]. This approach may be defined as new ideas and concepts based on recent mineral studies. Ten years ago the fundamental task for Mexican mineralogists was rise to an agreed level of development of Advanced Mineralogy as occur in other countries.

During the last 10 years (2000-2009) the Mexican mineralogists have worked to improve the situation in Mexican mineralogical science. The aim of this paper is to report the results of the recent investigations in Mexico from different areas of Advanced Mineralogy: physics and crystal chemical features of minerals, environmental mineralogy, applied mineralogy to the prospecting of mineral deposits, and mineral discovery of new species and deposits [4-11]. As a result of all these research, Mexico is now on the map of the Advanced Mineralogy and in WEB publications [12,13]

The author emphasizes the importance of the creation of the Mexican mineral catalogue with its base in the modern crystal chemical classification that signifies the first scientific and systematic inventory of mineralogy of the country. The intention of this inventory was to analyze not only the present mineralogical catalogue from a scientific point of view, but also from the practical point of view, characterizing in detail those mineral species that can be used as an important guide in the exploration of the mineral deposits as well as in the mining and benefit of the ores.

The organization and realization of the systematic mineralogical research of the Mexican subsoil has great importance. As a result of this study, mineralogists will establish laws that will guide the exploitation and concentration of the economic minerals to allow the creation of the scientific bases of metallogeny and the mineralogical prospecting of new mineral deposits. Mineralogists must develop new areas of Advanced Mineralogy in Mexico to continue to study the different mineral formations: the mineral genesis in volcanoes, oceanic bottom, historical monuments, and mining wastes. The contemporary arsenal of analytical methods permits to analyze minerals together without influencing or modifying original properties; therefore complete and necessary information is obtained as a result which can be used towards the successful solution of pending or future mineralogical problems in Mexico.

Paleoenvironmental controls on clay mineralogy of Carnian sections from the Transdanubian Central Range, Hungary

Rostási, Á.* & Raucsik, B.
Dept. of Earth and Environmental Sciences,
University of Pannonia, Veszprém, Hungary
(*rostasi.agnes@almos.uni-pannon.hu)

Clay mineralogy is considered to be a powerful tool for interpretation of weathering conditions and paleoclimate in the source area. In general, illite and chlorite have been considered to be less sensitive to chemical weathering and may be used as internal standards or comparators, hence the kaolinite/illite and/or smectite/illite ratios are used by many authors as paleoclimate proxies. The abundance of kaolinite is especially a good indicator of landmasses with hot and humid (subtropical to tropical) climate supported by high water/rock ratio and steep slopes with good drainage. Smectite is generally suggested to form during weathering in seasonally wet and dry climates with low water/rock ratio and lower slopes, and low relief with poor drainage.

The Upper Triassic sediments both in NW Europe and in the Mediterranean show evidences for a generally arid climate regime. However, in the Carnian, a biotic crisis, extinction event, oceanographic changes, increased rainfall and an anomalous siliciclastic input to the oceanic basins occurred contemporaneously at this time, which interrupted the warm and arid climatic conditions. The paleoclimatic and paleo-environmental interpretation of the changes recorded by Carnian successions in Europe remain controversial.

The Carnian marine succession of Veszprém Marl and Sándorhegy Formations from the Transdanubian Central Range (Hungary) shows significant change in sedimentation: pelagic carbonate deposition was replaced by formation of fine-grained marly sediments. The clay mineralogical composition of 240 samples four boreholes (Bszü-1, Bfü-1, Met-1, and Zs-14) was determined by XRD analysis in order to model the paleoenvironment.

The clay fraction of the samples includes variable proportions of illite, illite/smectite mixed-layer minerals (IS), chlorite, and kaolinite. High degree of expandability (50–70%) and poorly ordered character (S=0) of the IS resulted from relatively low degree of diagenetic overprint. Therefore, the clay mineralogical composition seems to be an original signal applicable to reconstruct the paleoenvironment. The relatively large amount of detrital illite (~40–60%) and chlorite (~10–30%) associated with kaolinite (~10–20%) reflects strong erosion of high relief areas and increased rate of continental weathering. The IS (up to ~60%) can be formed from smectite via burial diagenesis and the originally smectitic material could be derived from altered volcanogenic rocks. Carbonate-rich intervals are enriched in IS whereas marl-dominated intervals are richer in illite which was caused either by fluctuations of terrigenous input or sea-level fluctuations. Based on these results, mixed carbonate-siliciclastic basinal sediments representing the 'Carnian Pluvial Event' in the Transdanubian Central Range could be a superimposed product of climatic change, sea-level variation and tectonism.

INSTRUCTIONS FOR AUTHORS

General

Acta Mineralogica-Petrographica (AMP) publishes articles (papers longer than 4 printed pages but shorter than 16 pages, including figures and tables), notes (not longer than 4 pages, including figures and tables), and short communications (book reviews, short scientific notices, current research projects, comments on formerly published papers, and necrologies of 1 printed page) dealing with crystallography, mineralogy, ore deposits, petrology, volcanology, geochemistry and other applied topics related to the environment and archaeometry. Articles longer than the given extent can be published only with the prior agreement of the editorial board.

In the form of two subseries, AMP publishes materials of conferences (AMP Abstract Series) and field guides (AMP Field Guide Series), or, occasionally supplement issues related to other scientific events.

The journal accepts papers that represent new and original scientific results, which have not appeared elsewhere before, and are not in press either.

All articles and notes submitted to AMP are reviewed by two referees (short communications will be reviewed only by one referee) and are normally published in the order of acceptance, however, higher priority may be given to Hungarian researches and results coming from the Alpine-Carpathian-Dinaric region. Of course, the editorial board does accept papers dealing with other regions as well, let they be compiled either by Hungarian or foreign authors.

The manuscripts (prepared in harmony of the instructions below) must be submitted to the Editorial Office in triplicate. All pages must carry the author's name, and must be numbered. At this stage (revision), original illustrations and photographs are not required, though, quality copies are needed. It is favourable, if printable manuscripts are sent on disk, as well. In these cases the use of Microsoft Word or any other IBM compatible editing programmes is suggested.

Language

The language of AMP is English.

Preparation of the Manuscript

The different parts of the manuscript need to meet the instructions below:

Title

The title has to be short and informative. No subtitles if possible. If the main title is too long, an additional shortened title is needed for the running head.

Author

The front page has to carry (under the main title) the full name(s) (forename, surname), affiliation(s), current address(es), e-mail address(es) of the author(s).

Abstract and keywords

The abstract is required to be brief (max. 250 words), and has to highlight the aims and the results of the article. The abstracts of notes are alike (but max. 120 words). As far as possible, citations have to be avoided.

The abstract has to be followed by 4 to 10 keywords.

Text and citations

The format of the manuscripts is required to be: double-spacing (same for the abstract), text only on one side of the page, size 12 Times New Roman fonts. Margin width is 2.5 cm, except the left margin, which has to be 3.5 cm wide. Underlines and highlights ought not be used. Please avoid the use of foot and end notes. Accents of Romanian, Slovakian, Czech, Croatian etc. characters must be marked on the manuscript clearly.

When compiling the paper an Introduction – Geological setting – Materials and Methods – Results – Conlclusions structure is suggested.

The form of citations is: the author's surname followed by the date of publication e.g. (Szederkényi, 1996). In case of two authors: (Rosso and Bodnar, 1995) If there are more than two authors, after the first name the co-authors must be denoted as "et al.", e.g. (Roser et al., 1980).

References

The reference list can only consist of published papers, M.Sc., Ph.D. and D.Sc. theses, and papers in press.

Only works cited previously in the text can be put in the reference list. Examples:

Best, M.G., Christiansen, E.H. (eds.) (2001): Igneous petrology. Blackwell, Edinburgh, 458p.

Upton, B.G.J., Emeleus, C.H. (1987): Mid-Proterozoic alkaline magmatism in southern Greenland: the Gardar province. In: Fitton, J.G., Upton, B.G.J. (eds.): Alkaline Igneous Rocks. Blackwell, Edinburgh, 449–472.

Rosso, K.M., Bodnar, R.J. (1995): Microthermometric and Raman spectroscopic detection limits of CO_2 in fluid inclusions and the Raman spectroscopic characterization of CO_2. Geochimica et Cosmochimica Acta, **59**, 3961-3975.

Szederkényi, T. (1996): Metamorphic formations and their correlation in the Hungarian part of Tisia Megaunit (Tisia Megaunit Terrane). Acta Mineralogica-Petrographica, **37**, 143-160.

Bakker, R.J. (2002): http://www.unileoben.ac.at/~buero62/minpet/Ronald/Programs/Computer.html. Accessed: June 15, 2003.

The full titles of journals ought to be given. In case more works of the same author are published in the same year, then these has to be differentiated by using a, b, etc. after the date.

Illustrations

Finally, each figure, map, photograph, drawing, table has to be attached in three copies, they must be numbered and carry the name of the author on their reverse. All the illustrations ought to be printed on separate sheets, captions as well if possible. Foldout tables and maps are not accepted. In case an illustration is not presented in digital form then one of the copies has to be submitted as glossy photographic print suitable for direct reproduction. Photographs must be clear and sharp. The other two copies of the illustrations can be quality reproductions. Coloured figure, map or photograph can only be published at the expense of the author(s).

The width of the illustrations can be 56, 87, 118, or 180 mm. The maximum height is 240 mm (with caption).

All figures, maps, photographs and tables are placed in the text, hence, it is favourable if in case of whole page illustrations enough space is left on the bottom for inserting captions. In the final form the size of the fonts on the illustrations must be at least 1,5 mm, their outline must be 0,1 mm wide. Digital documents should be submitted in JPG-format. The resolution of line-drawings must be 400 dpi, while that of photographs must be 600 dpi. The use of Corel Draw for preparing figures is highly appreciated, and in this case please submit the .CDR file, as well.

Proofs and offprints

After revision the author(s) receive only the page-proof. The accepted and revised manuscripts need to be returned to the Editors either on disc, CD or as an e-mail attachment. Proofreading must be limited to the correction of typographical errors. If an illustration cannot be presented in digital form, it must be submitted as a high quality camera-ready print.

The author(s) will receive 25 free offprints. On payment of the full price, further offprints can be ordered when the corrected proofs are sent back.

Manuscripts for publication in the AMP should be submitted to:
